**Background:** Land use change (LUC) is one of the most important causes of climate change and soil degradation. In the last 5 years, the soil erosion rates at global scale have increased in 0.69 Pg $yr^{-1}$ and 0.20 Pg $yr^{-1}$ in croplands and grasslands, being the Global South the most affected area [1]. In Chile, 40% of the land is cover by bare soil and sparse vegetation, 24% by trees and 21% by grasslands. In the past (ca. 1550), the land in Southern Chile was covered by native forest (NF) and transformed to grasslands (G) and/or croplands (C). These LUC caused a detriment on soil functions; however, this process and the soil changes are still unknown in remote areas such as Western Patagonia. Human necessities are wide, and the soil is more than a food provider. Nowadays, society demands food, fiber and water produced in a clean and sustainable way that helps to mitigate climate change (e.g., carbon sequestration). The ecosystem services could be inferred through soil quality indexes, which depend on inherent (i.e., colloidal fractions) and dynamics soil properties [2] which are modified by soil management [3]. These changes caused by land reconversion could be evaluated from soil quality perspective, centered in the re-distribution of soil organic matter fractions [4].

**Objective:** To develop soil quality indices (SQI) in a climate gradient under contrasting land uses, considering inherent and dynamics properties and changes fractions of organic matter in soils of Western Patagonia.

**Methodology:** To cover the main environmental conditions in W. Patagonia xeric (X), mesic (M), and hydric (H) moisture conditions were be considered in the sampling design. In each condition, three land uses were selected; native forest (NF), grassland (G) and cropland (C). 3 pits were excavated by land uses to describe and took undisturbed and disturbed soil samples. 3 seasons and 2 depths were sampled (0-20 cm and 20-40 cm) to represent the surface and subsurface soil horizons. To determine the Al and Fe fractions, specific dissolution techniques were implemented, and physical, chemical, and biological properties were analyzed to build-up soil quality indexes. Soil organic matter fractioning is in progress to separate the particulate organic matter (POM) and mineral-associated organic matter (MAOM). Principal components analyses (PCA) and linear regressions were used to analyze the datasets. SQI were constructed by ecoregion and land cover for the functions of carbon storage *f*(C) and biomass accumulation *f*(BM).

**Results and Discussion:** The bulk density (BD) varied between 1.04 y 0.28 Mg $m^{-3}$ in xeric grasslands. The highest wide coarse pore volume (wCP = 29.7%) was found under NF soils which coincide with the maximum surface able to conduct air (Ka = 2.92 log $\mu m^2$). In xeric environments, BD explained the variability in wCP ($R^2 = 0.91$; $p < 0.001$) under croplands and wCP explained the Ka in NF conditions ($R^2 = 0.82$; $p < 0.001$). 66.6% of the variance was explained by two first PC. The PC1 (42%) was compound by ECEC, pH NaF, $Al_a$, Olsen-P and BD and PC2 (24.6%) by SOC, Total-N and pH $H_2O$. The soil reactivity increases from xeric to hydric conditions, which means changes in dominant colloidal fractions (*i.e.* from crystalline to amorphous), supported by the relationship between $Al_a$ and pH NaF ($R^2 = 0.90$; $p < 0.001$). SOC was inversely related to BD ($R^2 = 0.63$; $p < 0.000$) and directly related to Sulphur ($R^2 = 0.85$; $p < 0.001$). The functions of carbon storage were X = 0.6 < M = 1.2 < H = 2.4, while biomass ranged from: X = 2.8 > M = 2.4 < H = 2.9. SQI-*f*(C) were 33% higher in G = 1.7 than in C = 1.3, while for *f*(BM) the difference was 20% (G = 2.9 > C = 2.4).

**Conclusions:** Soil reactivity increases from east (xeric) to west (hydric) ecoregions, which have better soil conditions to store carbon, while for biomass accumulation function the differences are smaller among ecoregions. Grasslands have better potential than crops for performing the evaluated functions, however the transformation from native forest to grasslands and croplands affects the physical functions of soils in W. Patagonia.

## ABSTRACT

There is a growing concern on the pitiable level of degeneration of water quality for irrigation and domestic purposes occasioned my incessant anthropogenic activities that have contributed to this menace. This Current investigation aims at insight about the level of contaminants of surface water and sediment analysis of selected locations of Imo river of imo State of Southeastern Nigeria over a twelve months period. The physico-chemical analysis was employed to assess the water and sediment quality of the samples. Air-shade temperature (28.6 - 29.6 0C), Surface Water Temperature (26.8 - 27.4 0C ), pH (6.2 - 6.6), Electrical conductivity (24.3 - 44.2 µscm-1), Total Dissolved Solid (11.8 - 21.1mgl-1), Total Hardness (82.3 – 99.6 mgl-1),Total Alkalinity (25.1 -39.2 mgl-1), Dissolved Oxygen (5.6 -7.8 mgl-1), Biochemical Oxygen Demand (2.5 - 3.7 mgl-1), Chloride (22.7 - 29 mgl-1) , Nitrate (0.4 -0.6 mgl-1), Sulphate (11.2-14.9 mgl-1), Silica (1.2 - 2.6 mgl-1), Total phosphorus (2.2-29 mgl-1), Potassium (1.5 - 2.5 mgl-1), Sodium (2.3 - 4.2 mgl-1), Calcium (0.6 - 1.02 mgl-1), Magnesium (0.9 - 1.3 mgl-1) , Zinc (0.01 - 0.02 mgl-1), Iron (0.14-0.50mgl-1) and Manganese(0.0 - 0.07mgl-1),while the following ranges were recorded for sediment: Temperature (27.6 - 28.6 0C), pH (5.5 - 5.8), Conductivity (93 - 211 µscm-1), Total Dissolved Solid (45.2 - 105 mgkg-1 DW), Manganese (2.4 – 19.5 mgkg-1 DW), Zinc (0.20 - 6.1 mgkg-1 DW), Iron (0.11 – 0.52 mgkg-1 DW), Potassium (5.76 - 11.8 mgkg-1 DW), Sodium (19.9 - 22.3 mgkg-1DW), Calcium (48.7 - 93.9 mgkg-1DW), Magnesium (3.6 -87.2 mgkg-1DW), Copper (0.0 - 0.01 mgkg-1 DW), Cadmium (0.0 -0.05 mgkg-1DW) and Arsenic (0.0 - 0.01 mgkg-1DW). All the values recorded for the physico-chemical parameters were within the range recorded for other water bodies of lower Niger Delta Region. They also fall within the permissible limit of S.O.N., W.H.O, E.U. and U.S.E.P.A. Standards except for dissolved oxygen and Ortho-phosphate phosphorus that slightly deviated. The Cationic order recorded for water column was: Na>k>Ca>Mg, While sediment cationic order was Ca >Na> Mg>K, with PFARSALL ‘S Index of 6.96mgl-1 (water) and 128.29 mgkg-1DW sediment. Air-Shade Temperature, Surface Water Temperature, Conductivity, T.D.S, Transparency, Total Hardness, D.O.,B.O.D., Chloride, Sulphate, Silica, Magnesium and Calcium showed monthly significant differences ($p < 0.05$), while Conductivity, T.D.S, Transparency, Silica and Calcium showed station/station significant differences ($P < 0.05$). Positive significant correlation were observed between Air-Shade Temperature and Total hardness, as well as dissolved oxygen with chloride ($p < 0.05$). The positive relationships observed depicts an interplay between the overlying water and the bottom sediment.

# Agriculture as a strategy to improve the food – water – energy nexus in Atlantic Forest, Brazil

**Ana Paula Dias Turetta**[1,2*]

[1] *Brazilian Agriculture Research Corporation – Embrapa Solos, Rio de Janeiro, RJ, Brazil*

[2] *Federal Rural University of Rio de Janeiro, Department of Architecture and Urbanism, Postgraduate Program in Territorial Development and Public Policies, Seropédica, Rio de Janeiro, Brazil*

*ana.turetta@embrapa.br

**ABSTRACT**

Global agricultural production is on a trajectory to double by 2050 due to both increases in the global population and the dietary changes associated with growing incomes. This increase also means more pressure on water resources, as agriculture accounts for 70% of global water withdrawal, and for energy production, as the whole food supply chain accounts for about 30% of total global energy consumption.

The water, energy, and food (WEF) nexus examines the interrelations among the three resource sectors, including the synergies, conflicts, and trade-offs that emerge from their management. These interconnections are extensive and significant. Managing one of them must not be treated in isolation but rather as part of an interconnected system.

Agriculture influences these three vital components of human livelihood that are being discussed here: food, water, and energy. The implementation of an ecosystem strategy to tackle agricultural food production can improve crop yield by utilizing ecosystem services that facilitate the decrease of external inputs, such as mineral fertilizers and pesticides. In this context, the principles of conservation agriculture (CA) serve as a central strategy because they enhance the use of agricultural resources by integrating the management of soil, water, and biodiversity, promoting multifunctionality in agriculture while also reducing reliance on external inputs. It can create synergies to maximize natural resource efficiency in alignment with societal objectives, boosting the WEF nexus strategy.

This study presents a novel methodology framework based on accessible secondary data to evaluate the impacts of three rural practices based on CA principles - agroforestry, spring protection, and pasture rotation - on the WEF nexus in the Atlantic Forest, southeast of Brazil, which is the Brazilian biome with the greatest population density within the country, hosting 72% of the population and contributing to 70% of the Brazilian GDP.

The results of the business as usual scenario indicated concern regarding water security, particularly in relation to sewage treatment and water commitment. The analysis revealed a similar pattern in energy security, with only two indicators showing positive performance. Conversely, a scenario of reduced vulnerability was observed in food security, as evidenced by the indicators of food production, nutritional value, and annual gross revenue. However, in the scenarios proposed by experts, the adoption of the rural practices that were assessed here can lead to consistent improvements in WEF security, evidencing the multifunctional capabilities of agriculture. Hence, the methodological framework presented here demonstrates its potential to be incorporated into decision-making processes to promote the multifunctionality of agriculture and sustainable use of rural areas.

# Microbial innovation for nitrogen management in paddy soil: A success story of Endophytic Azotobacter chroococuum MCC 3432 (NRRI-EndoN)

**Upendra Kumar***

*Senior Scientist (Microbiology, Crop Production Division, ICAR-Central Rice Research Institute, Cuttack, India)*

*ukumarmb@gmail.com

**ABSTRACT**

Among biofertilizers, diazotrophic bioinoculants are one of the microbial interventions for managing chemical nitrogen; but the potentiality of these microbes is really a question mark at field level mainly due to environmental constraints. Endophytes are less prone to environmental factors, therefore, *Azotobacter chroococcum* MCC 3432 (NRRI EndoN), a native endophyte diazotroph was harnessed as effective nitrogen-fixing bacteria for rice crop. NRRI EndoN was isolated from rice root and established its endophyte character by using FRET-based imaging technique. The potentiality of NRRI-EndoN was proved through lab and field study in rice crop. Finally, a liquid formulation of NRRI-EndoN, having shelf life of more than a year was developed and evaluated at 30 different locations covering about 1000 acres in the farmer's field. Based on validation data, NRRI-Endo N could enhance yield by 10.31% besides saving about 25% chemical N. The mean yield advantage of 0.53 t/ha could be achieved over farmer practice irrespective of rice cultivars which can lead to a monetary benefit of about 80 to 90 US dollar per hectare over farmers practice. The technology is certified by ICAR, India and Expression of Interest (EOI) has been published in AgriInovate, New Delhi, India for commercialization. For mass production, a large scale commercial biofertilizer production unit was established at CRRI which has capacity to produce 0.15 million liters annually. Revenue of around 35,000 US dollar was generated during 2024-2025 after selling of this product to different stakeholders. Besides, this product has been promoted through mass awareness, live demonstration, mass media and by existing farmer producing organization.

**Acknowledgments**

I truly acknowledge to Director, ICAR-Central Rice Research Institute, Cuttack and other researchers in supporting to develop NRRI-EndoN as an excellent technology for nitrogen management in rice.

# Effect of organic materials and sulfate addition on cadmium bioavailability and accumulation of rice in cadmium sulfide nanoparticles- and cadmium chloride-treated soil

**Yanhua Qiu**[1*]

[1] *Institute of Plant Nutrition, Resources and Environment, Beijing Academy of Agriculture and Forestry Sciences, Beijing 100081,China*

**ABSTRACT**

Water-soluble and extractable cadmium (Cd) govern Cd bioavailability. However, cadmium sulfide nanoparticles ($CdS_{np}$) bioavailability remains unclear. Pot experiments investigated how organic materials (1 % wheat straw and pine needles) and sulfate (30 mg S/kg) affect Cd bioavailability and accumulation in rice in $CdCl_2$- and $CdS_{np}$-treated soils. Sulfate addition alone immobilized Cd through sulfate-reducing bacteria-mediated Cd-precipitation in $CdCl_2$-treated soil, thereby reducing Cd accumulation in brown rice. However, it promoted $CdS_{np}$ dissolution and Cd transfer, increasing Cd accumulation in $CdS_{np}$-treated soils. Organic materials alone promoted Cd re-release from immobilized Cd through sulfur-oxidizing bacteria (SOB)-induced oxidation and dissolved organic matter (DOM)-assisted complexation to increase Cd availability in $CdCl_2$-treated soil at the maturity stage. Consequently, organic materials alone increased brown rice Cd accumulation in $CdCl_2$-treated soil, while combination with sulfate had no effect. In $CdS_{np}$-treated soils, organic materials promoted $CdS_{np}$ dissolution through driving SOB, decreasing pH, and increasing DOM complexation, which increased Cd availability and transfer, promoting brown rice Cd accumulation. $CdS_{np}$ exhibited lower Cd bioavailability and accumulation than $CdCl_2$ due to lower solubility and slower Cd release, suggesting $CdS_{np}$ smaller contributions to rice Cd accumulation. Therefore, sulfate addition alone is recommended to reduce Cd accumulation, with organic materials only used in combination with sulfate.

## ABSTRACT

Arsenic (As) contamination in paddy soils is a major environmental and agricultural issue. Sediment microbial fuel cells (SMFCs) have been operated as a sustainable method for reducing As mobility in contaminated soils while generating electricity. Soil factors such as Fe, Al, Mn, S, organic matter, pH, texture, and P levels affect As availability, but SMFC effectiveness across diverse soil types remain unclear. This study evaluated SMFC's impact on As availability in soil solutions from three Japanese paddy soils over an 80-day column experiment. Lab scale single chamber SMFC setups were established using cylindrical acrylic columns (height, 200 mm; diameter, 90 mm; thickness, 3 mm). Flame oxidized stainless steel mesh (180 × 40 mm) and carbon felt (60 × 50 mm) served as the anode and cathode materials, respectively. A total of 18 columns were constructed, and six sets of treatments were prepared in triplicate: Yamagata soil (Y-soil), Toyama soil (T-soil), and Kesennuma soil (K- soil) each operated under control (open-circuit (OC)) and SMFC-operated (closed-circuit (CC)) conditions. All the treatments were preincubated under OC conditions for one week at 25°C conditioned room, followed by 80 days of incubation. Cell voltages were recorded every 10 minutes throughout the experiment by a data acquisition system. Soil porewater was sampled for As and elemental analysis on days 0, 10, 20, 30, 40, 50, and 80 at 4 cm soil depth using samplers with 0.2 µm microporous membranes. Results showed that a maximum OC voltage of 1.1, 1.03, and 0.7 V, and CC voltage of 0.12, 0.2, and 0.15 V in T-soil, Y-soil, and K-soil treatments, respectively. The cumulative charge transferred by CCs was observed to be 329 C in T-soil, 501 C in K-soil, and 642 C in Y- soil, indicating varied electrochemical activity across the different soil types. Results further indicate that the operation of SMFC reduced available As in the soil solution by 12%, 20%, and 33% in T-soil, Y-soil, and K-soil, respectively compared to the controls. In T-soil and Y-soil, the concentration of As in the soil porewater was occasionally reduced by CCs during the first 50 days by keeping Fe and Mn steady perhaps through promoting oxidative process in the anode, which in turn inhibits arsenic release into the porewater. Eventually, the performance of SMFCs is likely limited by the depletion of organic matter required to suppress As release into the porewater of these soils. Whereas in K-soil the inhibition of As by CC continued until day 80, which correlates with higher levels ofFe, Mn, S, and DOC, supporting longer term reduction. Further statistical analyses showed that As correlated positively with pH, Ca, Mn, and Fe, but negatively with sulfur in pore water. Findings suggest that SMFC strongly affects As mobility in paddy soils, though soil chemistry may influence its remediation performance, extent and duration.

## ABSTRACT

Optimizing micronutrient use efficiency while minimizing chemical dependency is crucial for sustainable rice production. Zinc (Zn) deficiency remains a pervasive global challenge, affecting approximately one-third of cultivable soils. In submerged paddy ecosystems, Zn bioavailability is further compromised by elevated iron ($Fe^{2+}$) and manganese ($Mn^{2+}$) concentrations, which promote Zn adsorption onto hydroxide surfaces and the formation of insoluble compounds like franklinite ($ZnFe_2O_4$). While mineral fertilizers such as zinc sulphates provide highly soluble Zn, they are prone to rapid precipitation into unavailable carbonate or phosphate pools. This study investigates a synergistic "Inorganic-Organic-Microbial" approach using mineral Zn, cow dung, and zinc-solubilizing microbial consortia (ZSM)- *Acinetobacter calcoaceticus* and *Pantoea agglomerans* to enhance nutrient recovery efficiency and ensure long-term soil health. A two-year field experiment was conducted at the research farm of the Institute of Agricultural Sciences, Banaras Hindu University (BHU), Uttar Pradesh, India, located at 25°18' north latitude and 83°03' east longitude. The soil was alkaline in nature (pH 7.3) and had 0.78 mg $kg^{-1}$ DTPA-extracted Zn. The experiment was statistically designed in randomized block design (RBD), with twelve treatments and three replications. Among the treatments, plot received 9.8 kg ZnO $ha^{-1}$ with ZSM showed better biological yields, and outperformed the higher doses of mineral fertilizers applied in isolation. However, 25.0 kg Zn sulphate heptahydrate (ZnSHH) $ha^{-1}$ + ZSM was recorded statistically comparable to the former treatment. Notably, the addition of cow dung (CD) decreased the grain yield when combined with (9.8 kg ZnO $ha^{-1}$ + ZSM + 200 kg CD $ha^{-1}$) and (14.6 kg ZnO $ha^{-1}$ + ZSM + 200 kg CD $ha^{-1}$). Different use efficiency of applied Zn such as Partial factor productivity of applied Zn computed and it varied from 347.2 to 1762.2 and 369.6 to 1855.6 kg grain $kg^{-1}$ Zn, physiological Zn efficiency from 487.4 to 2075.3 and 775.5 and 2035.2 kg grain $kg^{-1}$ Zn, agronomic use efficiency of Zn from 20.1 to 189.6 and 28.7 to 180 kg grain $kg^{-1}$ Zn, the recovery efficiency of Zn fertilizer varied from 3.58 to 11.9% and 3.57 to 11.8% among the all treatments in both seasons, respectively. The recovery efficiency of Zn reached a maximum of 11.9%, representing a significant advancement in nutrient cycling compared to conventional practices. This research highlights a "microbial-organic-inorganic" triad that not only rehabilitates soil nutrient dynamics but also aligns with regenerative practices by reducing chemical dependency.

# Earthworm burrows enhanced rice root growth under a no-tillage rice-rapeseed rotation system

**Lingling Liu[1*], Chao Li[1], and Hu Zhou[2]**

[1] *Hunan Cultivated Land and Agricultural Eco-Environment Institute, Changsha 410125, Hunan, China*

[2] *College of Land Science and Technology, China Agricultural University, Beijing, China*

*E-mail: llliu@hunaas.cn

**ABSTRACT**

Earthworm burrows are an important class of biopores that facilitate gas and water transport and affect plant root growth. However, in paddy soils that experience periodic flooding during the rice growth season, the effects of earthworm burrows on rice root growth have often been overlooked. In this study, we used X-ray Computed Tomography (CT) to investigate the impact of earthworm burrows on the growth of rice roots in paddy fields under two contrasting tillage practices. Undisturbed soil cores (0-36 cm depth) were collected from rotary tillage (RT) and no-tillage (NT) paddy fields, and then used for an incubation experiment that simulated a rice-rapeseed rotation system either with (RTE, NTE) or without (RTN, NTN) the addition of earthworms during the rapeseed season. Earthworm burrows, rice roots and their interaction were determined with CT imaging in the rice season. Rotary tillage resulted in 1.70 times greater soil macroporosity (>146 μm) than the NT soil. After earthworm introduction, the volume and surface area of earthworm burrows in the RTE treatment were 2.4 and 1.7 times greater, respectively, than those in the NTE treatment. However, the newly formed earthworm burrows in the RTE treatment did not significantly affect rice root traits or their utilization of these burrows. On the contrary, the increased earthworm burrows in the NTE treatment significantly enhanced rice root volume, surface area, length, mean diameter, and the utilization of these burrows by roots was 189% greater than in the NTN treatment. Additionally, the increase in earthworm burrows of the NTE treatment notably increased root density in the subsoil. Our results show that the increase of earthworm burrows has an important role in promoting rice root growth under NT, suggesting earthworms are crucial to the success of no tillage system for the rice paddies.

# Carbon Storage Capacity of Peat Soils from High Bogs and Low Bogs

**Wolfgang Burghardt**[1]

[1]Soil Technology, Faculty of Biology, University Duisburg-Essen, Essen, Germany
*Email: wolfgang.burghardt@uni-due.de

**ABSTRACT**

Peat soils became now of more interest due to their potential to store atmosperic $CO_2$. There are attempts to increase areas covered by peat soils. This concerns primary high bogs by rewetting former peat land areas. Low bogs are not much in the focus of reestablishing peat land. However, they have a high potential to store atmosperic $CO_2$ in their dead and by water conserved plant mass.

The presentation will compare peats from high bogs and low bogs. $CO_2$ storage related to 1000 $cm^3$ peat and of peat profiles of 1 m depth will be given. The $CO_2$ storage is much depended on the bulk density of organic matter of peats. Thus about the bulk densities of the investigated peats will be reported too. Given examples are from the North German Low Land.

**ABSTRACT**

Peat is an important archive for reconstructing past ecosystems and human activities in mountainous regions. This study presents a high-resolution multi-proxy analysis of the Zhaogongting (ZGT) peatland in southern China, spanning the past ~9,000 years. We analyzed mercury (Hg) concentrations, pollen assemblages, total organic carbon (TOC), total nitrogen (TN), and stable isotopes ($\delta^{13}C$, $\delta^{15}N$) using quantitative modeling approaches, including stepwise multiple regression and eXtreme Gradient Boosting (XGBoost), to reconstruct environmental evolution and quantitatively evaluate the relative contributions of natural and anthropogenic factors to long-term mercury deposition. During 9.3–5 cal kyr BP, the ZGT area was probably a shallow, minerotrophic swamp, with relatively low Hg concentrations due to limited peat development and low atmospheric Hg inputs. Between 5 and 4 cal kyr BP, enhanced organic matter accumulation and cooler–drier climatic conditions promoted the transition to an ombrotrophic system, markedly increasing Hg retention. Around 4.2 cal kyr BP, synchronous changes across multiple proxies reflect a regional response to this cooling event. After 4 cal kyr BP, Hg concentrations continued to rise, with human activities such as widespread use and mining of cinnabar overtaking natural factors as the dominant control on Hg deposition. This study provides new quantitative evidence for the climate–peat–Hg coupling in subtropical East Asia and highlights the increasing anthropogenic influence on the remote area since the late Holocene.

**ABSTRACT**

Peatlands are waterlogged areas where the rate of organic matter (OM) accumulation is greater than the rate of OM decomposition, thus resulting in the formation of peat, a complex material that consists of partly fossilized plant residues. Peatlands can be found in the arctic, boreal, temperate and tropical zones, and support a unique biodiversity in terms of plants, animals and microorganisms (bacteria, filamentous fungi and yeasts). Fungi are the main responsible for the degradation of recalcitrant peat components; on the opposite, yeasts are involved in the utilization of simple carbon compounds and are generally considered secondary saprotrophs. However, their ecological roles in this ecosystem still need to be clarified (Thormann 2006, 2007; Rydim *et al*. 2013; Juan-Ovejero *et al.* 2020). The aim of this work was to isolate and identify the culturable fungal community (filamentous fungi and yeasts) from peat. Samples were collected from two alpine peatlands (Northen Italy) at different depths, diluted 1:10 and plated on YM agar, supplemented with sodium propionate to inhibit filamentous fungi growth, and PDA agar. The identification was carried out with single or multi-locus sequences (LSU, ITS, benA, RPB2, tef1, ACT, GPDH3, HSP60). A total of 26 filamentous fungi and 12 yeasts were isolated.

The fungal taxa isolated from peatlands represent species that play fundamental roles in the OM decomposition. Some species rely on carbohydrates that leach out from plant tissues (e.g., *Cladosporium, Aureobasidium*), together with pioneer saprobes of OM derived from plant residues (e.g., *Linnemannia*, *Mortierella*, *Mucor*). Other taxa were identified as polymer degraders (e.g., *Fusarium*, *Trichoderma*). On the other hand, taxa associated with high activity in the degradation of recalcitrant polymers (e.g., lignin) were not detected; in fact, the isolates were mainly filamentous ascomycete fungi, whereas lignin degradation is primarily carried out by basidiomycetes. In addition, several plant pathogens were detected (*Fusarium commune*, *Didymella pomorum*, *Cadopohora luteo-olivacea, Zymoseptoria* sp.). Yeasts were also recovered, and most of them corresponded to taxa previously reported from peatland environments (e.g., *Cyberlidneria, Rhodotorula*).

Notably, the occurrence of the species filamentous fungi and yeasts species (such as *D. pomorum*, *Solicoccozyma aquatica*, and *Phaeotremella ovata*) represents a new record for this ecosystem. Furthermore, phylogenetic analyses showed that seven filamentous fungal taxa (*Chlamydocillium* sp., *Coniella* sp., *Myriosclerotinia* sp., *Cladosporium* sp., *Talaromyces* sp., *Coniochaeta* sp., *Zymoseptoria* sp.) and two yeasts (*Halobasidium* sp. and *Sterigmatospora* sp.) could not be assigned to any recognized species. Overall, this study revealed the fungal biodiversity associated with alpine peatlands in Italy, with particular emphasis on the isolation of taxa not previously recovered from similar environments, as well as putative new species.

**ABSTRACT**

Free-floating islands, mysteriously moving around on lakes, were described by several Latin authors almost two millennia ago. Seneca (4 BC-AD 65) in his *Naturales quaestiones*, and by Pliny the Elder (AD 23-79) in his *Naturalis historia* ("Of Islands Ever Floating and Swimming"), for example, have left us suggestive descriptions of floating islands, reporting details about their size and shape, buoyancy and vegetation.

These fascinating ecosystems have been often investigated from ecological, hydrological and management points of view, but there have been almost no studies of their rates of accumulation of organic matter, as well as on their possible role as a natural archive of climate and vegetation changes, as well as of the historical human activity.

A 4-m long peat core was collected from the center of the free-floating island of Posta Fibreno, a relic mire in Central Italy. This is the thickest accumulation of peat ever found in a free-floating mire, yet it has formed during the past 700 yr (Zaccone et al., 2017). This free-floating mire shows anomalously high accretion rates (0.5–0.6 cm/yr), that are 10× greater than other terrestrial peatlands (0.02–0.08 cm/yr) (Zaccone et al., 2017), and preserves some peculiar microbial taxa (Zaccone et al., 2018) which show an unusual concurrent species convergence between this sub-Mediterranean site and far Nordic or circumpolar environments (Concheri et al., 2017). Thus, this free-floating island has the potential to be also used as archive of natural and human-induced environmental changes occurring during the last centuries.

In this work, the first high resolution records of organic matter accumulation, trace element and dust depositions, and environmental changes from a free-floating island will be presented, and the reliability of this peat archive for geochemical and environmental studies suggested and demonstrated.

**ABSTRACT**

Tropical peatlands, vital carbon stores, are degraded by drainage, fires, and dependence on synthetic fertilizers, necessitating Nature-based Solutions (NbS) for sustainable management. While NbS frameworks promote nutrient cycling, empirical data on their crop-specific efficacy in perennial systems, such as coconut (Cocos nucifera) on peatlands, remain scarce. This study assesses regenerative practices in an organic-certified coconut estate (Indragiri Hilir, Indonesia), focusing on natural weeds as understory cover crops to implement the nutrient cycle. Seasonal sampling targeted natural weed biomass under coconut trees (n=12 randomized quadrats), soil (0–20 cm, n=12), and coconut leaves (n=9). Analyses included macro-and micronutrients, pH, and bulk density. The dominant fern (Nephrolepis sp., ~50% biomass) was manually weeded every 4 months and left to decompose in situ, emulating closed-loop nutrient cycling. The peat soil was acidic (pH 3.72 ± 0.19) with low base saturation but stable density (0.144 ± 0.01 g cm_3), indicating compaction recovery. Weed biomass averaged 7.8 ± 0.3 t DM ha_1 cycle_1, supplying ~19.8 kg P, 314 kg K, 97 kg Ca, 130 kg Mg, and 13 kg Na ha_1 yr_1 (with an average 75% of nutrient content released within 8-week periods). Leaf nutrient analyses revealed optimal status and no deficiencies, with yields comparable to those in fertilized systems. This approach delivered ecosystem services, including ~Rp 33 million (USD 1,985) ha_1 yr_1 in input savings, while contributing to minimized emissions and subsidence. The findings validate weed-mediated NbS for peatland perennials, offering scalable, low-cost alternatives amid fertilizer volatility. Replication in smallholder contexts could enhance socio-economic resilience and biodiversity, advancing sustainable peatland agriculture.

*Lars.Elsgaard@agro.au.dk

**ABSTRACT**

Peatlands play a central role in the global carbon cycle by storing a disproportionate share of the world's soil organic carbon. However, drainage for agriculture has transformed many peatlands from long-term carbon sinks into major sources of greenhouse gas (GHG) emissions. In particular, organic-rich soils transitioning from peat to organo-mineral soils represent a poorly documented component of national carbon budgets (Liang et al., 2024). At the same time, important knowledge gaps remain regarding how peat subsoils contribute to carbon dioxide ($CO_2$) emissions from drained agricultural peatlands and how this should be represented in GHG inventories and mitigation strategies (Kandel et al., 2025).

Here we report on depth-specific GHG fluxes from drained agricultural peatlands using intact peat cores collected from topsoil and subsoil layers at temperate arable and permanent grassland sites. GHG fluxes were measured across a gradient of temperatures and soil water tensions to disentangle the interacting effects of temperature, moisture and depth on GHG emissions. Carbon dioxide fluxes were consistently high-er in the topsoil than in the subsoil, with emissions on average three times greater, demonstrating that near-surface peat dominates short-term $CO_2$ losses. Temperature exerted a strong control on $CO_2$ emissions, particularly in the topsoil, whereas subsoil layers showed lower fluxes and reduced temperature sensitivity. Rewetting substantially reduced $CO_2$ emissions from topsoil at elevated temperatures but had little effect on subsoil fluxes.

Our results support modelling approaches that assume a decline in microbial $CO_2$ production with soil depth, consistent with sigmoidal water table depth response functions used in recent national inventory frameworks. However, the study also highlights uncertainties in linking annual mean water table depth to net $CO_2$ emissions, underscoring the need for improved depth-resolved process representation to enhance the accuracy of national GHG inventories and assessments of peatland rewetting as a climate mitigation strategy.

# Breaking metabolomics limits for a molecular to pathway multidimensional analysis of metabolism alpine peatlands soil dissolved organic carbon

**Shuangchao Wang[1]*, Hui Sun[1], Yujia Tang[1], Junxi Li[1]**

[1] *Sichuan University (Department of Environmental Science and Engineering, School of Architecture and Environment, Chengdu, China)*

*shuangchaowang@stu.scu.edu.cn

**ABSTRACT**

As a critical component of the alpine peatland labile carbon pool, soil dissolved organic carbon (DOC) undergoes complex metabolic processes that are essential parameters for improving the understanding of soil carbon storage and mineralization systems, which have not yet been systematically elucidated. Traditional metabolomics and spectroscopy technology, as statistics-based compound analysis methods, fall short of providing a refined elucidation of the complex metabolic dynamics of alpine peatlands soil DOC (WDOC) at the molecular level. This study investigated the mineralization rate, changes in compound composition and quantity, and transformation of WDOC by integrating non-target metabolomics and spectroscopy with molecular simulation and comparative analysis against transformation databases. 84 samples were distributed along the tributaries of the Yellow river in the Zoige plateau, China. During the 0-48 hour in situ incubation, WDOC exhibited the highest metabolic rate within the initial 6 hours with 635 new compounds identified. The removal rate of topsoil WDOC (0-5 cm) (50.62%) was higher than that deep soil (15-20 cm) (47.34%). Compounds removed from WDOC were primarily unsaturated hydrocarbons, lignins, proteins, and lipids, characterized by O/C of 0-0.7 and H/C of 0.5-2.5. The newly produced compounds were mainly lipids and unsaturated hydrocarbons. Transformation-resistant compounds within WDOC are mainly low O/C (0-0.3) lipids and unsaturated hydrocarbons. Some tannin were retained during the metabolism of WDOC derived from deep soil contrast to topsoil. Comparative analysis of molecular simulations and the transformation database revealed that deoxygenation (30), demethylation (32), and decarboxylation (33) serve as primary pathways for the molecular transformation of WDOC. Microbial and photochemical processes transformed WDOC into more stable organic carbon with high saturation (DBE=6.4422), low aromaticity ($AI_{mod}$=0.1797), and high oxidation state (NOSC=-0.6655). Transformation pathways predicted across 3 levels via the KEGG database provided molecular level validation of WDOC metabolic processes. Compounds involved in WDOC metabolism were mainly found in metabolic pathways (ko01100), biosynthesis of secondary metabolites (ko01110), biosynthesis of cofactors (ko01240) and metabolism of xenobiotics by cytochrome P450 (ko00980) characteristic pathways.

## ABSTRACT

Soil organic carbon (SOC) in alpine peatlands constitutes a major fraction of the global soil carbon pool and is assumed high sensitive to global environmental change especially soil moisture loss due to long-term low temperature environment. Despite soil moisture loss exacerbates the loss of alpine peatlands soil carbon pool, the response of SOC fractions to changes in soil moisture remain unexplored. Here we assess the mechanisms underlying the response of alpine SOC pools to soil moisture loss using a field survey of SOC in peat wetlands and dried peatlands (a peatland with degraded soil moisture) in the same ecological setting at the fraction scale. Despite a significant decrease in the SOC pool, the proportions of mineral-associated organic carbon (MAOC) and heavy-fraction organic carbon (HFOC) (more stable SOC forms) increased by approximately 25% and 20% in dried peatlands. We find that soil moisture loss caused about 40% of SOC mineralization and concentrated in the 0 - 15 cm soil layer. The larger size of particulate organic carbon mineralized up to 75 mg/g (about 60% of the total organic carbon), while about 39% for MAOC (smaller size). Soil dissolved organic carbon (DOC) decreased significantly in dried peatlands despite the smaller particle size (< 0.45 μm) of the more active soil DOC. From the density scale, the mineralization of HFOC is about 30 mg/g, which is much lower than that of light-fraction organic carbon (LFOC) (66 mg/g). While size and density scales are useful for explaining the stability of soil organic carbon based on its resistance to decomposition, direct supporting evidence is still lacking. We find that the content of more reactive aliphatic compounds decreased and the proportion of more stable aromatic compounds increased during soil moisture loss. The recalcitrance index (RI) and aromaticty (Ar), representing higher resistance to decomposition and more chemically stable structure, are significantly higher in dried peatlands ($RI_{DPL}$, 1.4-1.7; $Ar_{DPL}$, 2.0-10.1) than in peat wetlands ($RI_{WPL}$, 1.4-1.7; $Ar_{WPL}$, 2.0-10.1). The decrease of Gram-negative bacteria content, which is significantly positively correlated with more labile SOC, by 3.0 μmol/g in dried peatlands also indicated that stable SOC dominate the SOC pool in dried peatlands. Overall, our results find that soil moisture loss in alpine peatlands accelerate labile SOC mineralization at the size, density, compound and microbial scales but highlight the increased stability.

## ABSTRACT

Nitrogen plays a central role in regulating soil biogeochemical processes in peatlands; however, degradation of approximately 12% of global peatlands has substantially altered soil nitrogen cycling. Stable nitrogen isotopes ($\delta^{15}N$) are widely used to trace soil nitrogen sources and transformations, yet their responses to peatland degradation and associated controlling factors remain poorly constrained, particularly in alpine peatland soils. In this study, we investigated variations in soil and plant $\delta^{15}N$ and their relationships with soil nitrogen pools and environmental drivers along a degradation gradient in alpine peatlands of the Zoige (Ruoergai) peatland, eastern Tibetan Plateau, China, including flooded wetlands, wet meadows, moderately degraded meadows, and severely degraded meadows. Soil and root samples were collected across degradation stages, and $\delta^{15}N$ patterns were analyzed together with soil physicochemical properties. The result showed that soil $\delta^{15}N$ increased from flooded wetlands to wet meadows and moderately degraded meadows, indicating enhanced nitrogen mineralization and loss associated with peat drying and increased aeration. In contrast, soil $\delta^{15}N$ declined under severe degradation, likely reflecting constrained microbial activity and reduced nitrogen transformation capacity under strongly moisture- and nutrient-limited conditions. Across all degradation stages, plant roots were depleted in $^{15}N$ relative to soils, with progressively more negative $\Delta\delta^{15}N_{root-soil}$ values toward degraded sites, suggesting shifts in plant nitrogen acquisition pathways and isotope fractionation during uptake. Random forest results identified soil water content as the dominant control on soil and plant $\delta^{15}N$, followed by soil phosphorus and nitrogen availability, highlighting the interactive effects of hydrological change and nutrient limitation on soil nitrogen cycling. Overall, peatland degradation alters soil $\delta^{15}N$ signatures and enhances isotopic decoupling between soil and plants, reflecting a transition toward more open soil nitrogen cycling and increased nitrogen losses. These findings demonstrate the sensitivity of soil $\delta^{15}N$ to hydrological degradation and its value as an integrative indicator for assessing changes in soil nitrogen dynamics across peatland degradation gradients.

# Soil drying accelerates CO2 emissions in global cold and wet ecosystems

**Shaobo Sun**[1*]

[1] *Institute of Surface-Earth System Science, School of Earth System Science, Tianjin University, Tianjin, China*

*E-mail: shaobo.sun@tju.edu.cn

**ABSTRACT**

Cold and water-saturated ecosystems, including permafrost regions, northern peatlands, Arctic tundra, boreal wetlands, and alpine swamp meadows, store substantial reservoirs of soil organic carbon (SOC). These systems are widely recognized as being highly sensitive to climate warming, which accelerates SOC mineralization. However, at broad spatial scales, the extent to which soil water status modulates SOC decomposition and associated $CO_2$ emissions through its control on oxygen ($O_2$) availability remains insufficiently constrained. We combine *in-situ* measurements from 107 field sites with global observational datasets and process-based model simulations to examine how soil water dynamics regulate $CO_2$ emissions via limitations on $O_2$ diffusion across cold and wet ecosystems. Field observations consistently demonstrate that elevated soil water levels suppress SOC decomposition and $CO_2$ release, indicating that the removal of this hydrological constraint under drying conditions represents a key mechanism amplifying $CO_2$ emissions, in addition to the direct effects of warming. In contrast, global data-driven products and Earth system model simulations exhibit highly variable and often inconsistent relationships between soil $CO_2$ effluxes and soil water levels. Many current models rely on simplified soil moisture scalars or empirical parameterizations, which fail to adequately capture water-controlled $O_2$ diffusion and its impact on SOC decomposition in cold and wet environments. Our findings highlight the necessity of integrating more mechanistic representations of soil hydrological controls on SOC dynamics, alongside improved spatially explicit hydraulic properties, to strengthen projections of soil carbon-climate feedbacks.

# Warming Amplifies Iron-Mediated Carbon Loss from Peatlands: A Positive Feedback Modulated By Soil Properties

**Chunmei Chen[1*], Jialin Wang[1], and Yilin Lan[1]**

[1] *School of Earth System Science, Tianjin University, Tianjin, China*

*E-mail Address of Presenting Author: cmchen88@tju.edu.edu

**ABSTRACT**

The vast organic carbon (OC) stocks in peatlands are highly vulnerable to global warming. While reactive iron (Fe) phases are known to regulate OC persistence, how warming affects the coupled Fe-OC dynamics in peatlands remains unclear. Through anoxic microcosm experiments with Zoige peatland soils (Qinghai-Tibet Plateau) across a temperature gradient (5–30°C), we demonstrate that Fe(III) reduction drove ~52% of anaerobic $CO_2$ production and mobilized substantial dissolved OC (DOC). FT-ICR-MS revealed that the mobilized DOC was selectively enriched in lower-molecular-weight, unsaturated compounds, whereas high-molecular-weight aromatic compounds remained more resistant to mobilization. Warming stimulated Fe-reducing bacteria (e.g., *Geothrix*), accelerating Fe(III) reduction and the concurrent release of $CO_2$ and low-molecular-weight DOC. The temperature sensitivities of $CO_2$ and DOC release were positively correlated with those of Fe(III) reduction. Soils with higher OC and reactive Fe(III) sustained greater rates of these processes but exhibited lower temperature sensitivity. Methanogenesis was disproportionately favored in OC-rich soils and at elevated temperatures. These findings suggest that warming will amplify Fe-mediated carbon loss and labile DOC export from peatlands, with the magnitude of this feedback modulated by inherent edaphic properties.

# Harnessing the soil food web for sustainable ecosystems: Current evidence and future perspectives

**Uffe N. Nielsen**[1*]

[1] *Hawkesbury Institute for the Environment, Western Sydney University, Penrith, NSW, Australia*

*u.nielsen@westernsydney.edu.au

**ABSTRACT**

Terrestrial ecosystem function is governed by the intricate interactions among the constituent plants and soil biota. Plants fuel soil processes through carbon inputs and moderate biochemical cycles via ecosystem engineering, quantity and quality of litter deposition, and plant-soil biotic interactions. In turn, microbes drive nutrient mineralization fundamental to plant growth and directly influence plants as beneficial associates or as antagonists. In addition, the larger soil fauna modifies the soil physico-chemical landscape and regulate microbial activity, plant growth and ecosystem functions, and thereby plant community dynamics. A wealth of knowledge demonstrates the importance of the interactions among plants, microbes and soil fauna in driving ecosystem function, yet engineering of soil food web structure and biotic interactions to enhance ecosystem sustainability remains underutilized. In this presentation I will provide an overview of general principles of how better management (or engineering) of soil food webs can be applied across landscapes to both enhance the sustainability of production systems and restoring healthy and functionally resilient ecosystems to combat the ongoing biodiversity decline. I will leverage examples from ongoing research programs with collaborators and theory throughout the presentation. I will finish the talk by illustrating key knowledge gaps and perspectives on how we can better integrate knowledge of soil food web structure to future proof natural and managed ecosystems.

**ABSTRACT**

An important aim of ecology is to understand the ecological strategies of organisms, how strategies relate to species traits, how traits and strategies of species affect ecosystem functions, and how these effects may be mediated by, or affect, other species. As for many aspects of the Earth, far less is known about the world belowground than aboveground. Although our knowledge has been advanced by ecological strategy schemes applied individually to plants, soil organisms and ecosystem function, evidence for their coordinated dynamics remains limited. Here, we take a holistic view to explore how the traits of ecosystem components – plants and soil nematodes – and of soil carbon cycling are coordinated across diverse ecosystems. We first identified a nematode trait space capturing two primary dimensions: the nematode economics spectrum (NES), balancing body construction costs against growth potential; and a reproduction dimension, varying from low to high fecundity. Regression analysis revealed their coordinated relationships with plant trait-strategy dimensions: the NES aligns with the plant economics spectrum (PES), and reproduction dimensions align with the root collaboration dimension. Notably, these coordinated plant-nematode trait dimensions correspond to distinct axes of soil carbon cycling: carbon fluxes are associated with the collaboration–reproduction dimension, whereas carbon pools are linked to the PES–NES dimension. This cross-kingdom coordination defines an integrated belowground trait space that provides a holistic perspective on ecosystem-level functional dynamics and opens new avenues for predicting ecosystem responses to changing environments.

*xuzhenxin21@mails.ucas.ac.cn

**ABSTRACT**

Understanding how global change factors affect soil biodiversity through deterministic versus stochastic communities assembly processes remains a central challenge in ecology. We conducted a long-term multifactorial experiment to assess the impacts of drought, nitrogen deposition, and delayed snowmelt on soil communities. Using high-throughput sequencing for bacteria, fungi, and nematodes, and microscopic identification for mesofauna, we assessed the β-diversity and quantified the relative importance of assembly processes. Our results show that stochastic processes dominate in bacterial and mesofauna communities, whereas deterministic processes dominate in fungal and nematode communities. Drought increased the relative role of stochasticity in fungal and mesofauna communities but decreased it in bacterial communities. Nitrogen deposition enhanced stochasticity only in the fungal community. Furthermore, the degree of stochasticity in bacterial communities was positively correlated with their β-diversity, whereas the strength of deterministic processes was positively linked to β-diversity in fungal and nematode communities. Finally, we found that both within- and cross-trophic interactions jointly mediated the β-diversity of soil biotic community. Our findings demonstrate that delayed snowmelt can affect the impacts of drought and nitrogen deposition on soil biodiversity through multi-trophic interactions, providing new insights for grassland conservation and a critical theoretical basis for predicting biodiversity responses to global change.

**ABSTRACT**

Livestock grazing is known to significantly affect steppe ecosystems. However, the effects of grazing on ground-dwelling arthropods is still poorly studied, especially on the Stipa breviflora desert Steppe. We investigated the effects of varying intensities (light grazing (LG),moderate grazing (MG),heavy grazing (HG)as well as no grazing (CK) on the abundance and richness of ground-dwelling arthropods using pitfall trapping on August 2015. Plant communities and soil physicochemical characteristics were also measured to explore the relationships between the structure of ground-dwelling arthropod communities and key environmental variables.The abundance and group richness of ground-dwelling arthropods as well as the diversity index were significantly lower in the moderate and heavy grazing treatments ($P< 0.05$). Light grazing had no significant negative effect on ground arthropods, plant or soil characteristics($P>0.05$).Principal component analysis (PCA) showed that arthropod communities could be separated into two groups: control-light and moderate-heavy. Based on these results, light grazing may be an appropriate grazing intensity in this desert steppe.Partial redundancy analysis showed that community density and vegetation cover play the most important roles in regulating ground-dwelling arthropods responses to grazing.

# Mechanism of soil fauna on soil microbial necromass carbon accumulation in a subtropical forest under nitrogen addition

**Shixing Zhou[1*], Junxi Hu[1], Kaiwen Pan[2], and Congde Huang[3]**

**ABSTRACT**

Microbial necromass is an important source and component of the soil organic carbon pool and plays a crucial role in soil carbon cycle and climate change mitigation. Soil fauna, as the core of the belowground food webs, plays a critical role in controlling the formation and turnover of microbial necromass. However, due to the insufficient understanding of how nitrogen deposition affects soil fauna and their cascading effects on microorganisms, it is difficult to assess the contribution and regulatory role of soil fauna in microbial necromass carbon accumulation in the context of global change. To fill this gap, we conduct a field in situ manipulation experiment in a subtropical evergreen broad-leaved forest, three simulated nitrogen deposition treatments (i.e., 0, 50, and 150 kg N $ha^{-1}$ $yr^{-1}$) and two soil fauna treatments (i.e., non-defaunated and defaunated treatment) were established to examine to the effects of soil fauna on soil microbial necromass carbon accumulation in a subtropical forest under nitrogen addition. DNA metabarcoding and biomarker technology was used in this study to explore the effect of nitrogen addition on soil faunal communities and microbial necromass carbon contents. Soil microbial structure and function, key enzyme activities, and soil physicochemical properties were also be investigated. The main results are still under analysis, and we are confident of presenting a perfect report before the conference begins. We believe the results can provide theoretical support for further understanding the biological regulatory mechanism of the soil carbon cycle under the context of global change.

# Proteobacteria as keystone bridges in the micro-food web: a new strategy for biocontrol design

**Huiyu Chuai, Gen Li, and Ting Liu***

*College of Resources and Environmental Sciences, Nanjing Agricultural University, China*

*E-mail: ting.liu@njau.edu.cn

**ABSTRACT**

Trait-mediated interactions across trophic levels drive trophic cascades in macroecological systems, yet their relevance in microbially dominated soil ecosystems remains underexplored. We combined a regional field survey with controlled experiments using a defined 122-strain synthetic bacterial community and bacterivorous nematodes to test whether faunal predation reorganizes root-associated microbiomes to suppress soilborne disease. Field observations showed that sites with stronger nematode-Proteobacteria associations had lower bacterial wilt incidence. In controlled experiments, nematode predation selectively enriched Proteobacteria in the rhizosphere and reduced Ralstonia solanacearum populations and disease incidence. Preferential grazing drove this enrichment: Proteobacteria constituted over 95% of sequences in nematode guts, and focal taxa showed moderate antagonism, small cell size, and high metabolic activity. Together, these results identify Proteobacteria as key bridging taxa in cross-trophic interactions. Trait-linked responses to predation contribute to pathogen suppression and suggest a biocontrol framework that integrates microbial traits with trophic connectivity.

# Impacts of chemical free turfgrass renovation on soil arthropod and nematode communities

**Zhiqiang Cheng[1*], and Jennifer Michalski[1]**

[1] *Department of Plant and Environmental Protection Sciences, CTAHR, University of Hawaii at Manoa, Honolulu, HI 96822 USA*

*cheng241@hawaii.edu

**ABSTRACT**

Non-selective herbicides such as glyphosate have been used traditionally as the first and key step of turfgrass renovation. However, there has been an elevated public concern of exposure to chemicals in the USA and worldwide. One non-chemical alternative is light exclusion, which is more widely used in agriculture settings but not much on turfgrass management. This research proposed a turfgrass renovation approach using light exclusion that can reduce weed pressure when replanting turfgrass, switching turfgrass types, or completing a total renovation of a designated turfgrass area. In this study, we addressed the feasibility of using black, geo-textile weed mats made of woven polypropylene plastic in the alternative turfgrass renovation approach. The specific objectives were to test if this alternative approach can effectively renovate the turfgrass area, and to evaluate changes in the biotic communities in the soil indicated by arthropods and nematodes. This research was conducted at Magoon Research Station of University of Hawaii at Manoa on the island of Oahu, Hawaii. There are six steps to complete a chemical free light exclusion turfgrass renovation: 1) Cover existing weedy turfgrass area for about 6 weeks to eliminate all above ground vegetations; 2) Remove cover, and then remove dead weeds and turfgrass (and re-establish the desired site grade if necessary); 3) Fertilize to stimulate weed seed germination; 4) Allow for maximum weed seed germination and growth with overhead irrigation; 5) Cover the site a second time for about 3 weeks to eliminate newly emerged young weeds; and 6) Remove the cover for second time and re-plant new turfgrass. Our results indicated that the chemical free approach was effective in turfgrass renovation. Soil arthropod diversity and abundance changed significantly over time after each major renovation step. The largest diversity index values were seen after the first covering, and the lowest diversity values were seen after the fertilization and second covering. This trend was also observed for soil arthropod abundance, where the largest abundance occurred after the first covering, and the smallest after the fertilization and second covering. Soil nematode abundance (free-living nematodes and plant parasitic nematodes), maturity index, and combined maturity index were generally reduced after the turfgrass renovation steps. However, this
may not be an inherently negative outcome, especially when plant parasitic nematodes need to be managed in some turfgrass systems.

## ABSTRACT

Soil fauna contributes to a wide range of ecosystem functions. Here, we investigate how trophic diversity of soil animals varies across functional groups and major biomes. We use stable isotope analysis ($^{13}C/^{12}C$ and $^{15}N/^{14}N$ ratios) of 17,306 samples of 28 high-rank taxa from 456 sites across 19 countries to inspect the variability in trophic diversity across climate regions and land-use types. Trophic diversity of soil animal communities is higher for microbial feeders than for detritivores and predators, in agricultural ecosystems compared to woodlands (+32%), and in tropical compared to temperate climates (+40%). Higher trophic diversity is related to more diverse basal resources and longer trophic chains, which could reflect greater niche partitioning in resource-limited environments. Our findings suggest that soil animals could broaden their trophic niches under agricultural land use and possibly in response to warming, but whether such foraging flexibility may offset the loss of trophic specialists remains to be investigated.

**ABSTRACT**

Worldwide, forest structure is being profoundly altered by intensifying disturbances that cause large-scale tree mortality. In unmanaged forests, disturbances leave both canopy gap and deadwood, whereas timber harvest creates gap but removes most deadwood. How these legacies of disturbances and management scenarios affect ecosystem functioning, especially belowground, remains unclear. Here, we reconstructed 116 soil animal food webs across 29 temperate forests in a full-factorial experiment manipulating canopy gap and deadwood addition. We quantified energy fluxes of soil food webs as an integrative measure of belowground ecosystem multifunctionality and characterized their network architecture. Canopy gap reduced total food web energy fluxes by 11.6% and decreased network connectance, while shifting energy flow towards the bacteria-dominated "fast" channel, indicating impaired ecosystem multifunctionality, simplified soil food webs and reduced energy retention belowground. However, the presence of deadwood in canopy gap increased total energy flux by 56.1% relative to gap without deadwood, mainly driven by enhanced fungivory and wood-feeding associated with elevated fungi-to-bacteria ratios in litter. Further, deadwood addition into canopy gap restored the network connectance and cycling rate to the level of closed-canopy forests. Our results demonstrate that deadwood acts as a critical structural component that buffers belowground ecosystem multifunctionality against canopy gap, highlighting deadwood retention as a key lever for sustaining soil functioning in disturbed forests.

## ABSTRACT

Legume intercropping is widely considered an effective strategy to improve soil fertility and ecosystem functioning in tropical plantations, yet its mechanisms through regulating soil aggregate–scale soil micro-food webs remain poorly understood. In this study, we investigated natural forest, monoculture rubber plantations of different stand ages, and rubber-based agroforestry systems intercropped with the leguminous shrub Flemingia macrophylla in Xishuangbanna, Southwest China. Soils were fractionated into large macroaggregates, small macroaggregates, and microaggregates to assess bacterial, fungal, and nematode communities, their co-occurrence networks, and micro-food-web–mediated nutrient dynamics on soil nutrient availability. Results showed that land-use change was the primary driver of microbial and nematode community composition and structure, while aggregate size played a secondary but enhanced role in microaggregates. Rubber monocultures, particularly young stands, reduced microbial and nematode diversity and promoted plant-parasitic nematodes, leading to simplified food-web structures. In contrast, agroforestry systems effectively suppressed plant-parasitic nematodes, maintained higher microbial diversity, and enhanced cross-trophic interactions comparable to those in natural forests. Structural equation modeling revealed that stand change and soil aggregates regulated dissolved organic carbon, dissolved organic nitrogen, inorganic nitrogen, and available phosphorus through coordinated effects of soil pH, microbial diversity, enzyme activities, and nematode involvement. Aggregate structure dominated ammonium nitrogen regulation, whereas microbial processes played key roles in organic nutrients and phosphorus cycling. Our findings demonstrate that legume intercropping enhances soil nutrient dynamics by restructuring aggregate-scale micro-food webs, providing a sustainable management pathway for improving the stability and functioning of tropical rubber plantations.

## ABSTRACT

Understanding the regulatory mechanisms by which the rhizosphere micro-food web mediates phosphorus (P) absorption and utilization in maize roots is critical for improving P use efficiency. In this study, various P forms and P supply levels were established, high-throughput and transcription sequencing were respectively conducted on the maize rhizosphere soil and root, in conjunction with the the biologically based phosphorus (BBP) fractionation method. We aimed to elucidate the role of a representative micro-food web, which comprised protists, arbuscular mycorrhizal (AM) fungi, and P solubilizing bacteria, in driving the transformation of soil P forms and the underlying mechanisms of P uptake and utilization in maize roots. Our findings revealed that the components of the micro-food web responded differentially to P forms and supply levels, AM fungal α diversity was strongly affected by both P forms and application rate, whereas the α diversity of protists remained unaffected by both factors. Network analysis revealed that P application enhanced negative correlations among taxa, and trophic interactions mediated by protists were significantly positively correlated with network complexity. Root transcriptomic analysis identified P-responsive differentially expressed genes (e.g., *SPX*, *Phts*, and *PAP*), which were primarily associated with shoot P uptake. Metabolomic and Partial Least Squares Path Modeling (PLS-PM) modeling analyses further revealed that inorganic P enhanced maize P uptake by increasing root exudation of organic acids, which stimulates protistan predation on *pqqC*-harboring bacteria, thereby mobilizing the active rhizosphere P pool ($CaCl_2$-P and Citrate-P). Conversely, the organic P source (phytate) influences flavonoid-mediated interactions between *phoD*-harboring bacteria and predatory protists, regulating the stable P pool (Enzyme-P and HCl-P) and upregulating *PAP* genes and the phosphatase activity for organic P mineralization. In contrast, organic fertilizer, as a complex P source, integrates both pathways to promote P uptake. In summary, different P sources regulated rhizospheric enzyme activities and physicochemical properties, which shaped the community composition and stability of the micro-food web. These changes modulated multi-trophic interactions and synergized with P-responsive genes and rhizosphere metabolites to enhance P acquisition in maize. This study provids a scientific basis for levergaing the soil micro-food web to improve P-use efficiency and maize productivity.

## ABSTRACT

Soil animals form complex food webs that support nutrient cycling and organic matter turnover in forests. However, the role of soil faunal size classes in energy channelling remains unclear for ecosystems dominated by arbuscular (AMF) or ectomycorrhizal (EMF) fungi, which differ fundamentally in soil biogeochemistry. To address this gap, we combined compound-specific stable isotope analysis (CSIA-AA) of carbon and nitrogen and energy flux analysis to reconstruct soil food webs, examining energy channeling from basal resources (plants, fungi, bacteria) across nematodes, microarthropods, macroarthropods, and earthworms in AMF- and EMF-dominated deciduous forests. We found that despite moderate taxon-specific differences, total energy flux, its distribution among major channels (herbivory-detritivory, bacterivory, fungivory) and predation were similar between forest types. Across forests, energy channelling exhibited a consistent size-structured pattern: (1) the relative contributions of herbivory-detritivory and predation to total energy flux peaked in small nematodes and macroarthropods but were low in microarthropods and earthworms; (2) bacterivory was highest in the smallest (nematodes) and largest fauna (large macroarthropods and earthworms); while (3) fungivory peaked in small nematodes, microarthropods, and large earthworms but remained low in macroarthropods. These findings show high consistency of soil food web functioning across temperate deciduous forests and link the size spectrum of soil fauna to energy channeling and, therefore, to the ecosystem functioning of forest soils.

## ABSTRACT

Humans have substantially transformed the global land surface, leading to a decline in the variation of biotic communities across scales—a phenomenon termed biological homogenization. While this process has been widely recognized, the underlying mechanisms driving biological homogenization remain poorly understood, with critical knowledge gaps including: (1) the differential responses of distinct soil biotic taxa and functional groups to human land-use changes; (2) the relative contributions of the introduction of widespread generalist taxa versus the loss of narrow-ranged specialist taxa to homogenization; (3) the role of prey/host biota and environmental factors in mediating homogenization patterns; (4) the link between cross-regional dispersal of soil organisms and biological homogenization.

To address these knowledge gaps, we conducted a large-scale metabarcoding investigation of the biogeography of soil protists and their associated prey/hosts (prokaryotes, fungi, meso- and macrofauna). The study covered three human-dominated ecosystem types (farmlands, residential areas, and parks) as well as natural forest ecosystems across subtropical and temperate regions in China. We found that the degree of community homogenization varied markedly among soil protist taxa and functional groups, and was strongly positively correlated with their colonization ability in human land-use systems. In addition, the introduction of widespread generalist operational taxonomic units (OTUs), rather than the loss of narrow-ranged specialist OTUs, was identified as the primary driver of biological homogenization. Importantly, human land-use systems expanded the distribution range of generalists, predominantly facilitating the range expansion of temperate soil taxa into subtropical regions. This dispersal was largely enabled by increased soil pH in human-altered habitats that mitigates the natural acidity barrier of subtropical ecosystems. Finally, cross-regional spread of soil protists was more prominent in phagotrophs than in phototrophs and parasites, which reflects the co-dispersal of phagotrophic protists and their microbial prey (especially bacteria) due to tight predator–prey specialization and/or shared responses to environmental changes.

This study advances our mechanistic understanding of how human land-use changes shape soil biological homogenization, revealing varying responses of soil biota to land-use changes. Importantly, this variation is not random but predictable, and governed by their ability to colonize human land-use systems. Furthermore, our results provide important insights into how human land-use systems reshape the distribution pattern of soil biodiversity, highlighting that tropical and subtropical areas are likely to be disproportionately affected by biological homogenization driven by exotic species introductions.

## ABSTRACT

Eutrophication, including nitrogen (N) enrichment, can alter soil carbon cycling through changes in trophic interactions. However, it remains unclear how N enrichment affects the role of soil bacteria and fungi in regulating soil organic carbon (SOC) formation through changes in plant communities and soil nematodes. To bridge this knowledge gap, we employed an integrated research framework combining multiple experimental approaches. Firstly, our global meta-analysis revealed that N enrichment reduces microbial biomass in natural grasslands and forests primarily through soil acidification and declines in omnivorous-carnivorous nematodes. To further investigate these processes, we conducted a long-term gradient N addition experiment (initiated in 2000) in a typical steppe in Inner Mongolia. This study systematically monitored responses in plant communities, soil nematodes, microbial biomass and necromass carbon, and SOC physical fractions (particulate and mineral-associated organic carbon). Our findings demonstrated that N addition significantly reduces predatory nematode abundance, and further suppress the contribution of fungal necromass to mineral-associated organic carbon (MAOC). To directly quantify the contributions of bottom-up (plant-derived) and top-down (nematode-mediated) effects on SOC formation, we are currently conducting laboratory incubation experiments. These involve the addition of $^{13}C$-labeled root exudates and inoculation with key soil nematode functional groups. Using isotope tracing techniques, we will track the flow and stabilization of plant-derived carbon through the microbial–nematode food web. Collectively, this multi-scale experimental approach (spanning meta-analysis, long-term field observation, and controlled laboratory tracing) will elucidate how plant-nematode-microbe trophic interactions regulate SOC dynamics under N enrichment, offering mechanistic insights into the effects of N deposition on soil carbon sequestration.

# Testing the scaling effects and mechanisms of N-induced belowground biodiversity loss

## ABSTRACT

Atmospheric nitrogen (N) deposition is widely recognized as a primary driver of belowground biodiversity loss. however, the extent of its impact and the underlying community assembly mechanisms remain poorly understood, largely due to a lack of explicit consideration for observation scale. Standardized sampling protocols often overlook scale-dependence, potentially obscuring the true sensitivity of soil fauna to environmental stressors. To address this, we systematically investigated soil nematode communities along a long-term N addition gradient (0, 1.75, 10.8, 28 g N $m^{-2}$ $yr^{-1}$) using a nested sampling design across three spatial scales (0.5, 10, and 100 g soil). This multi-scale approach allowed us to decouple the interactive effects of N enrichment and spatial heterogeneity on taxonomic diversity, functional structure, and community assembly processes. Our results revealed that N induced loss of nematode α diversity was not uniform but exhibited a strong scale-dependent amplification, with significantly steeper species loss at the macro-scale (i.e., 100 g) than at the finer scale (i.e., 0.5 g). Furthermore, N enrichment drove biotic homogenization (decline in β diversity), a pattern pronounced at larger scales where communities deviated farthest from their initial states. Mechanistically, community assembly shifted from deterministic filtering toward stochastic drift as scale increased. Specifically, N stress acted as a deterministic filter, selectively eliminating stress-sensitive K-strategists while favoring dispersal efficient r-strategists. This turnover was strongest at broader scales, thereby reinforcing stochastic dominance and leading to functional degradation. Importantly, these findings demonstrate that conventional small-scale sampling significantly underestimates the severity of N-induced biodiversity loss and functional decline. By elucidating the coupling between observation scale and N stress, this study provides a framework for accurately assessing belowground ecosystem vulnerability to global change.

## ABSTRACT

[Objective] This study aims to investigate the influence of soil microorganisms on organic carbon sequestration under the addition of exogenous organic materials in saline-affected agricultural ecosystems, thereby providing theoretical support and technical guidance for the remediation of saline-alkali soils in the Hetao Irrigation District. [Methods] Utilising the long-term fixed-site experimental base at the Wuyuan Maize Science and Technology Courtyard within the Hetao Irrigation District of Inner Mongolia, four organic materials (straw, cattle manure, sheep manure, biochar) were applied. The study examined the relationship between soil microorganisms and soil organic carbon at different aggregate scales.[Results] (1) Soil organic carbon ranged between 8.27 and 12.34 g·kg$^{-1}$. The sheep manure treatment yielded the highest organic carbon content in the whole soil at 10.82 g·kg$^{-1}$, followed by the straw treatment. Organic carbon in small aggregates under sheep manure treatment increased significantly by 14.8% compared to the control (CK). Medium aggregates exhibited higher organic carbon content than both large and small aggregates. Soil pH under straw treatment decreased by 0.02, 0.1, and 0.06 units in bulk soil, medium aggregates, and small aggregates respectively compared to the control. Goat manure addition reduced electrical conductivity in bulk soil and large aggregates by 10% and 34% respectively, with straw treatment showing the next greatest reduction.(2) In the whole soil, PLFAs from Gram-positive bacteria (GP), Gram-negative bacteria (GN), non-specific bacteria (Bact.), and actinomycetes (Actin.) were all significantly higher in the straw treatment compared to other treatments, increasing by 60%, 64%, 70%, and 59% respectively relative to the control (CK). In the three aggregate fractions, sheep manure treatment resulted in varying degrees of increase for all four bacterial PLFAs. Bacterial PLFAs in the whole soil were generally higher than those in the aggregate fractions.(3) The trends in fungal PLFAs (Fungi) and arbuscular mycorrhizal fungal PLFAs (AMF) across treatments were largely consistent with those observed for bacteria. In the whole soil sample, both Fungi and AMF showed significant increases under the straw treatment, rising by 56% and 78% respectively compared to the control (CK). Within soil aggregates, sheep manure treatment yielded higher Fungi and AMF levels than other treatments. Protist PLFAs exhibited markedly lower concentrations than bacterial and fungal PLFAs, with sheep manure treatment producing higher Protist levels in aggregates than other treatments.(4) Throughout the entire soil profile, GP, Actin., and Fungi exhibited a significant positive correlation with soil organic carbon. Within small aggregates, GP, Bact., Actin., Fungi, AMF, and Protists all showed a highly significant positive correlation with soil organic carbon. [Conclusion] The addition of sheep manure and straw enhanced the biomass of soil bacteria, fungi, and protists, thereby strengthening soil organic carbon sequestration and improving the physicochemical properties of saline-alkali soils. This holds significant implications for the remediation of saline-alkali lands in the Hetao Irrigation District.

# Pesticide contamination in agricultural soils in Shanghai: residual characteristics and ecological risks to soil biota

**Muyuan Wang[1*], and Yinsheng Li[1]**

[1] *School of Agriculture and Biology, Shanghai Jiao Tong University, Shanghai, China*

*wmy040549@sjtu.edu.cn

**ABSTRACT**

While pesticides enhance crop productivity, their persistence in soils threatens soil biota critical for ecosystem functions. Existing studies have inadequately characterized the contamination profiles and ecological risks of multiple pesticide residues in Shanghai's agroecosystems. Hence, this study investigated the occurrences of 70 pesticide residues in agricultural soils in Shanghai, assessed their ecological risks to soil biota, and identified the currently used pesticides warranting concerns. In total, 40 pesticides were detected, and the ranges of total concentrations were 11.76–296.33 $ng \cdot g^{-1}$, with the mean concentration of 83.71 $ng \cdot g^{-1}$. Contamination from pesticide mixtures has become widespread, with 52.94% of agricultural soils containing more than 5 species. Meanwhile, pesticide residues exhibited associations with cultivation methods, with greenhouse systems demonstrating 54.81% higher average concentrations compared to open-field systems, whereas crop type demonstrated a limited impact. Furthermore, individual pesticides mostly exhibited low exposure risks to soil biota including *Eisenia fetida*, *Enchytraeus crypticus*, *hypoaspis aculeifer*, *Folsomia candida*, and N-mineralizing microorganisms based on toxic exposure ratio (TER). In contrast, confronting the pervasive issue of pesticide mixture contamination, the Risk Quotient (RQ) assessment, taking into account the most sensitive soil biota, quantified integrated ecological risks posed by multiple pesticide. The results revealed that 33.82% of agricultural soils demonstrated high ecological risks ($RQ_{site} \geq 1$), indicating potential disruption to essential ecosystem function, and priority pesticides posing severe threats to soil biota were identified as *p, p'*-DDE, chlorpyrifos, bifenthrin, and metolachlor. Consequently, three currently used pesticides requiring priority attention were identified combing correlation analysis, hierarchical cluster analysis, and principal component analysis based on residual characteristics, ecological risks and pesticide properties: chlorpyrifos, metolachlor and terbuthylazine. This study provides scientific insights for developing environmental monitoring programs and management measures, ultimately contributing to ecosystem functions critical to sustainable agriculture.

# Effects of earthworms and their combined application with functional attractant on soil organic carbon dynamics: Regulation of organic carbon fractions, aggregate formation, and their carbon sequestration

**Muyuan Wang[1], and Yinsheng Li[1*]**

[1] *School of Agriculture and Biology, Shanghai Jiao Tong University, Shanghai, China*

*yinshengli@sjtu.edu.cn

**ABSTRACT**

Earthworms, as ecosystem engineers, regulate soil organic carbon (SOC) turnover through burrowing, feeding, and excretion behaviors. This study investigated the effects of *Metaphire guillelmi* and its co-application with a functional attractant (composed of saccharides, animal-derived, and plant-derived materials) on SOC dynamics via field experiments in orchards amended with decomposed cow manure. Results demonstrated that earthworms significantly increased SOC content by 15.90%, and facilitated the transformation of exogenous organic carbon into readily oxidizable carbon (ROC) and humic acids. This enhancement is primarily attributable to their capacity to elevate soil nutrient availability, primarily by enhancing nitrate nitrogen and available phosphorus. Earthworms also enhanced particulate organic carbon (POC) but had limited effects on mineral-associated organic carbon (MAOC). Regarding physical protection, earthworms elevated the proportions of large macroaggregates (>2 mm) and silt-clay fractions (<53 μm) along with their sequestered organic carbon, while improving aggregate stability, evidenced by higher MWD and GMD. Attractant alone slightly increased macroaggregate proportion, and its co-application with earthworms further promoted the formation of large macroaggregates and small macroaggregates (0.25-2 mm), simultaneously enhancing organic carbon in small macroaggregates. This study demonstrates that earthworms enhance SOC content and its stability, and their co-application with attractant promotes aggregate formation and its carbon sequestration, providing a theoretical basis for orchard soil carbon pool management and fertility enhancement.

**ABSTRACT**

Soil Ecology studies interactions among soil organisms and their environment, emphasizing a holistic approach to soil biodiversity and ecosystem function. Because soils, and particularly organisms within them, are crucial for sustaining terrestrial productivity and mitigating climate change, increased financial support worldwide has enabled Soil Ecology research to advance at an unprecedented pace over the last four decades. The development of new techniques, such as isotopes and various spectrometry techniques, has greatly improved our capability to monitor and quantify biological transformations of nutrient elements and organic pollutants in soil. Notably, molecular techniques, including the increasingly popular metagenomics and meta-transcriptomics, have provided deeper insights into microbial populations, revealing previously unknown species or species consortia and clarifying their roles in nutrient cycling and disease resistance. Yet, development of Soil Ecology theories continues to lag, partly due to the complexity of soil ecosystems and a shortage of unifying theoretical frameworks. This presentation will revisit key milestones in Soil Ecology – including the introduction of the soil food-web model, the discovery of mycorrhizal networks, Comammox bacteria, the multifunctionality of trophic diversity, and advances in soil biodiversity research – to highlight their significance and discuss the major challenges facing soil ecology in the context of climate change and a growing human population.

# Aggregate-Scale Microbial Communities: Spatial Heterogeneity, Potential food-webs & The Effect of Tillage

**Arthur Taylor**[1*]

[1] *School of Biological Sciences, University of Edinburgh, Scotland*

*s1654132@ed.ac.uk

**ABSTRACT**

What is a soil microbial community?
At what spatial scale does communities of soil microbes interact?
How does tillage change or disrupt these communities?

Despite growing awareness of the role of complex microbial food webs in soil functionality and ecosystem services, the specific compositions of soil food webs are yet to be discovered and their dynamics yet to be understood. Co-occurrence network analysis of environmental DNA amplicon-sequencing has been increasingly used over recent years to discern ecologically interacting microbial communities or soil food webs to understand better how they may be maintained or disrupted by environmental and land use change and agricultural management.

But there are two important methodological issues that make inferring microbial communities from these co-occurrence networks problematic (Goberna & Verdú, 2022). Firstly, the scale of sampling typically employed is an entire soil core (cm), homogenized and sub-sampled such that spatial heterogeneity is destroyed and averaged-over, making differences at the scale of microbial interaction and habitat, the (µm-mm) range, impossible to see. This study samples *individual macro-aggregates*, a sampling unit that acts as proxy for relatively stable and isolated pore space and that provides a sampling scale relevant to the life of microbes. Secondly, different microbial domains and broad trophic groups are typically targeted using separate amplicons and through separate laboratory pipelines making comparisons between bacteria, fungi and protist abundance impossible. This study employs internal standards based on a DNA construct spiked into the samples to quantify differences between bacteria, fungi and protist amplicons and to enable more meaningful assessment of which taxa are found together.

By combining these approaches, this study, for the first time, can discern the cross-kingdom microbial communities *at a scale in which they live and interact*. The aggregates sampled come from an experimental field trial employing both regenerative and conventional tillage practices and so the study can also see how mechanical soil disturbance can alter soil microbial communities.

The research answers the following questions:
- What is the spatial heterogeneity of bacteria, fungi and protist communities within the *cm* scale of a soil core and between *mm* scale macro-aggregates? And how does mechanical soil disturbance due to tillage affect this heterogeneity?
- What potential soil food-webs are harbored in the relatively stable and isolated pore space that macro-aggregates are a proxy for? And how does mechanical soil disturbance due to tillage affect the diversity, structure and composition of these potential soil food-webs?

## ABSTRACT

Nematodes are abundant and diverse in soil, and they can influence microbial community composition, plant performance, and nutrient cycling, serving as vital bioindicators for soil ecology and health. While metabarcoding techniques have become highly standardized in the identification of microbial (i.e., bacterial and fungal) communities, similar techniques are still under development for soil animals. As metabarcoding techniques become increasingly popular for characterizing soil animals, establishing protocols that are adapted to larger-bodied organisms is necessary. To optimize nematode metabarcoding workflows, we assessed how different identification techniques and soil sample sizes influence nematode ecological estimates and nematode community indices. We compared three identification techniques: traditional morphological identification, and two molecular methods using either nematode-extracted DNA or total soil DNA. Each technique was tested across varying soil size gradient (0.25 g – 32 g). DNA was amplified using nematode-specific 18S rRNA primers (Nemf/18Sr2b) and sequenced on an Illumina MiSeq platform. Sequencing data obtained from different protocols were processed using the DADA2 pipeline, followed by taxonomy assignment using the PR2 References database.

Our results demonstrated that nematode alpha diversity generally increased with greater soil mass, although significance was observed only for observed genera richness (q = 0). Morphological ID technique yielded the lowest genus counts, while soil DNA technique recovered more genera than nematode DNA in smaller samples. Community clustering revealed clear separation among the three identification techniques, especially between morphological and molecular methods, although community dispersion did not differ significantly among methods. Specific taxa were affected by technique and sample size; for instance, *Paratylenchus* and *Aphelenchoides* were significantly reduced in molecular data. Significant methodological differences were also evident among feeding guilds, particularly plant feeders, predators, and omnivores. Furthermore, soil mass significantly influenced key community indices, including the Structural, Plant-Parasitic, and Channel Indices. Together, these findings underscore that both methodological choice and sampling strategy critically shape the ecological interpretation of soil nematode communities, serving as a guide for the selection of appropriate protocols in soil nematode assessment.

# Fertilization Dictates Nematode-Microbe Trophic Interactions to Shape Plant Health and Soil Functions

**Xu Xu[1,2*], Stefan Scheu[2], and Rong Li[1]**

[1] *Educational Ministry Engineering Center of Resource-Saving Fertilizers, Nanjing Agricultural University, Nanjing 210095 Jiangsu, China*

**ABSTRACT**

Fertilization practices profoundly reshape belowground trophic interactions, but how fertilizer regimes interact with soil nematodes to influence microbe-mediated pathogen suppression, nutrient cycling, and plant performance remains unclear. By integrating global meta-analyses with multi-omic profiling, machine-learning predictions, and field, greenhouse, and microcosm experiments, we demonstrate that fertilizer type is a major determinant of nematode-microbe-plant dynamics. Organic fertilizers promote bacterivore-dominated food webs that enhance plant productivity, strengthen the activity of pathogen-antagonistic bacteria such as *Bacillus*, and suppress the bacterial wilt pathogen *Ralstonia solanacearum*, whereas mineral fertilizers weaken these beneficial links and amplify negative herbivore-plant relationships. Microcosm experiments further show that bacterivorous nematodes such as *Protorhabditis* reduce $N_2O$ emissions by enriching Bacillus and denitrification genes (e.g., *nosZ*) through restructuring bacterial communities and stimulating microbial growth. Finally, multi-omic analyses reveal that root-knot nematode (*Meloidogyne*) invasion reprograms plant metabolism and disrupts rhizosphere homeostasis, shifting microbiomes from suppressive to permissive states by depleting antagonistic *Streptomyces* and enriching *Acidovorax* that synergizes with *R. solanacearum*. Together, these results show that fertilization fundamentally dictates the direction and strength of nematode-microbe trophic interactions, with major implications for disease suppression, greenhouse gas mitigation, and crop productivity.

## ABSTRACT

Soil microbial communities and microbial-derived carbon (MDC), including microbial biomass carbon (MBC) and microbial necromass carbon (MNC), are key drivers of soil organic carbon (SOC) dynamics under long-term straw return. However, how shifts in microbial community structure and life-history strategies under prolonged straw return affect MDC and subsequently alter SOC remains unclear. In this study, we employed 16S RNA sequencing technology to analyze the soil microbial community characteristics of maize fields in Northeast China under four different straw returning durations: 0 (0Y), 3 (3Y), 5 (5Y), and 7 (7Y) years. The results revealed that, compared to the no-straw-return treatment (0Y), straw return shifted microbial communities toward a stronger resource acquisition tendency. Fungal diversity decreased with increasing straw return duration, while bacterial richness increased. Bacteria employing the "resource acquisition strategy" (A-strategy), particularly Acidobacteriota, became dominant in the bacterial co-occurrence network. Further analysis of SOC and its fractions showed that MBC increased significantly with straw return duration, but the contribution of MNC to SOC declined. The rate of SOC increase slowed by the 7Y mark. These findings suggest that prolonged straw return promotes a shift in microbial life-history strategies toward resource acquisition, leading to reduced efficiency of microbial necromass carbon accumulation and consequently diminishing the effectiveness of SOC enhancement. Random forest analysis and path analysis indicated that MDC dynamics, shaped by changes in microbial community structure, drive the alterations in SOC fractions and overall SOC content as straw return duration increases. In summary, this study provides direct evidence of how microbial communities influence SOC through MDC and organic carbon fractions, offering a microbiological basis for black soil conservation and the development of agricultural carbon sequestration strategies.

# Enchytraeid Bioturbation as a Key Driver of Microplastic Redistribution in Soils

**Yin Liu[1], Patria Novita Kusumawardani[1], Steven Sleutel[1], Richard Hoogenboom[2], Andre Skirtach[3], Stefaan De Neve[1], Junwei Hu[1]***

*junwei.hu@ugent.be

**ABSTRACT**

Microplastics have emerged as a global environmental concern, with soils acting as a major sink and posing risks to soil functioning and human health through entry into the food chain. Their bioavailability is closely linked to redistribution from point-source to non-point-source pollution during fragmentation and decomposition. Among the factors influencing this process, bioturbation by soil fauna plays a crucial role, yet research has been extremely limited and has largely focused on macrofauna such as earthworms and relatively coarse particle sizes. It is still unclear whether, and to what extent, smaller soil fauna can affect small sized microplastic redistribution at fine spatial scales. Here, we quantified microplastic transport by enchytraeid bioturbation both in vitro and in soil microcosms. Our results show that enchytraeids can transport microplastic beads of 2, 10, and 50 μm, with the highest transport capacity for 2 μm particles, relocating 1 ng over 9.8 cm after 3 days of incubation with 50 individuals in vitro. In soil microcosms, enchytraeids significantly increased the spread of 2 μm microplastics from the original location to surrounding areas, relocating $1\times10^3$ ng over 20.3 cm after 108 days of incubation. Overall, our findings demonstrate for the first time that enchytraeid bioturbation substantially enhances the transport of small-sized microplastics, highlighting bioturbation by soil fauna as a non-negligible mechanism of microplastic redistribution in soils.

## ABSTRACT

Grassland management practices profoundly alter soil properties and microbial communities, yet their effects on gut microbiota of soil animals remain unclear. Using the soil collembolan Folsomia candida as a model organism, this study employed indoor microcosm experiments to investigate changes in gut microbial community structure, function, and assembly mechanisms after 30 and 60 days of cultivation in soils from three typical grassland utilization types (enclosure, annual mowing, and heavy grazing) in the Hulunbuir Grassland. 16S rRNA gene sequencing analysis revealed that different treatments significantly altered the composition and diversity of collembola gut microbes. At the phylum level, Proteobacteria exhibited absolute dominance, though its relative abundance fluctuated across treatments and time. α-diversity (Chao1, Shannon index) differed significantly among treatments. β-diversity analysis (PcoA) confirmed that both grassland utilization type and incubation duration were significant drivers of community structure change. Functional prediction revealed alterations in key genes and pathways related to metabolism and signal transduction. Network analysis indicated differences in complexity and stability of microbial interaction networks across treatments. Further ecological process analysis (βNTI, niche breadth) revealed that deterministic processes (particularly homogenizing selection) dominated community assembly, while grazing enhanced the influence of stochastic processes. This study systematically reveals for the cascading effects of grassland management practices on collembola gut microbiota via the soil medium. It highlights the potential of soil animal gut microbiota as sensitive indicators of environmental change, providing new insights into soil animal-microbe interactions and their ecological functions within grassland ecosystems.

# Earthworm Responses to Veterinary Antibiotic Contamination in Soil and their Role in Mitigating Crop Toxicity

**Sang Woo Han [1], Chae Yeon Kim [1], Dokyun Lee [1], Myung Hoon Kim [1], Yunah Do [1], Ji Eun Hwang [1], Keum-Ah Lee [2], Young-Nam Kim [1*]**

[1] *Kyungpook National University (Department of Crop Science, Sangju 37224, Republic of Korea)*

[2] *Gyeongsang National University (Institute of Agriculture and Life Science, Jinju 52828, Republic of Korea)*

**ABSTRACT**

Antibiotics, introduced in the 1940s, have been vital in controlling diseases and achieving economic gains. Yet, undigested veterinary antibiotics (VAs) excreted from livestock are increasingly contaminating terrestrial ecosystems. In agricultural soils, VAs in various concentration ranges have been detected, which is mainly considered a legacy of livestock manure application and wastewater irrigation. Notably, various types of VAs have been reported to have adverse effects on crop growth and development as well as productivity. As soil-dwelling fauna, earthworms can have high resistance to antibiotic toxicity while simultaneously facilitating the degradation of antibiotic residues and resistance genes in soil. This study was conducted to identify the sensitivity of earthworms to soils contaminated with major VAs such as chlortetracycline (CTC), sulfamethazine (SMZ), oxytetracycline (OTC), Penicillin (PC) etc. and to investigate the influences of earthworm addition on physiological responses and production of crop plants to VAs toxicity, via mesocosm experiments. The sensitivity test consisted of five concentration treatments of each antibiotic: 0, 50, 100, 250, and 500 mg/kg, and the incubation assay consisted of six concentration treatments of 0, 10, 100, 500, 1,000, and 5,000 mg/kg. In both experiments, adult earthworms (*Eisenia fetida*, >1 g) were selected, and field soil served as the test medium. For a pot experiment, CTC was applied to artificial soil at six concentrations (0, 1, 5, 10, 20, and 40 mg/kg), and one-week-old lettuce seedlings were cultivated for three weeks with or without the presence of *E. fetida*. Results from the sensitivity test revealed that earthworm avoidance patterns toward antibiotic toxicity changed with varying VAs treatments. SMZ and PC triggered the strongest avoidance in *E. fetida* at <100 mg/kg, while avoidance was universal at higher concentrations (to 500 mg/kg). In addition, the incubation assay showed that *E. fetida* exhibited no mortality in OTC, SMZ, and PC treatments, whereas exposure to CTC led to increased mortality at concentrations ranging from 500 to 5,000 mg/kg. Indeed, long-term bioassays showed increased biomass and soil water retention at 10–100 mg/kg CTC, reflecting earthworm tolerance to toxicity at these concentrations. According to the pot experiment, the fresh weight of lettuce shoots (the edible part) decreased by 34–47% at 5–40 mg/kg CTC compared with the control; however, the addition of earthworms prevented this reduction. Moreover, the presence of earthworms positively influenced plant physiology, as evidenced by enhanced photosynthetic efficiency (Fv/Fm), increased chlorophyll and anthocyanin contents, reduced oxidative stress indicators ($H_2O_2$ and malondialdehyde), and stimulated ascorbate peroxidase activity. These findings suggest that earthworms may alleviate CTC phytotoxicity by promoting plant growth, improving photosynthetic performance, and enhancing antioxidant enzyme activity.

## ABSTRACT

Despite the recognized benefits of diverse vegetation for terrestrial biodiversity and ecosystem services, its role in island ecosystem restoration remains poorly understood. We established five artificial vegetation types (grassland, windbreak and sand fixation, shelterbelt, public green space, roadside trees) on tropical coral islands and compared their soil properties and microbial communities with those of native forests. Artificial vegetation showed different levels of soil properties (except total potassium), microbial biomass (excluding fungi), enzyme activities, diversity indices (excluding fungi). Additionally, the community composition and network structure of soil microbes in artificial vegetation were distinct from those in native forests. Both ecosystems exhibited co-limitation by carbon and phosphorus. Fungi dominated in early restoration stages, while bacteria emerged as keystone drivers in later phases. Initial fungal inoculation accelerated vegetation establishment, and late-stage labile carbon inputs enhanced bacterial-mediated ecosystem stability. Phosphorus supplementation is recommended to alleviate nutrient co-limitation given that phosphorus is indispensable for microbial growth. Future research should focus on long-term dynamics to better assess restoration sustainability.

## ABSTRACT

Microplastics can bind to pollutants such as heavy metals through surface complexation and chelation, forming combined pollutants. However, research on the ecotoxicological effects of such combined pollution on soil fauna remains limited. This study, the model organism Folsomia candida was selected as the test subject, and a 28-day microcosm incubation experiment was conducted to explore the ecotoxicological effects of combined pollution by thallium (Tl) and polylactic acid microplastics (PLA-MPs) at different concentrations on Folsomia candida, focusing on functional traits including external morphology, biological characteristics, and gut microbiota. The results showed that high-concentration PLA-MPs (10%, w/w) had significant impacts on mortality rate and fecundity, significantly reduced gut bacterial community diversity, and reshaped the functional structure of the microflora by enriching Actinobacteriota, Bacteroidota, and Patescibacteria while inhibiting Pseudomonadota. Low-concentration (0.1%, w/w) and medium-concentration (1%, w/w) PLA-MPs drove the transition of gut bacterial community assembly from a deterministic to a stochastic process, reducing the contribution of heterogeneous selection while enhancing the importance of drift. In contrast, low-concentration Tl (1 ppm) significantly inhibited the body length and antenna length of Folsomia candida, while increasing the diversity index and niche breadth of the gut bacterial community. High-concentration Tl (10 ppm) promoted the relative abundance of Bacteroidota but inhibited that of Bacillota. The combined pollution of PLA-MPs and Tl exhibited certain synergistic or antagonistic effects on the functional traits of Folsomia candida. For instance, PLA-MPs exacerbated the inhibitory effect of Tl on the reproduction of Folsomia candida, while Tl could attenuate the disturbance effect of PLA-MPs on the gut microflora. The comprehensive effects of Tl and PLA-MPs on the functional traits of Folsomia candida were characterized by amplified combined effects and trait-specific responses. Compared with other indicators, external morphology was relatively insensitive to pollution stress. In conclusion, the combined pollution of Tl and PLA-MPs exerts significant negative effects on the functional traits of Folsomia candida by altering the abundance and assembly mechanism of the gut bacterial community, thereby regulating nutrient metabolism, immune defense, and energy allocation functions. The findings of this study will provide data support for understanding the ecotoxicological effects of combined Tl and PLA-MPs pollution on soil fauna, and contribute to assessing the ecological health risks of heavy metals and microplastics in soil.

# Rice straw return by water-logged press-bury in autumn Enhanced Black Soils Carbon Stability in Northeast China Paddy Fields

**Dongju Bai[1*], Yanmei Dong[1], Bingqian Fan[1], and Hongbin Liu[1]**

*[1] State Key Laboratory of Efficient Utilization of Arable Land in China, Key Laboratory of Non-point Source Pollution Control, Ministry of Agriculture and Rural Affairs, Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing 100081, China.*

**ABSTRACT**

Long-term intensified cultivation of paddy fields in Northeast China has triggered black soils degradation and threatened national food security. Although straw return has been widely accepted as an effective agricultural practice to restore soil structure and improve soil quality, traditional straw return approaches such as rotary tillage and deep plowing usually result in slow straw decomposition, straw floating under flooded irrigation and lower soil organic carbon sequestration. In the present study, a novel straw return approach termed as water-logged press-bury in autumn (WPB) was developed and a 3-year field experiment was conducted to examine variations in soils properties under three treatments: rotary tillage without straw return (RT), deep plowing with straw return (DP), and the WPB. Results showed that compared with the RT treatment, the WPB treatment significantly increased soil organic carbon (SOC) by 24.2%. In addition, the higher increments of particulate organic carbon (POC) (40.0%) and mineral associated organic carbon (MAOC) (53.2%) was found in the WPB treatment. The enhanced SOC stability in the WPB treatment was attributed to the physical protection of SOC by macroaggregates and the transformation efficiency of carbon sources by microorganism. Firstly, it was found that both the proportion of large macroaggregates（>2 mm）elevated by 15.3%, and the distribution of SOC fractions in macroaggregates by 12.68% and 42.26%. On the other hand, the proportions of alkyl C and O-alkyl C were increased by 5.4% and 5.0%, respectively, while the proportions of aromatic C and carboxyl C declined by 8.6% and 16.1%. This indicated the transformation of SOC towards a higher degree of humification. These findings provide a novel approach for returning rice straw to paddy fields in Northeast China, offering significant scientific and practical value for safeguarding black soils health and promoting sustainable agricultural development.

## ABSTRACT

Gully erosion is a severe form of land degradation that threatens food production worldwide. A region substantially affected is Northeast China, where Mollisols dominate and which serves as the nation's greatest commodity grain base despite its relatively young arable history. Many field-based studies have quantified gully erosion and its drivers, yet individual studies always remain limited in spatial and temporal scope and thus cannot comprehensively assess the variation over time and space and its dominant natural and/or anthropogenic influences. Here, we compiled 475 records of gully growth from over 121,000 gullies in 40 studies to evaluate regional and temporal variation in gully growth across NE China. Geostatistical analysis indicated that all four growth rates, including length, area, volume, and density, exhibited pronounced spatial patterns. Approximately 80% of the gullies were concentrated in the northern parts of the Northeast Rolling Hilly and Sloping Region. The average gully length was 385 ± 423 m, with a maximum length of 3,733 m. Studies with an observation duration of less than 10 years showed significantly higher growth rates (10 ± 12 m $yr^{-1}$) than longer studies (6 ± 4 m $yr^{-1}$). Short-term (< 10 yrs) studies, especially in areas containing fewer than 50 gullies, are likely to be biased by extraordinarily large events which initiated the study. Gully growth rates increased with greater seasonal variability in temperature and precipitation, as well as with larger drainage areas. The pronounced difference in spatial patterns in different landscapes cannot be related to one simple climate or soil use variable. The pattern is the result of the interaction of several variables. Gully growth rates increased over time, particularly after the year 2000, creating an accelerating threat to China's breadbasket. Region-specific conservation measures are urgently needed to conserve soil and safeguard food security especially in Northeast China which is currently experiencing soil loss rates at 20 t $ha^{-1}$ $y^{-1}$.

**ABSTRACT**

Sustainable utilization of Northeast China's black soils requires balancing exploitation and conservation. Conventional tillage (CT) enhances utilization but degrades soil, whereas no-tillage (NT) conserves soil and water but may reduce yield. Strip tillage (ST), combining tilled in-row zones (ST-IR) and non-tilled between-row zones (ST-BR) under straw mulch, integrates the advantages of CT and NT, offering a potential balance between productivity and conservation. However, its effects on soil macropore structure and hydrothermal properties remain unclear. This study employed time domain reflectometry (TDR) and X-ray computed tomography (X-CT) to evaluate soil hydrothermal conditions, key physical properties, and macropore characteristics under CT, NT, ST-IR, and ST-BR. Results showed that ST produced two distinct soil environments. The hydrothermal conditions, bulk density (BD), penetration resistance (PR), air capacity (AC), air permeability (AP), and available water capacity (AWC) in ST-IR were similar to those in CT. In contrast, ST-BR resembled NT but exhibited higher BD and PR, with markedly lower AC, AP, and AWC. Likewise, ST formed two distinct macropore structures. ST-IR aligned with CT, characterized by high macroporosity, large irregular non-biopores, and strong connectivity, with higher compactness (CP), specific surface area (SA), and fractal dimension (FD), but lower anisotropy (DA). Conversely, ST-BR and NT were dominated by elongated tubular biopores, showing lower macroporosity, CP, SA, and FD, but higher DA. Overall, ST integrates the structural and hydrothermal traits of CT and NT, forming a spatially heterogeneous system that supports both soil conservation and crop production. These findings enhance understanding of how ST promotes sustainable management of black soils.

# Spatial Patterns of Ephemeral Gullies and Their Impacts on Farmland and Crop production in the Black Soil Region of Northeast China

**Chunmei Wang[1*], Jilong Wei[1], Wei Wang[2], Xinru Qiao[1], Lei Ma[1], Huadong Du[2]**

*[2] School of Geology and Environment, Xi'an University of Science and Technology, Xi'an, China*

## ABSTRACT

Gully erosion has become a major threat to farmland sustainability and food security in the black soil region of Northeast China, while most existing studies have focused on permanent gullies. Ephemeral gullies, which are characterized by their small scale, temporary nature, and tendency to be filled during tillage, have long been underestimated. Nevertheless, their widespread occurrence and frequent recurrence cause substantial but often overlooked losses to farmland and crop yield. More importantly, preventing ephemeral gullies from developing into permanent ones is crucial for effective erosion control. This study quantifies the spatial distribution of ephemeral gullies and their impacts on farmland and crop yield across multiple spatial scales. At the regional scale, a systematic survey was conducted across approximately 101,000 km² of the typical black soil belt. Ephemeral gullies within 620 small watersheds were visually interpreted from sub-meter-resolution remote sensing imagery and validated in 50 watersheds using UAV photogrammetry and GNSS RTK field measurements. A Random Forest based model integrating topographic, rainfall, soil, and crop factors was developed to map gully density. The interpretation accuracy reached about 80%, with an average gully number density of 4.02 per square kilometer and length density of 0.38 km·km$^{-2}$. Gully distribution was strongly controlled by topography; both slope gradient and slope length exhibited nonlinear threshold effects on gully density. At the watershed scale, UAV-based mapping and field measurements revealed a strong linear relationship between damaged farmland area (DFA, m²) and gully length (GL, m), expressed as DFA = 1.15GL, with an NSE of 0.89. At the hillslope scale, nine cross-sections were established across three representative ephemeral gullies, including 81 sampling points and two control sites. Ten soil physicochemical variables and eight crop trait indicators were analyzed. Results showed that corn and soybean yields decreased by 14.35% and 36.85%, respectively, within 3 m from the ephemeral gully bottom, and total crop failure occurred within 1 m downslope. The study elucidates a process chain linking ephemeral gully formation, microtopographic alteration, soil degradation, crop stress, and yield reduction. This work provides a multi-scale quantitative assessment of ephemeral gully spatial patterns and their agricultural impacts in the black soil region of Northeast China. The findings offer theoretical and practical support for developing preventive and integrated gully erosion control strategies in fragile agricultural landscapes.

# Health regulation of black soil under the dual carbon strategy

**Ying Zhang**[1*]

[1] *School of Resources and Environment, Northeast Agricultural University, Harbin 150030, PR China*

*zhangying_neau@163.com

**ABSTRACT**

Black soil is a vital agricultural resource characterized by high fertility, formed through the accumulation of humic substances under unique climatic, vegetative, and topographic conditions. As China pursues its "Dual Carbon" strategy, the Northeast Black Soil Region plays a dual role as a cornerstone of national food security and a critical terrestrial carbon sink. However, long-term intensive farming has led to severe degradation, marked by declining organic matter, thinning of the fertile layer, and accumulation of pollutants such as pesticides, plasticizers, antibiotics, and heavy metals. These challenges threaten both soil health and agricultural sustainability.

To address these issues, research has focused on agricultural carbon neutrality and soil remediation. Innovations include developing cold-tolerant microbial agents for degrading pesticides and plastic films, creating biochar-based biofertilizers, and advancing integrated "remediation while producing" strategies. Techniques for expanding the soil plow layer, enhancing soil organic matter, and facilitating straw decomposition have been implemented to synergize agricultural productivity with ecological restoration. A comprehensive technical system has been established, encompassing in-situ remediation, saline-alkali soil improvement, and precision nutrient management. Supporting these efforts, monitoring protocols and digital platforms for fertilizer and pesticide reduction have been developed to guide sustainable soil management.

Aligned with carbon neutrality goals, an integrated "Block-Increase-Stabilize" framework has been introduced to enhance carbon sequestration. This approach combines conservation tillage to minimize carbon loss, deep loosening and organic amendments to boost carbon input, and biochar-humic acid composites to stabilize soil carbon pools. For pollution control, functional microbial agents and biochar-based materials have been engineered to degrade chemical residues and immobilize heavy metals, enabling productive and eco-friendly agriculture. These advancements provide a scientific and practical foundation for achieving green development in black soil regions, ensuring food security, and fulfilling carbon sequestration targets..

*E-mail Address of Presenting Author: wmm971007@163.com

**ABSTRACT**

The Northeast Black Soil Region is vital for China's grain production. Maintaining its fertility is crucial for national food security. Long-term intensive use and unsuitable fertilization have caused soil degradation. Understanding how soil organic matter (SOM), microbes, and soil structure interact under stable, long-term fertilization is key for sustainable management. This study, based on 25-year trials in four soil types (Black, Brown, Dark Brown soil) with stable fertility, compares four treatments: mineral fertilizer (NPK), organic manure (M), combined fertilization (MNPK), and no fertilizer (CK). We analyze three aspects: SOM stability, microbial traits, and soil structure stability, to uncover microbes' role in linking SOM and structure.

For SOM stability, we measured not just total organic carbon but also its quality. Analyzing fractions like particulate and mineral-associated organic carbon shows how different fertilizations affect carbon pools. Studying humus components reveals chemical stability. This identifies which SOM fractions are key for long-term fertility and how MNPK best enhances both active and stable carbon pools.

In microbial traits, we see microbes as the link between organic inputs and soil carbon/structure. We measure microbial biomass, community structure (using PLFA and metagenomics for diversity/species), and function (carbon metabolism genes). Amino sugars, as microbial residue markers, show how much microbes contribute to stable SOM, highlighting the "microbial carbon pump."

For soil structure stability, we focus on aggregates, which protect SOM and host microbes. We measure aggregate size distribution and stability (e.g., mean weight diameter). Advanced pore structure analysis (via CT scanning) shows how MNPK improves soil structure. Aggregate stability is closely tied to organic matter and microbes, connecting these three components.

Our main goal is to integrate all data to build a model of the SOM-structure-microbe relationships under stable fertility. We will use statistical models to test our hypothesis: MNPK supports a diverse, functional microbial community that drives stability by 1) using carbon to build its own biomass and residues, enriching stable carbon; 2) forming stable aggregates that protect carbon; and 3) creating better soil habitats that further support microbes, forming a positive loop.

In summary, this multi-dimensional study explains the synergistic mechanism where microbes mediate SOM and structure stability under long-term MNPK in black soils. It provides a theory for sustainable soil management focused on building healthy soil ecosystems.

## ABSTRACT

The black soil region in Northeast China plays a crucial role in national food security. However, decades of intensive cultivation have caused soil degradation. Although the degradation of black soils has been widely recognized, unclear boundaries and the limited spatial coverage of previous soil data have constrained the assessment of degradation extent and dynamics, while also limiting the quantification of key driving factors behind changes in soil thickness, fertility, and compaction.

To overcome these limitations, data from the 3rd National Soil Survey (2022–2025) were integrated with the 2nd National Soil Survey (1980s) to establish a standardized procedure for delineating the black soil boundary and assessing its degradation. The study covered the region in Heilongjiang, Jilin, and Liaoning provinces and the five eastern leagues or cities of Inner Mongolia (Xing'an, Xilingol, Hulunbuir, Tongliao, and Chifeng), using 10,071 soil profiles from the 3rd and 6,731 profiles from the 2nd National Soil Survey. The black soil horizon in each profile was identified, and its thickness was calculated by summing all recognized black horizons, excluding horizons buried deeper than 50 cm. Point observations from the 3rd and 2nd soil profiles were combined with environmental covariates in a machine-learning model to map black soil horizon thickness for current and historical periods. By overlaying each thickness map with cropland boundaries and the eight black-soil-related soil types (Phaeozem, Chernozem, Kastanozem, Meadow soil, Dark brown soil, Brown soil, Albic bleached soil, Paddy soil), the current and historical extents of black soils were delineated. The union of these two extents was defined as the final black soil region. Within the black soil boundaries, degradation over the past four decades was quantified by comparing soil organic matter, bulk density, and black soil horizon thickness between the 3rd and 2nd Soil Surveys. The degree of degradation was classified, and the thresholds for black soil thinning, fertility decline and compaction, were established and normalized to a [0–1] scale to construct a degradation assessment index. In addition, environmental covariates and land-use data were incorporated to quantify the relative contributions of different driving factors to black soil degradation.

Our results produced a high-resolution (30×30 m) map of black soil horizon thickness and delineated the boundaries of black soil region. Comparative analysis showed a widespread decline in black soil horizon thickness and a shrinkage of the black soil area, while other soil properties showed regional variability, indicating degradation in several core areas. The study establishes a standardized method for delineating the black soil region and identifies the driving factors of black soil degradation in Northeast China, providing scientific basis for its conservation and restoration.

**ABSTRACT**

The stoichiometric characteristics of soil carbon (C), nitrogen (N), and phosphorus (P) play a fundamental role in maintaining soil fertility, regulating ecosystem sustainability, and influencing crop growth. However, currently, there is still a lack of understanding of the spatial distribution patterns and driving mechanisms of C, N, and P stoichiometry. In this study, soil samples from 225 sampling points in the Songnen Plain were analyzed. Geostatistical methods and Empirical Bayesian Kriging interpolation were used to map the spatial distributions of soil organic carbon (SOC), total nitrogen (TN), total phosphorus (TP), and their stoichiometric ratios. Additionally, feature importance analysis and correlation analysis were employed to explore the effects of various factors on the soil C:N:P stoichiometric ratios. The results showed that the contents of SOC, TN, and TP exhibited a spatial distribution pattern of higher values in the north and lower values in the south. The average values of the C:N, C:P, and N:P ratios were 11.58, 32.78, and 2.84, respectively, with different spatial distribution characteristics. Feature importance analysis identified SOC as the most critical factor influencing the C:N:P ratios (importance values approximately 0.5~0.6), showing significant positive correlations with these ratios. Among the climatic factors, the mean annual temperature was significantly negatively correlated with the C:N:P ratios (correlation coefficients about -0.2~ -0.34), while the annual precipitation mainly affected the C:N ratio. Different soil types also had significant effects on the C:N:P ratios, with black soil exhibiting the highest C:N and C:P ratios (11.8 and 36.7, respectively). This study provides important scientific evidence for understanding the nutrient balance in farmland soils of the Songnen Plain and its influencing factors, which is of great significance for developing sustainable soil management strategies.

# Multi-temporal monitoring of crop residue cover for large-scale classification of tillage practices: linking deep learning of UAV images with satellite-based spectral modelling

**Pu Shi[1*], Jun Zhang[1], and Bas van Wesemael[2]**

[1] *College of Earth Sciences, Jilin University, Changchun, China*

[2] *Earth and Life Institute, UC Louvain, Louvain-la-Neuve, Belgium*

*shipu@jlu.edu.cn

## ABSTRACT

Obtaining spatially and temporally explicit information on agricultural management practices is crucial for accurately modeling soil organic carbon dynamics and verifying the impact of carbon farming activities. Conventional field-based and remote sensing surveys struggle with insufficient spatial and temporal coverage to capture the dynamics of crop residue cover (CRC) across large scales. Focusing on the various residue management practices in Northeast China, we will present a temporally transferable CRC mapping approach, by integrating deep learning of unmanned aerial vehicle (UAV) images with Sentinel-2 multispectral modelling.

A modified U-Net image segmentation algorithm with a ResNet-50 backbone was trained to generate CRC observations at high accuracy and efficiency. Independent tests showed satisfactory segmentation performance (mPA=92.02%), outperforming the traditional OTSU method by more than 30%. Through deep learning of UAV images, we developed a multi-seasonal CRC dataset across the Songnen Plain of Northeast China.

UAV-derived CRC ground References was then linked with Sentinel-2 surface reflectance for spectra-based CRC predictive mapping. The spectral model, trained on spring 2024 observations, demonstrated robust transferability, accurately predicting CRC in autumn 2024 ($R^2$=0.85, RMSE=12.64%) and spring 2025 ($R^2$=0.70, RMSE=10.05%). This temporally transferable framework thus enabled spatiotemporal monitoring of crop residue cover for large-scale classification of tillage practices. The mapping products revealed distinct residue retention patterns between conventional (abrupt clearance) and conservation tillage (persistent coverage). This work establishes a physically meaningful, transferable framework for field-level tillage classification and large-scale monitoring of conservation agricultural practices and their impact on soil carbon dynamics.

# Effects of Furrow Straw Mulch on Soil Erosion and Organic Carbon Redistribution in Soil Aggregates at Sloping Farmland

**Libo Ye [1], Frédéric Darboux [2], Linhui Zhou [1], Yu Zhang [1], Jialong Wu [1], Kunheng Li [1], Haiou Shen [1, *], Hongli Li [1, *]**

[1] *College of Resources and Environment, Jilin Agricultural University, Changchun 130118, China*

* shenhaiou@jlau.edu.cn (Haiou Shen)

**ABSTRACT**

The severe soil erosion at sloping farmland leads to soil structure destruction and organic carbon migration, threatening agriculture sustainable development. Furrow straw mulch effectively prevents soil erosion, but research on distribution characteristics of soil organic carbon on hillslope remains insufficient. This study designed ridge tillage without (CK) and with furrow straw mulch on 3°, 6°, and 9° hillslope of the Chinese black soil region to analyze soil erosion modulus (EM), soil erodibility (K), soil aggregate structure, stability, and organic carbon content at upper, middle, and lower hillslope positions after an 11-year situ monitoring study under natural rainfall and farmland conditions. The results showed that the soil erosion modulus ranged from 764.56 to 2214.84 $t \cdot km^{-2} \cdot a^{-1}$ at 3°, from 1415.78 to 3798.79 $t \cdot km^{-2} \cdot a^{-1}$ at 6°, and from -139.06 to 1839.07 $t \cdot km^{-2} \cdot a^{-1}$ at 9° for CK treatments. In contrast, the soil erosion modulus decreased by 40.89%-53.19% at 3°, 77.05%-116.56% at 6°, and 20.01%-481.25% at 9° for furrow straw mulch treatments. Furthermore, the K also decreased by 0.02%-0.95% and the percentage of aggregate destruction (PAD) decreased by 6.10%-38.39% for furrow straw mulch compared with those of CK for hillslope with different slope gradients. Meanwhile, the proportion of water-stable aggregates (>0.25 mm) increased by 0.30%-32.70%, the mean weight diameter (MWD) increased by 1.90%-58.50%, and soil organic carbon content in macroaggregates increased by 6.09%-102.69% at all hillslope positions. Therefore, furrow straw mulch not only decreased soil erosion at sloping farmland but also improved soil aggregate stability and increased soil aggregate organic carbon sequestration capacity.

**Keywords:** Furrow straw mulch, Soil aggregate, Soil organic carbon, Soil erosion, Black soil region.

# Benchmark and Near-Benchmark Chernozems: Assessing Human-Induced Transformation and Pedodiversity for Black Soils Conservation

**M.A. Smirnova [1*], Yu.G. Chendev [1,2], and A.N. Gennadiev [1]**

[1] *Faculty of Geography, Lomonosov Moscow State University, Moscow, Russia*

[2] *Institute of Earth Sciences, Belgorod State National Research University, Belgorod, Russia*

*summerija@yandex.ru

**ABSTRACT**

The conservation and restoration of black soils (Chernozems) require reliable benchmarks of their natural state to assess anthropogenic transformation. In the old-developed forest-steppe of the Central Russian Upland, this is challenging due to near-total agricultural development. This study evaluates morphological features (horizon thickness, structure, carbonate formations), physical characteristics (bulk density, texture), and chemical parameters (organic and inorganic carbon stocks) of Chernozems, along with soil cover patterns, across three distinct land-use types: a) protected benchmark soils; b) never-ploughed hayfields and pastures (near-benchmark); and c) long-term arable lands.

Our research focused on the Central Russian Upland within the Belgorod oblast, under a moderate continental climate. The soils formed on loess-like carbonate loams and clays on flat interfluves. We analyzed 41 full-profile soil pits to assess soil transformation: 11 in reserves, 18 in never-ploughed hayfields and pastures, and 12 in arable lands. The never-ploughed sites have remained undisturbed for at least 240 years, based on historical map analysis since 1783, while the arable soils have been cultivated for over 120 years. Large-scale soil mapping covered never-ploughed plots ranging from 0.1 to 0.25 ha.

Long-term ploughing leads to soil degradation: compaction in a plough pan at 20–30 cm depth, a substantial reduction in organic carbon stocks (240.4 t/ha in arable soils vs. 316.5 t/ha in benchmarks, 0–100 cm layer), and upward migration of pedogenic carbonates. Soils under hayfields and pastures also show increased bulk density in the upper horizons compared to protected benchmarks, due to animals trampling. However, they show no statistically significant differences in total organic carbon stocks, key morphological properties, soil texture, confirming their high value as near-benchmark References.

The spatial pattern of the soil cover on watershed plains appears similar across reserves, hayfield-pastures, and arable land. However, the component composition differs fundamentally. The never-ploughed sites lack the eroded soil varieties that are widespread on arable land. Under the Russian classification system, a 50x50 m area typically contains 10-20 patches belonging to 5-14 taxonomic groups. In contrast, the WRB system generalizes these same areas into only 3-4 patches and 2 taxonomic groups, highlighting a significant divergence in classification approaches.

Never-ploughed Chernozems in hayfields and pastures are vital for monitoring soil quality, reconstructing pre-industrial soil geographies, and developing sustainable land-use strategies. Their preservation is essential for halting black soil degradation and promoting their role in carbon sequestration.

# Organic Carbon Loss Process of Black Soil During Cultivation

**Weixin Ding*, Zengming Chen, and Ye Li**

*Institute of Soil Science, Chinese Academy of Sciences*

*E-mail: wxding@issas.ac.cn

## ABSTRACT

Black soils (Mollisols) with abundant organic matter (SOM) and high productivity in Northeast China play a crucial role in national food security and climate change mitigation. However, the content of SOM in this region showed a continuous decline since cultivation, introducing a potential threat to the quality of agricultural soils. In this study, black soils along a 100-year cultivation chronosequence were collected in Baoqing county, Heilongjiang province, China, to assess changes in the content and composition of SOM. Employing soil aggregate and density fractionation schemes and biomarker techniques, shifts in the mechanisms of SOM generation and stabilization were elucidated. The SOM content declined by 43% during the first 30 years of agricultural use, with a rate of 0.74 g C $kg^{-1}$ $year^{-1}$, while reduced by 60% with a rate of 0.31 g C $kg^{-1}$ $year^{-1}$ after 100 years of conversion from the marsh into upland field. Meanwhile, 100-year cultivation resulted in 68% and 19% decreases in the contents of total nitrogen and phosphorus, respectively, and lowered the mean weight diameter of soil aggregates from 4.2 to 1.2 mm. The depletion of soil nutrients and disruption of aggregate structure aggravated the environments for microbes, subsequently weakening soil extracellular enzymatic activities with a cascading consequence of declining soil quality. Biomarkers (lignins, alkanoic acids and amino sugars) were used to evaluate the relative contributions of plant- and microbial-derived C to SOM. With SOM decreasing from ~50 g C $kg^{-1}$ to ~20 g C $kg^{-1}$, the absolute content of plant-derived C decreased by approximately two-thirds, and in contrast, the content f microbial-derived C did not change significantly, which increased its contribution to SOM from 14% to 31%. The microbial-derived C accumulated mainly due to two processes. First, the increase of soil aeration promoted the aerobic microbial metabolisms and increased microbial biomass by 2.7 times, which in turn increased microbial carbon use efficiency from 0.11 to 0.29 and produced more microbial residues. Second, the generated microbial residues could have associated with soil minerals, as reflected by a three-fold increase in the contribution of microbial-derived C in mineral-associated OM (MAOM), which facilitated the maintenance of microbial necromass. The proportion of MAOM in SOM decreased from 85.6% to 72.8%. Meanwhile, the relative abundance of chemically active methoxyl and O-alkly carbon in particulate OM (POM) increased by nearly 100%. This indicated that with the decrease of mineral protection and increase of POM biochemical reactivity, the SOM stability decreased significantly along with its decreasing content. When the SOM content decreased from 50 to 20 g C $kg^{-1}$, dissolved organic matter (DOM) concentration declined by 68.6%, and in contrast, the biodegradability of DOM significantly increased. Spectroscopic analysis revealed that with the decrease in DOM concentration, its aromatic index escalated from 4.33 to 16.8, and spectral slope, indicative of the inverse of average molecular weight, increased from 0.56 to 1.41, and the fraction of protein-like components increased from 6.28% to 38.6%. These shifts suggested that the decline in complex polymers, coupled with the rise of small molecular weight aromatic substances and protein-like components, was the primary factors enhancing DOM bioavailability in black soils. Although SOM could be the main source of DOM, both composition exhibited to be decoupled. The increase in oxygen availability was identified as the main factor influencing the dynamics of DOM composition and bioavailability. As DOM concentration declined, the increased oxygen availability reduced DOM quality. The oxygen-induced oxidation of ferrous to ferric iron removed complex DOM compounds with large molecular weight. And, increased oxygen availability also stimulated oxidase-catalyzed depolymerization of aromatic substances, and promoted production of protein-like DOM components due to lower enzymatic C/N acquisition ratio. This study reveals that patterns of DOM dynamics in black soils are driven by oxygen availability, which extends results from tropical rainforests and wetlands to upland soils with great potential to be managed for soil C sequestration.

## ABSTRACT

Straw incorporation has been demonstrated an effective measure for soil and water conservation worldwide. Most endeavors have been devoted to evaluate the impact of incorporation rate on soil erosion, yet few attempts have been made to examine the influence of straw size. To fill this gap, rainfall simulation experiments were performed on a typical black soil collected in northeast China, which was packed in runoff plots and incorporated with the maize straw segments of four different lengths, i.e., 2, 5, 10 and 20 cm, at a constant rate of 6 t/hm$^2$. In the meanwhile, a bare black soil without straw incorporation was also subjected to the simulated rainfall, which was used as the control (CK). Designing two slope gradients of 3° and 6°, and two rainfall intensities of 60 and 90 mm/h, the impact of straw length on runoff initiation time, surface flow velocity, runoff depth, sediment concentration and sediment yield were analyzed. The results showed that in contrast to CK, straw incorporation generally delayed runoff initiation and reduced surface runoff. As the straw length increased, moreover, the runoff initiation time increased overall, and the runoff depth declined exponentially. Incorporating the straw segments with the maximum length of 20 cm, the runoff initiation time delayed by 2.8-9.5 times and the runoff depth decreased by 20.8%-37.2% compared to CK. With the increase of straw length, the surface flow velocities on the upper and lower slope sections both decreased initially and then increased, and reached their minima at the medium lengths of 5 and 10 cm. In contrast to CK, specifically, the flow velocities measured on the upper slope decreased by 18.5%-37.4% and 20.1-47.0%, and those on the lower slope section decreased by 35.9%-51.6% and 36.1%-51.6%, respectively. The sediment yields measured at each straw incorporation treatment were lower than those at CK on the whole. Similar with flow velocity, the sediment yield also exhibited decreasing-then-increasing trends with straw length. The sediment reduction benefits were generally the highest when incorporating 5 and 10 cm long straws. The corresponding sediment yields were 19.7%-69.1% and 14.2%-52.1% lower than those at CK, respectively. Nevertheless, the sediment reduction benefit of straw incorporation generally decreased as the rainfall intensity, slope gradient or both increased. Straw incorporation in general delayed runoff initiation, reduced surface runoff, lowered surface flow velocity and impaired soil erosion. However, the responses of runoff and erosion characteristics to incorporated straw length were not consistent. Considering runoff reduction, the application of the 20 cm long straw segments is recommended, which has been found to possess the highest benefits. From the perspective of sediment reduction, in contrast, it is suggested to incorporate the medium-sized straw segments of 5 and 10 cm long, which have been demonstrated the strongest in containing erosion.

*E-mail Address of Presenting Author: gliu@foxmail.com

**ABSTRACT**

The Mollisol region in Northeast China faces severe soil erosion on sloping farmland due to long-term intensive cultivation and complex terrain. This study integrates two research efforts to assess soil erosion and model performance across three slope shapes (straight, convex, and concave) in Heilongjiang Province. An integrated modeling framework combining field observations and artificial intelligence is developed to improve erosion prediction.

In the first part, $^{137}$Cs tracing and wavelet analysis were used to quantify soil erosion-deposition rates and their periodic characteristics across different slope shapes. Significant differences in erosion intensity were found: convex (2009 $t \cdot km^{-2} \cdot a^{-1}$) > straight (1466) > concave (1234). Dominant fluctuation periods were 45.1 m for straight, 55.0 m for convex, and 40.4 m for concave slopes, indicating the strong impact of slope shape on erosion patterns.

In the second part, the RUSLE2 model was enhanced by incorporating random forest regression to integrate slope shape correction factors and slope length parameters. The optimized model improved predictive accuracy, especially for concave slopes ($R^2$ = 0.985, RMSE = 160.2 $t \cdot km^{-2} \cdot a^{-1}$, AVE = 6.32%), demonstrating its effectiveness for erosion prediction in complex terrain.

This study provides a framework combining field data and machine learning to assess slope erosion, revealing spatial heterogeneity and supporting erosion risk zone identification, soil conservation optimization, and Mollisol protection.

# Straw return combined with fertility enhances soil organic carbon and soil aggregate formation in Mollisol soils

**Fenli Zheng** [1*]

[1] *College of Soil and Water Conservaton Science and Engineering, Northwest A & F University, Yangling 712100, PR China*

**ABSTRACT**

Straw return is a widely adopted agronomic practice across the world for enhancing soil organic carbon (SOC), which plays a crucial role in mitigating climate change and promoting sustainable agricultural. However, the effect of pelletized straw, a novel type of straw, on SOC dynamics and soil aggregation is insufficiently studied. Furthermore, the performance of different straw types on SOC pools under varying chemical fertility levels remains unclear. Thus, a field experiment was conducted in a typical Mollisol region of China to quantify effects of straw return types with chemical fertility application levels on SOC fractions and aggregate characteristics. The experiment includes 12 field treatments that combined three straw return types (chopped straw, ST, straw biochar, BC, pelletized straw, PST), and no-straw control (S0) under three chemical fertility levels (80%, 100%, and 120% of recommended fertilization). The results revealed that the ST, BC and PST significantly increased the SOC content by 10.7%, 41.8% and 14.8%, respectively, compared to the S0 treatment. More than 90% of SOC was stored in the form of mineral-associated organic carbon (MAOC) and heavy fraction organic carbon (HFOC). Among the three straw types, biochar application exerted remarkable effects in enhancing the content of SOC and its fractions. Relative to the S0, all straw return types increased the proportion of POC and LFOC, indicating a shift toward more labile carbon. Furthermore, straw return improved soil aggregation by increasing aggregate-associated carbon and elevating the macroaggregate fraction (> 0.25 mm), ultimately enhancing mean weight diameter (MWD) and soil structural stability (SSI). In terms of fertility, increasing fertility application alone enhanced SOC content and stocks while the trend gradually weakened, but it negatively influenced aggregate stability. In contrast, when fertility application combined with straw return, higher fertility level resulted in greater the MWD and SSI values. In summary, these results highlight the critical role of straw return in promoting the storage capacity and stability of soil aggregate. Pelletized straw and biochar could be considered as promising strategies for SOC sequestration in the Chinese Mollisol region.

**ABSTRACT**

Andosols, a typical tropical black soil of Cameroon are country's food basket and a sink for carbon storage. These soils are very fertile and intensively cultivated under various agricultural practices. However, little is known about the effect of these agricultural practices on andosol health and ecosystem functioning. To assess this, composite samples were taken at a depth of 0-25 cm, in seven soils cultivated under various agricultural practices (AgP) which include fallow (FA), crop rotation (CR), burning farm (BF) crop association (CA), non-tillage (NT) coffee plantation (CP) and conventional tillage (CT). After performing the physicochemical analyses, we have asses the soil health index as well as ecosystem functioning. The results showed a variation in physicochemical properties depending on the different AgP. Crop rotation improved total nitrogen by 61.1% while tillage degraded it by 27% compared to fallow. Burned farm and tillage degraded organic carbon by 15.25 and 47.8% compared to fallow. SOC, pH, K and silt were identified as key indicators of soil health in the four ecosystem services considered for this study. According to soil health index and ecosystem multifunctionality (EMFs), the following agricultural practices including CR, CA and NT were found to be the one maintaining soil health with SHIs very close to fallow while BF and CT were found to be degrading with SHIs lower by 32.2% compared to fallow. These two practices also decreased ecosystem multifunctionality by 12.85% while CR improved it by 22.7% compared to fallow. Ecosystem functions including nutrient cycling (NC) and physical structural stability (PSS) showed a positive response to the improvement of soil health while carbon cycle (CC) and buffering and filtering capacity (BFC) showed a moderate response. This study highlights the effects of tillage and burning on the degradation of soil health and ecosystem multifunctionality and the conservative role of crop rotation, crop association and non-tillage. These results will help to improve the sustainable management of black soils in the locality of Foumbot.

# Long-Term No-tillage Retains Intact Biopores in the Topsoil Compared to Conventional Tillage Based on the Soil Profile Study

**Jiao Yan[1], Hui Rong[1], Hu Zhou[1*]**

[1] *College of Land Science and Technology, China Agricultural University, Beijing 100193, China*

*zhouhu@cau.edu.cn

**ABSTRACT**

Soil structure controls various important soil properties and processes and is shaped by the interaction of different organisms (plants, soil fauna and microbes). Biopores, which are caused by growing roots or burrowing earthworms, can extend along the entire soil profile. They are cylindrical in shape and demonstrate low tortuosity and high vertical continuity. They significantly affect infiltration and preferential flow phenomena. In North-east China, earthworms have been shown to prefer the surface layer. Thus, biopores in the deep soil caused by roots are significant. However, how the root system develops under long-term no-tillage is still debated. Some studies suggest that it grows deeper, while others suggest that it accumulates in the surface layer. This study quantifies macro-pore and biopore characteristics under no-tillage (NT) and conventional tillage (CT) treatments, investigating how tillage practices influence vertical pore distribution. Based on a soil profile study in Lishu County, Jilin Province, undisturbed soil columns were collected and analyzed using X-CT scanning. Results show that no significant differences were observed in macro-porosity and pore connectivity across the entire soil profile between CT and NT, except at 40–50 cm depth where NT exhibited higher pore connectivity. At a soil depth of 10–30 cm, NT exhibited a significantly higher number of biopores, with these biopores displaying a greater length compared to CT. The fallow treatment exhibited low macro-porosity and bioporosity, attributable to an absence of tillage and plant roots.

# A Comprehensive Framework for Assessing Land Degradation Neutrality in Northeast China's Black Soil Region: Multi-Source Fusion, Driver Analysis, and Scenario Prediction

**Yuanfang Huang* and Wentao Zhou**

*China Agricultural University (College of Land Science and Technology, Beijing, China)*

*yfhuang@cau.edu.cn

**ABSTRACT**

Black soil is among the world's most valuable soil resources, yet only four major black soil regions exist globally, including one in Northeast China. Long-term intensive cultivation has led to widespread erosion and degradation, making the identification of degradation hotspots essential for effective restoration. The land degradation neutrality (LDN) framework proposed by the United Nations Convention to Combat Desertification (UNCCD) offers a key pathway for curbing degradation and supporting sustainable development. Accurate evaluation of land degradation is therefore critical for safeguarding food security and sustaining ecosystem services in this region. In this study, we developed a zoning-based decision fusion rule using consistency analysis and produced six phases of fused land use/land cover (LULC) datasets for 1995–2020. We conducted uncertainty analysis for land productivity (LP) assessments within the LDN framework, established a multi-source data fusion method, and further proposed a Land Degradation Neutrality Index (LDNI). Structural equation modeling was employed to quantify degradation drivers and to predict land degradation trends for 2030. The fused LULC datasets improved mapping accuracy by up to 31.64%, with Kappa coefficients increasing by up to 0.43. Forest-to-cropland conversion, farmland abandonment, and urban expansion were the key contributors to LULC-indicated degradation. Multi-source fusion substantially reduced LP assessment uncertainty, with maximum reductions of 65% in the baseline period and 82% in the assessment period. Degraded and improved land areas were $17.79\times10^4$ km² and $13.32\times10^4$ km², respectively, indicating that the region has not yet achieved LDN. Moreover, 66.6% of physiographic regions, 62.5% of cities, and 69.4% of counties failed to meet the LDN target. Functional disparities were evident: LDNI values for food production land ranged from –0.90 to 0.00, while those for ecosystem service land ranged from –0.32 to 0.38, suggesting higher LDN achievement in ecological land. Socioeconomic factors dominated LDN outcomes. Population exerted strong positive direct effects on both ESF_LDNI and FPF_LDNI (0.890 and 0.601), whereas GDP showed significant negative effects (–0.715 and –0.759). Among the nine future LULC scenarios combining three development pathways and three climate trajectories, the cropland-protection-plus-ecological-conservation scenario consistently produced the greatest improvements and the least degradation, especially under warming and drought-intensified conditions. Overall, this study presents a comprehensive LDN assessment for Northeast China's black soil region using multi-source fused datasets. The integration of driver analysis and scenario simulations provides crucial evidence to support black soil conservation and regional sustainable development.

## ABSTRACT

Species-diverse intercropping systems are associated with increases in soil aggregation but the underlying root mechanisms responsible for greater soil aggregation remain poorly understood. A three-year-long field study was conducted comprising two nitrogen (N) and phosphorus (P) application rates (with and without N or P), and five cropping systems: two maize-based intercropping systems (with peanut or soybean) and their corresponding monocultures (peanut, soybean and maize). Water-stable aggregates and six crop root traits were measured in both monoculture and intercropping. At the plot scale the percentage of soil macroaggregates ($R_{0.25}$), mean weight diameter (MWD), root length density (RLD), biomass density (RMD), volume (RV), and total surface area (RS) had significantly higher values in legume/maize intercropping and maize monoculture than in legume monoculture. At the field-strip scale, intercropping increased the $R_{0.25}$ and MWD of legume strips by 6.4-13.3% and 13.9-31.9% compared to the corresponding legume monocultures. This was induced by the synergistic effects of maize root residues from the previous growing season and the spatial extension of maize roots in the current growing season. Maize roots affected the soil aggregate stability of neighboring soybean and peanut strips in different ways. Intercropping promoted soil aggregation of neighboring soybean strips mainly via maize root traits within the growing season. In contrast, intercropping promoted soil aggregation of the same peanut strips mainly via pre-maize root traits. The results indicate that intercropping can promote soil aggregation, especially in the legume strips of the intercropping system, through interspecific maize-legume interactions that determine changes in root traits. These results provide critical insights into the underlying ecological processes that promote the sustainability of species-rich agricultural systems on mollisols.

**ABSTRACT**

The Black Soil Region, renowned for its high fertility, is a crucial grain production base. However, long-term conventional monoculture practices have led to soil degradation, threatening sustainable crop production. Therefore, to investigate the effects of integrating conservation tillage with diversified cropping on crop productivity and soil fertility, a long-term field (2021– ) study was conducted comprising two tillage (CT: conventional tillage; CST: conservation tillage), and five cropping systems (M: Maize monoculture; S: Soybean monoculture; M/S: Maize/soybean intercropping; M-S: Maize-soybean rotation; M-M-S: Maize-maize-soybean rotation). Grain yield, grain mineral concentrations, soil physicochemical properties, soil enzyme activities were assessed. Over the four-year study, CT-M/S and CST-M/S saved 18.37% and 4.38% of land, respectively. M/S increased maize yield by 52.38% but a 37.34% decrease soybean yield compared to their respective continuous cropping systems, and achieved higher temporal stability. Additionally, CST not only increased maize grain yield by 6.62%, but also significantly enhanced the concentrations of Fe and Mn in soybean grains by 6.55% and 29.38%, respectively, compared to CT. Moreover, CST improved soil structural stability and biochemical properties in the 0–5 cm layer, increasing soil organic carbon (SOC) and hemicellulase (BX) activity by 26.6% and 82.5%, respectively, when compared to CT. In the 0-5 cm soil layer, M-M-S significantly increased SOC compared with M and S, with increases of 34.01% and 34.73%, respectively. In the 5-15 cm soil layer, M/S significantly increased SOC compared with M and S, with increases of 19.18% and 17.74%, respectively. The integration of conservation tillage and crop diversification in the Black Soil Region by simultaneously stabilizing grain yield, improving grain quality, and enhancing soil fertility.

**ABSTRACT**

Plant biodiversity–productivity relationships become stronger over time in grasslands, forests and agroecosystems. Plant shoot- and root-litter is important in mediating these positive relationships, yet the functional role of plant-litter remains overlooked in long-term experiments. We propose that plant-litter strengthens biodiversity-ecosystem functioning relationships over time in four ways by: (i) providing decomposing detritus that releases N through time for uptake by existing and succeeding plants, (ii) overall enhancing soil fertility, (iii) changing soil community composition, and (iv) reducing the impact of residue-borne pathogens. We bring new insights into how diversity–productivity relationships may change over time and suggest that the diversification of crop residue retention through increased residue diversity from plant mixtures will improve the sustainability of food-production systems.

# Soil Erosion Processes and Dynamic Mechanisms under Soil Compaction and Freeze-Thaw Cycles in the Black Soil Region of Northeast China

**Boxiang Zhang**[1,2], **Renming Ma**[1,2*]

[1] *College of Water Conservancy, Shenyang Agricultural University, Shenyang, Liaoning, 110866, People's Republic of China.*

[2] *Liaoning Provincial Key Laboratory of Soil Erosion Control and Ecological Restoration, Shenyang, Liaoning 110866, People's Republic of China.*

**ABSTRACT**

Soil erosion resulting from the interaction between soil compaction and seasonal freeze-thaw (FT) cycles is a critical environmental issue in the intensive agricultural black soil region of Northeast China. While FT cycles are recognized for their potential to alleviate soil compaction, the cross-temporal mechanisms connecting pre-FT compaction-induced microstructural evolution to post-FT erosion dynamics remain poorly understood. This study integrated in situ field erosion experiments with X-ray computed tomography (CT) scanning to comparatively analyze soil properties, pore structure characteristics, and erosion responses under varying compaction levels before and after the seasonal FT period. Results indicated that prior to the FT period, soil compaction significantly increased bulk density and reduced porosity, creating a dense, layered microstructure with diminished pore connectivity and fractal dimension. This structural degradation led to a significant increase in total runoff and sediment mass, driven primarily by enhanced runoff scouring capabilities. Following the seasonal FT period, CT visualization revealed that FT cycles functioned as a natural restorative mechanism, significantly increasing total pore number, connectivity, and porosity in compacted soils. However, this physical recovery came at the cost of structural stability; FT cycles disrupted soil aggregates, leading to a significant decline in water-stable aggregate stability and shear strength. Consequently, while sediment mass in compacted soils decreased by 1.84%–57.73% post-FT compared to pre-FT levels due to improved infiltration, it remained 28.59%–148.22% higher than in uncompacted soils. Structural Equation Modeling (SEM) revealed a shift in erosion mechanisms: whereas pre-FT erosion was dominated by compaction-induced runoff, post-FT erosion was driven by the synergistic interaction between residual runoff scouring and reduced soil erosion resistance caused by microstructural fragmentation. These findings highlight that pre-FT compaction exacerbates spring erosion risks through legacy effects on soil microstructure, emphasizing the need for soil management strategies that mitigate compaction prior to the freezing season.

# Intercropping, soil microbiomes, and mycotoxin risk: mechanistic pathways for safer maize production

**Yu-Rui Tang[1,] *, Wei-Ping Zhang[1]**

**ABSTRACT**

Climate change has intensified fungal contamination in maize, leading to higher mycotoxin burdens and increasing risks to food safety and human health. Intercropping, as a biodiversity-based agroecosystem practice, is known to enhance ecological functioning and reduce disease pressure. Because *Fusarium* ear rot is a soil-borne disease closely linked to soil conditions in Northeast, soil may play a key role in regulating mycotoxin accumulation. However, the extent to which intercropping mitigates mycotoxin risks through changes in soil microbial communities remains unresolved. To address this question, we quantified maize kernel mycotoxins in 2024 under three cropping systems (maize monoculture, maize/peanut intercropping, and maize/soybean intercropping) and conducted metagenomic analyses of rhizosphere soils sampled at the jointing stage. We formulated two hypotheses: (i) intercropping reduces mycotoxin accumulation relative to monoculture; and (ii) this reduction is driven by shifts in rhizosphere microbial communities, particularly by increases in beneficial microbial taxa and decreases in pathogenic fungi associated with toxin biosynthesis. By integrating field mycotoxin measurements with rhizosphere metagenomic profiling, our study provides a mechanistic basis for understanding how intercropping-mediated microbial regulation can lower mycotoxin risks and contribute to more resilient maize production systems.

# Multi-platform monitoring method for the quality of Black soils cropland and site specific application

**Huanjun Liu**[1*]

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun 130012, China*

*liuhuanjun@iga.ac.cn

**ABSTRACT**

Recently, quantitative monitoring indicator systems and technical systems adapted to the resource characteristics of black soils cropland are lacking, leading to unclear baselines and dynamics of black soils quality and limiting the ability of existing assessments to accurately guide protection and utilization technologies. This study establishes a cropland system theory, analyzing relationships among system elements, structure, processes, and functions, and constructs a quantitative monitoring indicator system. An integrated multi-platform monitoring system suitable for black soil characteristics was created to obtain multi-scale datasets of key cropland quality elements for black soils, including both soil elements (soil organic matter (SOM), thickness of the black soil layer, texture, etc.) and utilization and productivity elements (field boundaries, ditches, forests, roads, and crop planting structure, etc.). This enables multi-temporal quantitative monitoring of SOM from field scale to Northeast China and to the world's four major black soils regions, as well as precise monitoring of spatial variation patterns of SOM and other elements within individual fields. The quantitative monitoring results have been extensively applied in the Beidahuang Group, constructing spatiotemporal big data that guides precision protection and utilization of black soils through prescription maps for variable-rate fertilizer applicators, subsurface drainage pipe installation machinery, and other equipment.

# Mechanistic Insights into Cover Crops and Straw Incorporation: Root Traits, Soil Properties and Carbon Controls on Erosion Resistance across Degradation Gradients in Mollisols

**Miaomiao Wang [1], Xingxing Dai [1], Haoru Xing [1], Jiyuan Zhou [1], Binglin Li [1], Xingyuan Liang [1], Enheng Wang 1, ***

**ABSTRACT**

Soil erosion is a primary driver of Mollisol degradation, yet the mechanisms through which cover crops and straw incorporation regulate erosion resistance across degradation gradients remain unclear. Here, straw incorporation, cover crops (winter wheat, ryegrass, hairy vetch, and a ryegrass–vetch mixture), and their combinations were tested under simulated slight, moderate, and severe degradation, using maize monoculture as the control (CK). Erosion resistance was jointly evaluated using aggregate stability (erodibility resistance) and detachment capacity (detachment resistance), while dominant drivers were identified using random forest and partial least squares path modeling. All treatments improved erosion resistance relative to CK. Grass cover crops enhanced soil erodibility resistance by 2%–22% under slight to moderate degradation and increased detachment resistance by 20%–310% across all gradients, both relative to straw. Under severe degradation, however, legume cover crops exhibited 8%–32% higher erodibility resistance than both straw and grasses. Moreover, cover crop–straw integration exhibited complementary effects on erosion resistance under slight to moderate degradation, but provided no additional advantage over cover crops alone under severe degradation. Root traits emerged as the primary drivers, exerting direct control over detachment resistance, while their influence on erodibility shifted from indirect (via soil properties and carbon) under slight degradation to direct under moderate–severe degradation. As degradation severely intensified, soil properties and organic carbon fractions gained stronger direct effects on soil erosion resistance. These degradation-dependent shifts reveal how root–soil–carbon interactions reorganize erosion resistance, providing mechanistic insights for adaptive conservation strategies in Mollisol regions and other erosion-prone agroecosystems worldwide.

# Bio-tillage: A new perspective for sustainable agriculture

**Zhongbin Zhang, Xinhua Peng**

*State Key Laboratory of Efficient Utilization of Arable Land in China, Institute of Agricultural Resources and Regional Planning, CAAS, Beijing 100081, PR China*

zhangzhongbin@caas.cn

**ABSTRACT**

For sustainable agriculture production, we proposed bio-tillage in this paper, which is defined as improving soil structure with plant roots for boosting growth of crops. Cover crops with thick and deep roots can be used for bio-tillage since they can effectively improve soil structure, water and air conductivity by forming biopores (root channels) which provide space with least resistance, high oxygen and nutrients to promote root growth. The effect of bio-tillage on crop yields varies with climate conditions and management practices. The effective bio-tillage cover crop should have thick and deep roots, rapid root growth rates and rapid decomposition of remnant roots, and good adaption to climate and soil constraints. Planting cover crops timely and killing at suitable stage with a roller-crimper can benefit bio-tillage. The limited understanding of ideal biopore architecture for root growth, more effective bio-tillage cover crop species, and field management of bio-tillage, requires to be addressed before widely application of bio-tillage.

# The impact of cover crops on the active components of organic carbon in black soil after straw return to the field

**Miaomiao Wang [1], Chaonan Liu [1], Yang Zhang [1], Fengqiang Yan [1], Zijun Liao [1], Enheng Wang [1*]**

[1] *Collage of Forestry, Northeast Forestry University, Harbin, 150040, China*

*E-mail Address of Presenting Author:erxin222@163.com

**ABSTRACT**

Straw returning is generally considered beneficial for maintaining and improving soil organic carbon (SOC). However, the higher carbon- to- nitrogen ratio of straw can induce nitrogen limitation in soil microorganisms, thereby hindering the accumu lation of SOC during straw decomposition. The integration of straw and legume- based cover crops theoretically enhances straw decomposition by fixing nitrogen and optimizing the carbon- to- nitrogen ratio. The greenhouse pot experiments were conducted to evaluate the effects of three legume cover crops (hairy vetch, white clover, and alfalfa) and two grass cover crops (ryegrass and winter wheat) separately in cooperation with straw amendment on the SOC and total nitrogen (TN) content at both bulk soil and aggregate scale. Compared to bare soil (CK), returning straw, planting cover crops alone, or combining straw with grass cover crops all enhanced SOC content, while simultaneously reducing TN content to varying degrees. Straw returning in cooperation with legume cover crops increased both SOC and TN, ranging from 4.40% to 5.51% and 1.38% to 2.81%, respectively. The en hancement of TN content resulting from the combination of straw with legume cover crops was 4.7% and 10.2% greater than that achieved through straw returning alone and combining straw with grasses. The combination of legumes with straw substantially enhanced the SOC and TN content across different aggregate scales, particularly demonstrating optimal results when combined with white clover. Legume cover crops produced a greater volume of root exudates and had coarse root systems that directly en hanced SOC and TN content, while indirectly promoting SOC sequestration by improving TN content. The integration of straw returning with legume cover crops showed significant potential to enhance SOC sequestration and TN fixation. This strategy offers a sustainable agricultural pathway to minimize nitrogen fertilizer usage, facilitate straw decomposition, and effectively elevate both carbon and nitrogen levels in the soil

## ABSTRACT

In West Africa, indigenous soil improvement has resulted in fertile soils known as African dark earths (AfDEs) similar to the Amazonian *Terra preta*. However, there is paucity of information on the biogeochemical processes of such soils. Here, we report soil carbon sequestration in such unique AfDEs in Ghana through assessment of persistent mineral-associated organic carbon (MAOC) and labile particulate organic carbon pools (POC) and quantified the carbon foot print thereof through in-situ greenhouse gas measurements. We also studied the vulnerability of soil organic carbon to decomposition through a 98-day laboratory incubation study. We compared AfDE sites with adjacent non AfDEs cropland including fallow land at stratified soil depths of 0-10, 10-20, and 20-30 cm. Four 20 m × 20 m subplots were demarcated in each land use type. Soil organic carbon pools were measured using the granulometric fractionation methods on Elemental Analyzer Vario Macro cube (Elementar, Germany). AfDE croplands had greater soil organic carbon stock (20.49- 50.91 Mg $ha^{-1}$) than the non-AfDEs (7.82-27.33 Mg $ha^{-1}$) at 0-10 cm depth. Out of these stocks, the cumulative $CO_2$ fluxes ranged from 1.04 ± 0.1 to 1.32 ± 0.18 Mg $CO_2$ $ha^{-1}$ from AfDE croplands and 0.92 ± 0.05 to 1.38 ± 0.01 Mg $CO_2$ $ha^{-1}$ for non-AfDE croplands at the 0-10 cm depth. There were 0.81 ± 0.1 to 1.18 ± 0.10 Mg $CO_2$ $ha^{-1}$ fluxes from non-AfDE fallow, and 1.5 ± 0.06 Mg $CO_2$ $ha^{-1}$ for converted fallow land. Overall, AfDE cropland emitted less $CO_2$ (< 2 %) of the stock and acted as a net sink for $CH_4$ due possibly to its greater persistent MAOC pool (18.06-31.13 mg C $kg^{-1}$ soil) than the non-AfDE croplands (5.41-19.25 mg C $kg^{-1}$ soil) and non-AfDE fallow (5.11-18.36 mg C $kg^{-1}$ soil). This was also confirmed by the low vulnerability of SOC to microbial decomposition as the 98-day soil incubation period showed lower $CO_2$ fluxes for AfDE cropland (118.28 mg $CO_2$ $kg^{-1}$ soil) than non-AfDE fallow (121.54 mg $CO_2$ $kg^{-1}$ soil) and non-AfDE cropland (128.70 mg $CO_2$ $kg^{-1}$ soil). Results showed that more of the soil organic carbon was stabilized in the mineral-associated organic pool (ca. 52.97-87.56 %) with AfDE cropland significantly ($P<0.003$) stabilizing more carbon (ca. 64.78-87.56%) than the non-AfDE cropland. A multivariate analysis showed soil factors *viz*. soil moisture, total N stock, mineral-associated N, sand, and clay, and climatic factors of rainfall, ambient temperature accounting for ca. 62.1 % of the variability in GHG emissions across locations. However, a stepwise regression analysis in linear mixed model showed soil moisture as the principal factor driving (32 %) the emission of greenhouse gases across land use types with less confounding effect from site, N fertilizer application, and management practices. The study provides a first-hand information on drivers of soil carbon sequestration and fluxes from AfDEs to inform climate-resilient decisions.

# SynCom-Driven Iron Modulation Synergistically Controls Maize Root Rot

**Minyu Jing[1*], Haiyan Chu[1, 2]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, No.298 Chuangyou, Road Nanjing, 211135, China*

[2] *University of Chinese Academy of Sciences, Beijing, 100049, China*

*E-mail: myjing@issas.ac.cn

## ABSTRACT

Maize root rot in the northeast black soil region of China is a soil-borne disease caused by *Fusarium graminearum*. Infected plants exhibit characteristic root decay and wilting, causing significant yield reduction. Traditional chemical control faces dual challenges of enhanced pathogen resistance and soil microecological damage. This necessitates eco-friendly biocontrol through rhizosphere microecological regulation. Although rhizosphere microorganisms offer a promising green control strategy, their application is hindered by the scarcity of highly efficient stable strains and insufficient understanding of the synergistic "microbiota-host-pathogen" disease resistance network. Recent studies indicate that the iron metabolism network as a central regulatory hub for tripartite interactions (Verbon et al., 2017). Beyond nutrition, iron regulates disease balance. Iron thus bridges microbial ecology and plant immunity, though its cross-kingdom signaling mechanisms remain undefined.

Here, we employed amplicon sequencing to identify the core antagonistic strain *Lysinibacillus* sp. R104 and the siderophore-producing strain *Pseudomonas chlororaphis* R36, constructing the synthetic microbial community (SynCom) R36+R104. We established both in vitro (SynCom-*F. graminearum*) and in vivo (SynCom-*F. graminearum*-maize) co-culture systems, integrating interaction transcriptomics with root metabolomics, and validating core gene functions through molecular genetic approaches. The SynCom demonstrated dual synergistic disease-suppression mechanisms: (1) Direct antagonism: Enhanced colonization via biofilm formation coupled with $Fe^{3+}$ reduction to $Fe^{2+}$, catalyzing fenton reactions that disrupt *F. graminearum* hyphal membrane integrity; (2) Plant immune synergy: Activation of maize iron deficiency response pathways significantly upregulated iron metabolism genes (*Zmspo3*, *ZmVIT1*, *ZmNramp2*, *Zmprx12*) to optimize rhizosphere iron allocation and stimulate lignin deposition. Root-secreted coumarin glycoside esculin maintains host iron homeostasis through chelation while damaging pathogen membrane structures to enhance resistance. Field applications achieved 65% disease control efficacy and 8.37% maize yield increase. This work elucidates the iron competition-mediated tripartite interaction network, providing a theoretical foundation for developing green microbial agents and technological support for sustainable agriculture.

# Mechanisms Underlying the Resistance of Rahnella sp. RS86 to Maize Root Rot

**Jiaojiao Liang[1,2*], Haiyan Chu[1,2]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, No.298 Chuangxou Road, Nanjing 211135, China*

[2]*University of Chinese Academy of Sciences, Beijing 100049, China*

*E-mail: liangjiaojiao@issas.ac.cn

**ABSTRACT**

Maize root rot is a major soil-borne disease threatening global maize production and is primarily caused by multiple fungal pathogens, among which *Fusarium graminearum* (Fg) is considered one of the predominant causal agents during the seedling stage. This disease not only results in poor early plant development and yield losses ranging from 10–30%, and even exceeding 50% under severe conditions, but also leads to the accumulation of mycotoxins such as deoxynivalenol (DON), posing serious risks to livestock health and food safety. Owing to the long-term reliance on chemical fungicides, which has resulted in environmental contamination and increased pathogen resistance, the development of efficient and environmentally friendly biological control agents has become an urgent requirement for sustainable agriculture. In this study, a rhizosphere bacterium with strong biocontrol potential, *Rahnella* sp. RS86, was isolated from maize fields with a high incidence of root rot in Tongyu County, Jilin Province, China.

Experimental results demonstrated that RS86 exhibited significant antagonistic activity against Fg in vitro, with an inhibition rate of 21.92%. In terms of plant growth–promoting traits, RS86 showed strong nutrient transformation capabilities, producing indole-3-acetic acid (IAA) at a high level of 39.61 mg/L, and possessing efficient organic and inorganic phosphate solubilization as well as nitrogen fixation abilities, thereby substantially improving plant nutrient acquisition. Greenhouse experiments revealed that inoculation with RS86 significantly reduced the root disease index of maize by 23.2% at 7 days post-inoculation. Moreover, at 14 days post-inoculation, the shoot fresh weight of maize increased by 46.6% compared with the control, indicating a pronounced early growth-promoting effect. Field trials further confirmed its practical application value, as RS86 treatment significantly increased maize yield by 5.8% under Fg infection pressure, effectively mitigating economic losses caused by the disease. Interaction transcriptome analysis revealed that RS86 modulates root immune responses in maize, alleviates Fg-induced reactive oxygen species (ROS) bursts, enhances antioxidant capacity, activates key defense-related pathways such as MAPK and jasmonic acid (JA) signaling, and promotes cell wall reinforcement and growth-related metabolism, thereby enabling maize plants to maintain growth while enhancing disease resistance.

In conclusion, Rahnella sp. RS86 is a promising biocontrol bacterium that integrates direct antagonistic activity, induced resistance, and systemic plant growth–promoting functions. It not only suppresses pathogen invasion through physical and chemical barriers but also coordinates disease resistance and growth by modulating phytohormone signaling balance. This study provides both a theoretical basis and valuable microbial resources for the development of novel biological control agents against maize root rot and holds important implications for black soil conservation and green agricultural production.

# Soil fertility and mean annual precipitation regulate the influences of tillage regimes on black soil organic C stocks in Northeast China

**Jianyu Tao[1*], Xiaoyuan Liu[2], Zhongbin Zhang[1], and Xinhua Peng[1*]**

[1] *State Key Laboratory ofEfficient Utilization of Arable Land in China, Institute ofAgricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing 100081, China*
[2] *School of Geography and Planning, Chizhou University, Chizhou, Anhui Province, 247000, China*
Corresponding e-mail: taojianyu@caas.cn

## ABSTRACT

Black soils (Mollisols) are widely recognized for their high soil organic C (SOC) content and agricultural productivity. Northeast China contains approximately 180000 $km^2$ of arable black soil (Sui et al., 2023) and has become a cornerstone for securing national food safety. However, long-term intensive agriculture and serious soil erosion have substantially degraded the quality and productivity of the black soils in Northeast China. Nearly 64% ofcropland in Northeast China experienced a decline in SOC content between 1985 and 2020, with a mean decrease of 3.07 g C $kg^{-1}$ and a C storage reduction of 0.32 Pg (Wang et al., 2023). Therefore, restoring SOC stocks has become an urgent priority for the conservation ofblack soils in Northeast China.
Zero tillage with straw mulching (ZT) is a typical conservation tillage practice that has been widely adopted to reduce soil erosion (Akplo et al., 2022), improve soil structure (Marahatta et al., 2025), and enhance SOC accumulation (Pramanick et al., 2024). However, a 20-year field experiment conducted by Zhang et al. (2023) indicated that ploughing with straw return enhanced SOC sequestration more effectively than ZT in warm and humid regions. In contrast, the meta-analysis by Ul Islam et al. (2023) demonstrated that ZT generally outperformed deep tillage with straw return (DP) in enhancing topsoil SOC stocks under warm and dry climatic conditions. Hermle et al. (2008) reported no significant differences in SOC stocks among deep ploughing, shallow tillage, and zero tillage under moist, cold-temperate climatic conditions. These findings suggest that the interactive effects of climatic conditions and tillage regimes on SOC stocks remain insufficiently understood. Given the vast heterogeneity of climatic and edaphic conditions across the black soil region ofNortheast China, a systematic evaluation of the effects of different tillage regimes on regulating SOC dynamics remains lacking. Here, a six-site networked field experiment was conducted to (1) compare the effects of different tillage regimes on SOC stocks, (2) identify the key environmental drivers of SOC stocks in the black soil region of Northeast China, and (3) examine the influences ofthese key drivers on SOC stocks across tillage regimes.
The networked field experiments were conducted at six sites located in the western semi-arid zone (Qiqihar, QQ; Baicheng, BC; and Chifeng, CF) and the eastern semi-humid zone (Hailun, HL; Gongzhuling, GZL; and Tieling, TL) of the black soil region of Northeast China (Fig. 1). Field experiments were performed following a randomized block design with three replications. Three tillage regimes were consistently implemented at each site: namely, zero tillage with straw mulching (ZT), deep plowing with straw incorporation (DP), and rotary tillage with straw removal (RT). RT is the traditional agricultural practice that has been adopted by the local farmers for decades. Specifically, a rotary tiller was applied twice to a depth of 10-15 cm after straw removal. In the DP treatment, maize straw was chopped twice using a straw rotary cultivator and incorporated into the subsoil by moldboard ploughing to a depth of 30-35 cm. Subsequently, the topsoil was tilled twice using a rotary tiller before sowing the following year. Similarly, soils in the ZT treatment received no tillage throughout the year. Maize straw was chopped following the same procedure as in the DP treatment and directly mulched onto the soil surface. The cropping system at each site was a continuous maize monoculture, with maize sown in May and harvested in October. Soil samples were randomly collected at 0-20 cm and 20-40 cm depths from each experimental plot using a soil auger before maize harvest, which were air-dried and sieved prior to SOC determination. Soil bulk density (BD) was measured by collecting undisturbed soil samples using cutting rings (100 $cm^3$) from the midpoints of the 0-20 cm and 20-40 cm soil layers. To eliminate the effects of tillage-induced soil disturbance, the equivalent soil mass (ESM) method was applied to calculate SOC stocks.

**Fig. 1** Locations of experimental sites and mean annual precipitation (mm) and temperature (°C) across Northeast China. QQ, BC, CF, HL, GZL, and TL stand for Qiqihar, Baicheng, Chifeng, Hailun, Gongzhuling, and Tieling.

Comparing with the traditional tillage regime (RT) adopted by the local farmers, zero tillage with straw mulching (ZT) increased SOC stocks in the 0-40 cm soil profile by 1.5%, 3.1%, 7.1%, and 14.7% in HL, CF, QQ, and GZL, respectively (Fig. 2). Further ANOVA results confirmed that only the SOC accrual in GZL was statistically significant. Deep plowing with straw return (DP) increased the subsoil SOC stock (20-40 cm) by 11.1% compared to RT, resulting in an overall SOC stock increase by 2.7% within the 0-40 cm soil profile (Fig. 2f). In contrast, DP significantly reduced the subsoil SOC stock in CF, leading to an overall SOC stock decrease of 12.8% in the 0-40 cm profile compared with RT (Fig. 2c). Moreover, changes in subsoil SOC stocks induced by different tillage regimes predominantly determined SOC stock dynamics throughout the 0-40 cm soil profile.

**Fig. 2** Soil organic C stocks estimated using the equivalent soil mass (ESM) method across six experimental sites. RT stands for rotary tillage with straw removal, which is the traditional agricultural practice adopted by local farmers. DP and ZT represent deep plowing with straw return and zero tillage with straw mulching, respectively.

Mean annual change rates of topsoil SOC stocks were estimated relative to initial conditions across all six experimental sites (Fig. 3). Results indicated that the influence of regional climatic conditions on SOC stock change rates exceeded that of tillage regimes. SOC stock accruals generally occurred in the semi-arid zone (Fig. 3a-c), whereas reductions in SOC stocks prevailed in the semi-humid zone of the black soil region in Northeast China (Fig. 3d-f). The ZT treatment exhibited a significantly greater resistance to SOC loss compared to RT in GZL, despite the negative mean SOC stock change rate (Fig. 3e). In addition, the rates of SOC stock reduction in HL were substantially higher than those in GZL and TL. This phenomenon is likely related to the high background SOC content in HL (approx. 3%). Linear regression analyses indicated that SOC change rates showed significant negative relationships with mean annual precipitation (MAP) and initial SOC content (Fig. 4a,c), whereas a significant positive linear relationship was observed with mean annual temperature (MAT; Fig. 4b). Furthermore, the estimated SOC change rates were compared among the three tillage regimes. The results showed that ZT was more effective in promoting SOC accumulation in the western semi-arid zone of the black soil region in Northeast China compared to DP and RT (Fig. 4d,e). Overall, by synthesizing results from six long-term field experiments, this study demonstrated that zero tillage has the potential to mitigate SOC loss in the black soil region in Northeast China. However, optimizing tillage regimes alone is insufficient to halt SOC degradation of the black soils in Northeast China, especially those in the semi-humid zone. Additional measures, such as exogenous C inputs, are required to fully restore SOC stocks in this region.

**Fig. 3** Soil organic C stock change rates across the experimental sites. SOC stocks (Mg $ha^{-1}$ $yr^{-1}$) were estimated by the equivalent soil mass method. QQ, BC, CF, HL, GZL, and TL stand for Qiqihar, Baicheng, Chifeng, Hailun, Gongzhuling, and Tieling. RT stands for rotary tillage with straw removal, which is the traditional agricultural practice adopted by local farmers. DP and ZT represent deep plowing with straw return and zero tillage with straw mulching, respectively.

**Fig. 4** Relationships between SOC stock change rates and mean annual precipitation and temperature and initial SOC content. Plot d and e were estimated by the multi-variable linear regression models, where the SOC change rates (SOCs.CR; % $yr^{-1}$) of ZT were subtracted by those of DP and RT respectively.

# Alleviating Soil Compaction under No-Till Management: Impacts of Cropping System

**Wenjuan Zheng**[1*]

[1] *College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing, 211800, PR China*

* zhengwj@njau.edu.cn

**ABSTRACT**

Background: Soil mechanical compaction presents a significant challenge in sustainable agriculture. No-till systems, while beneficial for soil conservation, can exacerbate this issue. The role of different crop species and rotations in mitigating compaction within these systems requires further elucidation.

Methods: A three-year field study (2022-2024) evaluated the effectiveness of four cropping systems under no-till conditions in remediating soil compaction: continuous soybean, continuous maize, soybean-maize rotation, and a diversified maize-forage legume rotation. Soil physical status was assessed via continuous monitoring of soil penetration resistance. Concurrently, crop yield was measured to assess agronomic performance.

Results: The maize-forage legume rotation demonstrated the most significant reduction in soil penetration resistance, indicating the best remediation of soil compaction. Continuous soybean followed as the second most effective system. In contrast, the soybean-maize rotation and continuous maize showed the least improvement in soil physical conditions. Crop yield trends generally aligned with the soil health benefits.

Conclusion: The choice of cropping system profoundly influences soil compaction dynamics under no-till management. Diversified rotations incorporating deep-rooted legumes, such as the maize-forage legume system, offer a superior strategy for mitigating mechanical compaction. The deep root systems of leguminous plants are hypothesized to be a key factor in enhancing soil porosity and structure. These findings highlight the critical importance of strategic crop sequencing, beyond simple no-till adoption, for achieving long-term soil health and productivity.

**ABSTRACT**

To adapt agriculture to long-term soil organic carbon sequestration, it is crucial to understand the spatial variability and drivers of its stock stability under farming conditions. Thermal techniques are effective tools to measure the intrinsic soil organic matter (SOM) stability, based on the analysis of the energy required to break chemical bonds in organic molecules and organic-mineral associations. This study quantified the spatial variability of thermal stability of SOM in Chernozem topsoil (0–10 cm) across contrasting management systems in a commercial agricultural setting. The study was conducted in the Russian forest-steppe (Samara region; 54.1°N, 50.3°E) capturing fields with conventional tillage (sunflower-wheat-bare fallow) and no-tillage for 5 and 8 years (soybean-sunflower-wheat). To collect 90 soil samples throughout the study area (291 ha), we used a model-based sampling design with a range of terrain covariates (i.e., conditioned Latin Hypercube sampling). The thermogravimetric analysis of the soil was carried out on the TGA/DSC 3+ (Switzerland) with samples heating from 30 to 650 C with rate of 10 C $min^{-1}$. SOM was divided into labile (mass losses at 200-400°C), stable (400-460°C), and persistent (460-600°C) pools. SOM stability was assessed using two integral indicators: the temperature at which half of the SOM is lost ($T_{50}$) and the ratio of the sum of the stable and persistent pools to the labile pool ($K_{stab}$). Across the study farmland area, the SOM content varied from 65 to 130 mg $g^{-1}$, half of which was the thermally labile pool (50-59%). The remaining half of the SOM was almost equally formed stable (17-22%) and persistent (20-33%) pools. No significant differences in the SOM stability were found between the management systems used. Concurrently, the lower the SOM content, the higher $T_{50}$ and $K_{stab}$ values (Pearson's correlation coefficient: $r$ = –0.74-0.72 at $P$-value <0.001). SOM thermal stability ($T_{50}$ and $K_{stab}$) increased with carbonate content ($r$ = 0.69–0.72, $P$ <0.001). At the same time, an inverse trend was found between the SOM stability ($T_{50}$ and $K_{stab}$) and soil microbial biomass content ($r$ = –0.30-0.33, $P$ <0.01). These findings emphasize that an increase in SOM thermal stability in Chernozems is associated with depleted SOM stocks and deteriorating nutrient availability. Therefore, the strategy for restoring soil fertility in farmlands should aim to boost the thermally labile pool, as it actively contributes to biochemical nutrient cycling.

# Short-term effects of overwintering on porosity of the compacted topsoil due to harvest traffic in Northeast China

**Shijie Qin[1*], Lingling Liu[1], Tusheng Ren[2], and Weida Gao[2]**

*[1] Hunan Institute of Agricultural Soil and Eco-Environment Institute, Changsha, 410125, China*

## ABSTRACT

The multi-hydrothermal processes in agricultural soils during overwintering modify compacted soil structure in cold winter regions. The depth-dependent changes in the topsoil pore-network within field-based compacted zones caused by harvest traffic, before and after winter, remain poorly understood. In this study, we aimed to investigate the short-term effects of overwintering on topsoil porosity of a clay loam soil in the harvest traffic zone in Northeast China using X-ray CT. Undisturbed soil cores were collected in the 0-10 cm layer of the non-traffic and traffic zones before and after winter. After harvest, both total porosity ($\varepsilon_{total}$) and porosity of > 0.04 mm ($\varepsilon_{X\text{-}ray}$) significantly decreased by 0.04 and 0.07 $cm^3$ $cm^{-3}$ due to the machinery traffic, respectively. Following winter, the $\varepsilon_{total}$ of the traffic zone significantly increased by 0.08 $cm^3$ $cm^{-3}$ and was greater than that of non-traffic zone porosity before winter. The loosening effects of overwintering on compacted soil in the traffic zone diminished with increasing soil depth, and marked alterations limited to the uppermost 3.5 cm. The increase in $\varepsilon_{X\text{-}ray}$ was primarily resulted from the changes in 0.04-1.0 mm pores. Therefore, it is indicated that overwintering can alleviate soil compaction of traffic zone only in the uppermost layer.

*E-mail Address: Weida_gao@cau.edu.cn

**ABSTRACT**

The increasing frequency of extreme rainfall events intensifies waterlogging-induced aeration stress on crops, highlighting the urgency for adaptive agricultural practices. This study evaluates the potential of long-term no-tillage (NT) farming to mitigate waterlogging risks on a silty clay loam in Northeast China by comparing with traditional moldboard plough (MP) farming using an 11-year field experiment. Rainfall simulation (40 mm $h^{-1}$) and dye-tracing were employed to study the dynamics water infiltration, and X-ray computed tomography (CT) was applied to examine soil pore characteristics (0–60 cm depth) and their responses (0–5 cm layer) to raindrop splashing. Results demonstrated that NT significantly enhanced water infiltration capacity, with a 161% higher maximum infiltration depth (*MID*), an 65% increase in total stained area (*TSA*), and 95% less surface ponding compared to MP. Although MP exhibited higher total porosity ($\varepsilon_{total}$), macroporosity (> 0.04 mm pores, $\varepsilon_{X\text{-}ray}$), and increased pore connectivity in the 0–20 cm layer, it had fewer biopores and greater vertical stratification of macroporosity compared to NT across the 0–60 cm profile. During rainfall events, the MP plot experienced a 28% reduction in porosity of pores sized 0.2–1.0 mm and a 19% increase in porosity of pores < 0.2 mm in the surface layer, likely due to raindrop splashing, while NT maintained pore integrity through straw mulching. We conclude that long-term NT is effective in enhance soil resilience to waterlogging by developing continuous vertical pore networks and maintaining surface mulch, thereby improving climate adaptability in the black soil region of Northeast China.

# Drivers of soil quality and maize yield under long-term tillage and straw incorporation in Mollisols

**Chunzhu Liu[1*], Wenxiu Zou[1]**

[1] *State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin, China*

*E-mail: liuchunzhu@iga.ac.cn

**ABSTRACT**

Proper tillage combined with straw management is crucial for maintaining agroecosystem sustainability and crop yield, especially under intensified agricultural activities. However, the optimal depth for tillage in combination with straw incorporation remains unclear. To address this, we established a field experiment in 2011 in Mollisols with five treatments: conventional tillage (CT, tillage depth 20 cm), no-tillage combined with straw return (SNT), conventional tillage combined with straw return (SCT), inversion tillage combined with straw return (SIT, tillage depth 35 cm), and subsoil tillage combined with straw return (SST, straw depth 20–35 cm). We assessed the effects of these treatments on soil quality by evaluating the Soil Physical Property Index (SPI), Soil Chemical Property Index (SCI), and Soil Microbial Property Index (SMI) in relation to the Soil Quality Index (SQI) and crop yield. Our findings shown that tillage combined with straw return significantly improved soil properties. Compared to the CT, SNT, and SST treatments, the SCT and SIT treatments increased SPI and SQI in the 0–20 cm soil layer by 43.9–845.4%. While the SIT and SST treatments enhanced SPI, SCI, and SMI in the 20–35 cm soil layer by 69.2–307.7% more than the CT, SNT, and SCT treatments. Among all treatments, SIT treatment resulted in the highest SPI, SCI, and SMI in the 0–35 cm soil layer. Additionally, SQI and maize yield under the SIT treatment were 11.7–140.5% and 15.6–78.0% higher, respectively, compared to other treatments. Linear regression analysis revealed that SPI in all layers had a significant impact on maize yield, while SCI and SMI were significantly correlated with yield only in the 20–35 cm layer ($P < 0.05$). SPI's contribution to maize yield was 18.6–156.8% higher than that of SCI and SMI. Partial least-squares path modeling identified SPI as a direct influence on SMI and SCI, making it the largest driver indirectly improving SQI and maize yield in Mollisols. Therefore, SIT treatment is a highly effective soil management practice for improving soil quality and crop yields in the Mollisols region. Our study provides guidance for enhancing soil environmental quality and designing sustainable agricultural policies in the Mollisols region and other arable soils.

# Divergent Pathways of Soil Pore Structural Recovery under No-Till across a Semi-Arid to Semi-Humid Climatic Gradient

**Wei Han[1*], Jing Tan, Yanli Yi[1]**

*[1] College of Land and Environment, Shenyang Agricultural University, Shenyang, China*

**ABSTRACT**

Conservation tillage, specifically no-till (NT), is globally promoted for soil health recovery. However, its impact on soil physical architecture and associated functions is highly site-specific, often modulated by climatic constraints on biological and physical processes. This study investigated the divergent mechanisms driving soil pore structural evolution after five years of NT compared to conventional tillage (CT) across two contrasting climatic zones in Northeast China: a semi-arid region (Beipiao) and a semi-humid region (Shenyang). We employed a multiscale approach combining X-ray computed tomography (CT) scanning for 3D pore morphology, soil water retention curves for pore size distribution, and relative gas diffusivity ($D_p/D_0$) measurements at varying water contents to quantify functional pore connectivity and tortuosity. Results revealed distinct structural responses driven by climatic context. In the semi-humid region, moisture availability facilitated vigorous biological activity under NT, resulting in the development of highly connected, large biopore networks visualized by CT. This translated into significantly higher gas diffusion efficiency at a given air-filled porosity, indicating reduced pore tortuosity compared to CT. Conversely, in the semi-arid region, moisture limitations constrained macropore formation. NT improvement was characterized by enhanced physical stabilization and an increase in meso- and micropores critical for water retention, with gas transport relying on a less tortuous, yet finer, pore network rather than large biological channels. Our findings demonstrate that climate fundamentally dictates the mechanistic pathway of structural recovery under NT—shifting from biologically-driven macropore construction in wetter climates to physical stabilization and micropore reorganization in drier regions. This underscores the need for climate-adaptive criteria when evaluating soil structural optimization in conservation agriculture.

# Coupling effects of freeze-thaw action and thawed soil depth on snowmelt erosion under near-surface hydrologic conditions in the Mollisol region of Northeast China

**Bin WANG[1*], Wengang WANG[1], Fenli ZHENG[2], and Farhan Iftikhar[1]**

**ABSTRACT**

Near-surface hydrologic conditions (NHC), including drainage, saturation, and seepage, are key drivers for summer rainfall-induced erosion. Among these, saturation and seepage intensify erosion compared to drainage, with their effects remaining relatively consistent under controlled hydraulic gradients. However, it remains unclear whether the erosive characteristics of NHCs, influenced by freeze-thaw action (FTA) and thawed soil depth (TSD) differ under winter-spring snowmelt erosion compared to summer rainfall-induced erosion. The Mollisol region of Northeast China is highly susceptible to both erosion types, posing a significant threat to agricultural productivity. This study investigated the impact of FTA on the erosive characteristics of NHCs during snowmelt erosion and compared it with summer rainfall-induced erosion. The mechanisms underlying these differences and the influence of FTAs on varying TSDs were identified. Three NHC conditions (drainage, saturation, and seepage) were tested alongside five TSDs: 1 cm (FS1), 3 cm (FS3), 5 cm (FS5) and 10 cm (FS10), as well as an unfrozen control (10 cm, UFS10). Experiments were conducted on silty clay loam with an 8.75% slope under three meltwater intensities (2, 3 and 4 L/min). Results showed that FTA enhanced the erosive effects of saturation and seepage compared to summer rainfall-induced erosion, by altering pore-water pressure. This effect was most pronounced under FS5 and FS10, where erosion increased with TSD stabilized. The contribution of NHCs to erosion rate reached 51.71% under FS5 and FS10, representing a 902.13% increase compared to UFS10 (5.16%). In contrast, no significant differences in erosion rate across NHCs were observed in FS1 and FS3 ($P > 0.05$). These results demonstrate that the erosive effects of NHCs on frozen slopes are strongly TSD-dependent and provide novel insights into the mechanisms of snowmelt erosion. Consequently, these findings are critical for considering NHC effects in snowmelt-dominated erosion process in cold and hydrologically variable regions.

## ABSTRACT

Northeast China serves as a core production region for maize and soybeans, yet it has long faced the dual challenges of black soil degradation and the sustainability of grain production capacity. Conservation tillage is increasingly recognized as a key approach to achieving the dual goals of protecting black soil and ensuring food security. However, its yield effects may exhibit considerable spatial heterogeneity under different climatic, soil, and topographic conditions, leading to inconsistent outcomes for the same practice. As a solution, we employed meta-analysis, four machine learning models, and the Shapley Additive exPlanations (SHAP) method to quantify the impacts of different conservation tillage practices on crop yield in Northeast China, identify their driving factors, and predict the spatial suitability of these practices. The results showed that, compared with conventional tillage, conservation tillage significantly increased crop yield by approximately 9.96% overall. Specifically, no-till/reduced tillage (NT/RT) increased yield by 11.86%, deep plowing (DP) by 10.58%, and straw return (SR) by 10.43%, which were higher than crop rotation (CR). SHAP analysis revealed that temperature, precipitation, and soil organic matter (SOM) were the dominant factors influencing yield, although their relative contributions varied across practices. Model comparisons revealed that Extreme Gradient Boosting (XGBoost) and Categorical Boosting (CatBoost) significantly outperformed Random Forest (RF) and the Light Gradient Boosting Machine (LightGBM). Spatial suitability analysis further delineated the suitable ranges for each practice. For instance, CR showed pronounced yield-increasing effects in the eastern and southern Songnen Plain, the Liaohe Plain, and areas with severe salinization in northwestern Jilin Province. SR was suitable for plains with favorable hydrothermal conditions but had limited effects in low-temperature or arid regions. NT/RT performed well in plains and western sandy areas but exhibited reduced effectiveness in regions with insufficient accumulated temperature. DP significantly increased yield in the core areas of the Songnen Plain but was unsuitable for regions characterized by low temperature, aridity, or steep slopes. Our findings could serve as important References for targeted promotion and implementation of conservation tillage in the region, which is of great significance for ensuring regional food security and the sustainable utilization of black soil resources.

**ABSTRACT**

Mongolia is a vast, land-dominated country in East Asia, where over 85 % of the territory is rangeland and only 0.7 % is arable land. The country is characterized by a harsh continental climate with increasing temperatures, low precipitation, and high spatial variability. Over the past six decades, air temperature has increased by approximately 2.46 °C, leading to intensified land degradation in pasturelands and enhanced soil erosion in cultivated areas.

Agricultural sustainability in Mongolia is strongly dependent on effective soil management; however, systematic soil monitoring and digital soil information systems remain limited. To address this gap, the AFACI-supported project aims to develop a National Soil Information System (NSIS) through the integration of legacy soil data, laboratory analyses, field surveys, and geospatial technologies.

The project focuses on building a harmonized national soil profile database, developing digital soil property maps, and supporting WRB soil classification correlation. Open-source GIS and remote sensing tools were applied for data processing, harmonization, and spatial modelling.

Results show that 9,891 soil observations, 1,550 soil profiles, and more than 6,000 analytical datasets were compiled and harmonized. Ten national soil property maps, including SOC, pH, salinity, nutrients, and texture components, were produced. The developed NSIS integrates soil profile, analytical, spatial, and metadata databases, enabling data storage, visualization, mapping, and decision support. This system provides a scientific foundation for sustainable land management, climate change adaptation, agricultural planning, and participation in the Soil Atlas of Asia initiative.

# SOIL ORGANIC CARBON CHANGES UNDER LONG-TERM CULTIVATION IN MONGOLIAN KASTANOZEMS

**Enkhtuya Bazarradnaa[1], Oyuntsogt Ganbaatar[2], Munkhtsetseg Togtokh[3]**

*[1,3] School of Agroecology and Business, Mongolian University of Life Sciences, Mongolia*

✉ Email: bazarradnaaenkhtuya@gmail.com

**ABSTRACT**

Soil organic carbon (SOC) is a key indicator of soil fertility and ecosystem functioning. Long-term cultivation can significantly alter SOC quantity and its distribution among functional fractions, particularly in fragile semi-arid ecosystems. This study evaluated the effects of long-term land use on SOC stocks and carbon fraction distribution in cultivated Kastanozems of Mongolia. The study was conducted in Jargalant soum of Tuv province, where a field cultivated for more than 50 years was compared with adjacent virgin land as a control. Soil samples were collected from the 0–5 cm and 5–10 cm layers. Soil agrochemical properties were analyzed, and SOC fractions were separated into particulate organic matter (POM), coarse fraction (>20 µm), and fine fraction (<20 µm) using density fractionation methods. SOC stocks were estimated using bulk density and carbon concentration data. The results showed a clear decline in soil fertility indicators under long-term cultivation. Soil organic matter content decreased to 1.71% in cultivated soil compared to 3.98% in virgin soil. SOC stock in the 0–5 cm layer was 442.8 g $m^{-2}$ in cultivated soil, while virgin soil contained 782.8 g $m^{-2}$, representing a reduction of 43.5%. Fractionation analysis indicated a decrease in the fine mineral-associated fraction (<20 µm) and particulate organic matter, while the proportion of the coarse fraction (>20 µm) increased under cultivation. These results indicate less stable carbon storage and faster decomposition of soil organic matter. The findings demonstrate that long-term cultivation in Mongolian chestnut soils significantly reduces SOC stocks and alters carbon fraction distribution, leading to soil fertility decline. Sustainable soil management practices, including nutrient replenishment and conservation-oriented tillage systems, are required to maintain soil health under ongoing agricultural use.

**ABSTRACT**

Black soils are vital for global food security and environmental sustainability due to their exceptional fertility and high organic carbon content. In Brazil, they occur in particular environments and occupy small areas with notable variation of climate, relief and parent material. Among them, a group of Black Soils originated from anthropic influence which modified significantly the soil properties. The most well-know is the Amazonian Dark Earths (ADE), and secondary the *sambaquis* or shellmounds. The *sambaquis* are situated along the Brazilian coast, and were constructed by fisher-hunter-gatherer groups through the long-term accumulation of shells, fish bones and sediments, combined in a complex stratigraphy, with material that includes burials, lithic and bone artifacts, charcoal, and food waste. Both types are included in the definition of Black Soils (FAO, 2022) and they have an important function of cultural heritage. Studies of these soils elucidate not only archaeological issues, but also soil management regarding practices that resulted in their high fertility, markedly high organic carbon (Corg), phosphorus (P), calcium (Ca) and other nutrients. An example is the increasing agricultural usage of biochar; practice originated from the studies of ADE. For this study, two locations of *sambaquis* in the coast of Brazil were selected: i) São José de Ribamar, Maranhão State, northeastern region; and ii) Cabo Frio, Rio de Janeiro State, southeastern region. Morphological, chemical and physical attributes of the soils in the *sambaquis* were evaluated and the results will be presented. Other analysis was: sequential phosphorus fractionation, quantification of shell contents, and magnetic susceptibility (MS) and spectroradiometry in the *sambaqui* from Rio de Janeiro, where a correlation was observed between MS, P bioavailability, Ca and Corg content in the soil. These characteristics are essential for understanding the dynamics of specific pedogenic processes in *sambaqui* soils. Overall, it is recommended urgent public policies and environmental education actions to preserve these archaeological sites, since their study may provide with insights of practices to sustainable management and restoration of Black Soils in other environments.

# Degradation severity shifts environmental controls and vegetation effects on soil respiration in restored Mollisols

**Jia Yang[1,*], Jinyang Wang[1], Shunzhong Wang[2], Huiyan Gu[1]**

## ABSTRACT

Soil respiration (Rs) is a critical component of the terrestrial carbon cycle, yet how degradation severity and vegetation restoration jointly regulate Rs dynamics in degraded ecosystems remains poorly understood. We conducted a field experiment in Northeast China's degraded agricultural soils, establishing a factorial design with three degradation levels (lightly degraded, LD; moderately degraded, MD; severely degraded, SD) and five plant treatments (*Populus simonii* × *P. nigra*, P. xh; *Larix gmelinii*, Lg; *Amorpha fruticosa* L., Af; *Bromus inermis* Leyss., Bi; and bare soil control, CK). Rs was measured biweekly during the growing seasons alongside soil physicochemical properties, microbial biomass, enzyme activities, and plant growth metrics. Results showed that daily mean Rs in CK declined significantly with increasing degradation severity (LD: 3.50, MD: 0.80, SD: 0.51 μmol $CO_2$ $m^{-2}$ $s^{-1}$)), driven by reductions in soil organic carbon (SOC) and total nitrogen. Vegetation restoration significantly enhanced Rs across all degradation levels, with effects most pronounced in SD where the ranking was Bi (107% increase) > Af (85%) > P. xh (76%) > Lg (59%) relative to CK. Structural equation modeling revealed that degradation primarily reduced Rs through direct SOC depletion and indirect pathways via decreased nutrient availability and enzyme activities. Importantly, the dominant environmental driver of Rs shifted from soil temperature in LD (β = 0.373) to soil moisture in SD (β = 0.412), reflecting degradation-induced alterations in enzyme activity and moisture constraints on heterotrophic activity. Vegetation effects operated through a cascade mechanism: SOC accumulation enhanced nutrient availability, which increased enzyme activities and subsequently stimulated Rs. Our findings demonstrate that degradation severity fundamentally reshapes Rs regulatory mechanisms, and that selecting plant functional groups matched to degradation conditions can effectively restore soil carbon dynamics in degraded ecosystems.

**ABSTRACT**

Effective conservation and utilization of black soil resources is an inevitable requirement for ensuring global food security and realizing sustainable agricultural development. This study systematically examines the core challenges and the degradation status of black soils in two representative black soil regions of China and Argentina. A comparative analysis is conducted on the key degradation indicators, including black soil layer thickness, soil erosion, soil fertility quality, soil acidification, and soil geochemistry elements accumulation. In addition, the study also compares the application of agricultural chemicals (fertilizers and pesticides) and the level of agricultural mechanization in China and Argentina. Both China and Argentina have adopted conservation tillage practices in the protection and utilization of black soils, actively engaged in agricultural science and technology innovation and have achieved notable progress. China focuses on the integration and application of a variety of conservation tillage techniques, such as less-till, no-till and straw mulching, and has introduced a series of laws and regulations on black soil conservation. While Argentina combines no-tillage with straw mulching and diversified crop rotations to promote the implementation sustainable practices. The two countries have their own characteristics, which provide multiple References examples for global black soil conservation and sustainable utilization. In the future, it is necessary to strengthen international exchanges and cooperation in the conservation and utilization of black soil between the two countries and even the world, strengthen the construction of technology research and development and application system, increase scientific and technological innovation and policy support, realize the complementary advantages of black soil conservation in different countries and regions, and promote and realize the conservation and sustainable utilization of global black soil resources.

# DSS for Sustainable Management and Conservation of Black Soils in Russia

**Ivan I. Vasenev***

*Ecology Department, Russian State Agrarian University-Moscow Timiryazev Agricultural Academy, Moscow, Russia*

*Vasenev@rgau-msha.ru

**ABSTRACT**

The general trend of increasing average monthly temperatures during the warm period, characteristic of global climate change, determines a gradual increase in the sum of active temperatures during the growing season of crops, creating potentially more favorable conditions for the development of highly profitable commercial crop production on Black soils in Russia. At the same time, the frequent frequency and increased intensity of adverse weather conditions lead to a marked increase in the environmental and economic risks of intensive agricultural production in the most regions with Blak soils. The 21st century is characterized by frequently changing market requirements, regular updating of zoned varieties, fertilizers and plant protection products that are differentially effective depending on weather conditions and soils, potential yields and payback of crops. A steady increase in the cost-effective production of high-quality and affordable food products in demand on the market requires the use of the best agricultural technologies in specific soil and agroecological conditions, affordable for ordinary land users.

Mesorelief is usually the dominant unregulated limiting agroecological factor in agrolandscape with Black soils (Fig. 1). Slope mesorelief determines the intensity of erosion processes, the thickness of humus horizons, the depth of carbonates, and reserves of soil productive moisture, on which wheat yield largely depend.

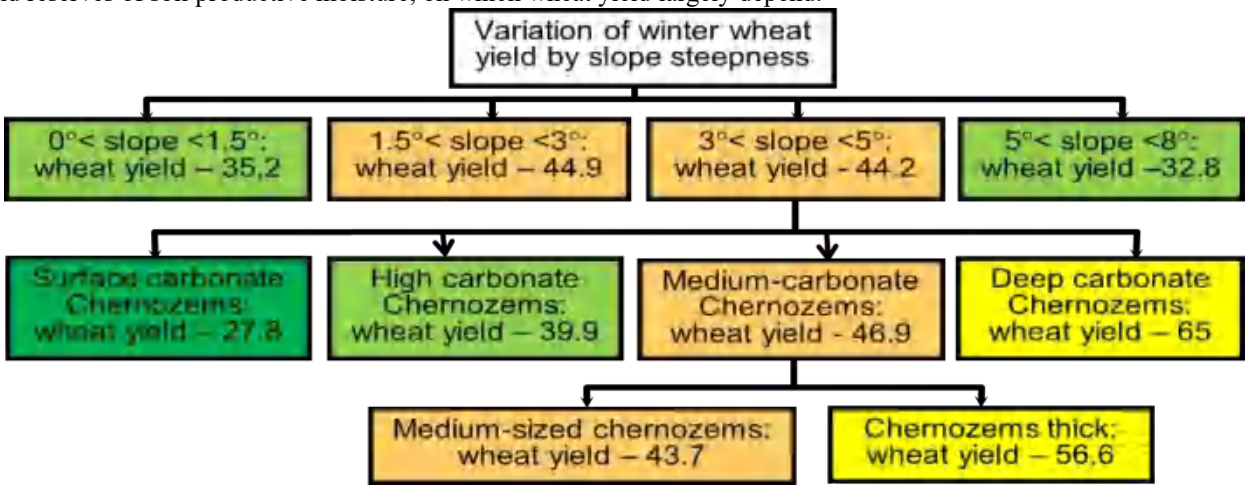

Fig. 1. Regression tree of the agroecological factors influence on the winter wheat yield (dt/ha) within representative field on Black soils in Kursk region.

In the context of global climate change with the shift of the second summer maximum precipitation by 2-3 weeks in the arid areas of Volga region and the Southern Urals, an effective means of minimizing agroecological risks of reducing durum wheat yields became to shift its sowing time by 1.5-4 weeks. The effect of this turned out (plus 10-35% of crop yield) to be higher than the aftereffect of the use of micro fertilizers – both in 2022 with the average annual rainfall of the growing season, and in the dry year 2023, at the same level of technological costs.

Over the past 10 years, the area of Black soils processed in Russia using No-till technology has increased by more than 3 times and exceeded 5 million hectares in 2023 (according to a review of data from the National Partnership for Conservation Farming). According to the results of 10-year monitoring of No-till technology, the effect of organic carbon accumulation in the topsoil has been confirmed with an average reduction in annual $CO_2$ emissions by about 1 ton per hectare.

Intelligent DSS for agroecological optimization of agriculture are necessary for the rapid adaptation of farming systems and flexible elements of the best available agricultural technologies to rapid changes and a wide variety of regional climate, soils and technologies that are specific for different regions with Black soils in Russia.

# Status of Black Soils in Rio de Janeiro: a legacy of mismanagement and recommended practices to reclaim their potential

**ABSTRACT**

Black Soils are recognized for their role in global food security and environmental sustainability. This is on account of their natural fertility and high-activity clays content that are essential in storing organic carbon (Corg) through the formation of highly stable organo-mineral complexes, and the high content of nutrients supporting agricultural production. Black Soils are less extensive in Brazil and their formation is highly dependent on parent rocks and unique environmental conditions to provide their mineral properties and organic matter accumulation. In the Brazilian Southern region of Rio de Janeiro, these soils are scarce and often associated with localized occurrences of diabase and basalt rocks, and calcareous materials. For this study, 12 profiles were selected following the definition of Black Soils (FAO, 2022), located in Rio de Janeiro state under different soil forming factors. Two profiles were initially classified in the 1st category of Black Soils and the other 10 in the 2nd category. Seven profiles were under degraded pasture, and five under no agricultural usage. Morphological, chemical and physical properties were evaluated, with the purpose of analyzing degree of degradation of these soils based on their properties and current land usage. Along history, the state of Rio de Janeiro has experienced profound exploitation of its rural landscapes, where land-use comprised intensive and successive cycles with sugarcane and coffee after removal of the Atlantic Forest. Today, approximately 70% of Rio de Janeiro's agricultural area is covered by pastures, with more than half showing some degree of degradation. The lack of conservation and unsustainable land management, as well as the history of intensive agricultural expansion, have led to widespread soil degradation, causing the few existing Black Soils to be impacted negatively by accelerated erosion and nutrient depletion, greatly diminishing their agricultural potential and threatening the environmental services. The studied profiles currently under no usage had the highest Corg contents, high base saturation and cation exchange capacity, indicating some recovery or preservation of characteristics of Black Soils of category 1. For the other soils, there were major changes in the properties due to accelerated degradation, primarily when the relief is more undulated. A significant portion of the profiles require implementation of sustainable soil management practices to safeguard their environmental services and to reinforce their land capability.

**ABSTRACT**

Straw returning to the soil plays a significant role in enhancing soil fertility. A field experiment was conducted to optimize the combination of maize straw returning and tillage method, in order to support the sustainable and efficient maize production in Fuxin, Liaoning Province, China. With conventional shallow roary tillage after no-straw returning without or with biodegradable mulches (RTNN, RTNB) and no-tillage after straw-covering (NTS) as controls, six treatments were established, including plow tillage 30cm-depth after straw returning without or with biodegradable mulches (PTSN, PTSB), deep rotary tillage 30cm-depth after straw returning without or with biodegradable mulches (RTSN, RTSB) and deep rotary tillage 30cm-depth after organic fertilizer application without or with biodegradable mulches (RTON, RTOB). Maize yield and soil physical properties such as bulk density, field capacity (FC), soil total porosity percentage, aeration porosity, capacity porosity and so on, were explored. The results showed that compared to the controls, PTSN significantly increased FC. PTSB also significantly improved FC compared to NTS and RTNB. There were no significant differences in field capacity among RTON, RTSN and PTSN, with no influence from mulching or not.

Compared to NTS, all other treatments reduced soil bulk density and increased both total porosity and capillary porosity. Furthermore, compared to NTS, all the treatments of straw returning and organic fertilizer application (PTSN, PTSB, RTSN, RTSB, RTON and RTOB) significantly increased maize yield. In conclusion, straw returning or organic fertilizer application can effectively enhance cultivated land fertility and improves soil physical properyies. These findings provide a theoretical foundation and data support for the rational utilization of maize straw and soil carbon sequestration.

**ABSTRACT**

Black soils, although rare globally, are essential for food security and climate change mitigation. In Tcheboa , their intensive exploitation to meet food needs threatens their health. This study analyzes the effect of agricultural intensification on the health of these soils. Five land cover types were identified, and samples were taken at three depths (0–10 cm, 10–20 cm, 20–30 cm) and then analyzed in the laboratory. The results reveal high variability among crops. Sorghum fields and fallow land have the highest surface organic carbon content (2.73% and 2.20%, respectively) and the largest carbon stocks (21.92 t/ha and 19.22 t/ha, respectively). In contrast, soils under onions and onion seeds show lower content (1.98% and 1.54%, respectively). The C/N ratio is higher under sorghum and fallow land. Phosphorus increases with depth under sorghum and onions (up to 3.73 ppm), while it remains low under peanuts and fallow. Soil bioavailability (SBA) reaches 14.56 meq / 100 g at 10–20 cm under fallow, where the highest potassium content is also observed (3.56 meq / 100 g). Nitrogen decreases with depth (0.17% to 0.10%). The overall soil health index, weighted by parameters, ranks onions (0.59) and fallow (0.58) at the top, followed by sorghum (0.54). Onion (0.45) and peanut (0.31) seeds are the most degraded. To restore the health of these soils, organic fertilization, cattle grazing followed by chemical fertilization, and fallow periods can be implemented. These results will enable policymakers and farmers to implement sustainable management of these soils.

**ABSTRACT**

Black soils are known as the breadbasket of global food production and a key element in combating climate change due to their high fertility and organic carbon content. However, they are subject to degradation due to climate change and overexploitation. This study aims to investigate the nutrient and carbon stock potential of black soils in an area within the city of Goma (Eastern DRC) to promote their effective management. To this end, three pits were dug along a toposequence, and a total of twenty-seven (27) samples were collected from different horizons for physicochemical analysis. This equates to nine samples per profile, representing three horizons for each profile. The results showed that the available phosphorus content was very high at the top of the slope (70.89 mg/kg) and low at the bottom (59.42 mg/kg). Furthermore, the surface horizons exhibited higher phosphorus levels compared to the underlying horizons. For nitrogen, the mid-slope profile showed the highest content in the surface horizon compared to the others (0.35%). Exchangeable bases $Ca^{2+}$, $Mg^{2+}$, $K^{+}$, and $Na^{+}$ showed moderately low to medium values in all profile horizons. Soil organic carbon (SOC) was highest in the mid-slope profile at 6.7%, followed by the bottom-slope profile (5.53%). All SOC levels were high, with the lowest value being 3.84%. Carbon stock reached up to 345.4 t/ha in the deeper horizons, indicating the role of these soils in mitigating climate change. The results of this study demonstrated the importance of these soils both for fertility, ensuring food security, and for combating climate change. These results will allow for the sustainable management of these soils, which are highly vulnerable to degradation.

# Evaluating the Effectiveness of Conservation Tillage in the Black Soil Region of Northeast China Based on the Apparent Characteristics of Crop-Residue-Soil

**Jing Wang[1,2,*], Huimin Yan[1,2]**

[1] *Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China*

[2] *University of Chinese Academy of Sciences, Beijing, China*

*E-mail Address of Presenting Author: wangjing0824@igsnrr.ac.cn

**ABSTRACT**

The black soil region of Northeast China is crucial for national food security(Xiao et al., 2024) but suffers severe degradation from intensive use(Wang et al., 2023). While conservation tillage is essential, accurately evaluating its effectiveness remains challenging due to limitations of current monitoring methods: Fixed-site observations offer high-precision data but lack generalizability—for instance, "no-till with straw return" may increase soil organic carbon while reducing maize yield in some areas(Chen et al., 2023) but show negligible effects in others(Jiang et al., 2025); Remote sensing enables rapid large-scale monitoring but is constrained in detecting internal soil properties by factors like moisture and vegetation cover(van Wesemael et al., 2023); Process models support long-term prediction yet are highly dependent on parameterization(Asseng et al., 2013); Soil surveys provide authoritative data but involve high costs and multi-year efforts, as seen in the 2025 national black soil survey.

To address these gaps, this study developed a field-applicable "Look-Fold-Dig-Pinch-Measure" methodology for rapid assessment of crops, straw, and soil. A simplified field manual converts technical indicators into graded scores, enabling farmer-led monitoring. Ground data collected through this system support remote sensing validation and model calibration while revealing underlying mechanisms.

Field surveys across four provinces demonstrate that straw return-especially soybean straw-enhances soil structure and erosion resistance, whereas corn straw return favors crop growth. These findings support region-specific tillage optimization. Future work will integrate apparent indicators with multi-source remote sensing via quantitative models, establishing a "point-to-area" monitoring framework to advance apparent indicators from qualitative observation to quantitative diagnosis, supporting the development of a apparent feature-based health evaluation system for black land conservation.

**ABSTRACT**

The improvement of soil quality through microbial regulation is crucial for soil fertility and crop yield. However, the mechanisms underlying the enhancement of deep soil quality under conservation tillage remain poorly understood. Based on a 6-year field experiment in the Mollisol region of Northeast China, comparing conventional no-tillage without straw (NT) to two conservation treatments: no-till with straw mulching (NTS) and subsoil tillage with straw mulching (STS). Soil bacterial and fungal community were analyzed to 1 m depth, alongside soil properties and a soil quality index (SQI) linked to maize yield. Both NTS and STS significantly enhanced microbial richness and diversity relative to NT, but displayed distinct depth-dependent patterns. NTS mainly increased bacterial diversity in the 0–10 cm layer by adding organic matter, whereas STS had the strongest effects in deeper layers, boosting fungal diversity in the subsoil (20–60 cm). Both practices promoted more complex microbial co-occurrence networks compared with NT, with STS exhibiting the highest network complexity, including more nodes, edges, and keystone taxa—particularly in subsoil. NTS mainly stimulated surface bacterial communities, whereas STS facilitated downward nutrient movement and supported diverse fungi and keystone taxa at depth. These shifts were functionally meaningful: NTS and STS improved SQI by 9–17% compared with NT, and STS yielded the highest gains in SQI and crop yield. The depth-stratified microbial responses, a bacteria-driven nutrient cycling in topsoil vs. a fungus-mediated carbon and nutrient pathway in subsoil, link closely to soil nutrient availability under STS. Our findings highlight that integrating straw mulch with subsoil loosening synergistically leverages bacterial and fungal communities across soil profiles, thereby enhancing soil quality and crop yield. This depth- dependent management offers a promising route to improve agroecosystem sustainability by tapping the potential of subsoil microbial communities.

# Sustainable Management and Restoration of Chernozem (Black Soil) in Vojvodina, the Republic of Serbia

**Maja Manojlović[1]* and Vladimir Ćirić[2]**

[1] *University of Novi Sad, Faculty of Agriculture, Novi Sad, Republic of Serbia*

[2] *University of Novi Sad, Faculty of Agriculture, Novi Sad, Republic of Serbia*

*E-mail maja.manojlovic@polj.uns.ac.rs

**ABSTRACT**

Chernozem or black soil, the most fertile soil type, covers approximately 1,000.000 ha of agricultural soil in Serbian part of the Pannonian Plain, and over 3,500,000 hectares across the entire multi-country plain. Studies in the Southeastern European region have shown alterations in chemical properties of soil, primarily characterized by significant soil organic carbon (SOC) depletion, and generally this trend was also confirmed in Serbia. The biggest threats to Chernozem soil health in Serbia include: intensive agriculture, erosion, organic matter decline, salinization and land use change. The Vojvodina province has been identified as the most vulnerable region in Serbia to wind (aeolian) erosion, due to flat topography, the lowest levels of forest cover in Europe (approximately 6.37%), and intensive agricultural practices. It is estimated that wind erosion risk is high, and even 60.41% of soils of Vojvodina is classified in the hazardous sensitivity category. In our study, the highest historical loss of SOC stock due to the conversion of native ecosystems (forest and meadows) to arable land was obtained in Chernozems (16-18%) compared to other soil types, due to intensive agricultural production and tillage. However, field experiments demonstrated that specific soil conservation measures can help to maintain SOC. Long-term trials reveal that integrating manure or harvest residues (HRs) significantly boosted crop yields. While mineral fertilizers showed no positive effect on SOC, treatments incorporating HRs, manure, or liquid manure increased both SOC concentration and stock compared to control groups or those receiving only mineral fertilizers. Compared to plowing, no-till and disc-tillage treatments have more SOC. Organic farming has been increasingly recognized as a sustainable alternative to conventional agriculture, largely due to its potential to preserve soil health and reduce environmental degradation. Long-term organic management (>10 years) in Chernozem compared to conventional systems, reduced SOC losses by 10.9% and improve physical soil properties. In conclusion, agricultural practice lead to decrease of SOC in all investigated field trials, because arable soils are source of SOC rather then sinks. To enhance SOC pool it is necessary to limit tillage and to incorporate of biomass with HRs and organic fertilizers. Recycling and use of plant- and animal-derived organic residues (e.g. compost, biogas residues) is and important element of sustainable management of organic waste, which has a great potential in Serbia due to limited use in agriculture so far. In general, the conservation and restoration strategies should include minimizing soil disturbance, maximizing soil cover as well as biodiversity. Moreover, introducing systematic monitoring and creating a centralized database at the national level is necessary for setting the goals in the field of preserving the soils in Serbia.

# Soil-landscape Modeling on Experimental Plots: RECSOIL on Black Soils in Central Russia

**A. Sorokin[1*], J. Meshalkina[1], A. Kasatskii[1] and V. Romanenkov[1]**

[1] *Department of Soil Science, Lomonosov Moscow State University, Moscow, 119991 Russia*

*E-mail leshasorokin@gmail.com

**ABSTRACT**

Black soils are well known as the world's food basket, but suffer from nutrient imbalances, acidification, compaction and soil biodiversity loss (INBS GSP FAO). The RECSOIL initiative was launched by the GSP FAO to expand soil management coverage with a focus on the binding of soil organic matter (SOM) to improve soil health. SOM serves as a key example of land productivity and serves as an indicator of land degradation in RECSOIL research. The RECSOIL in Russia was launched in 2024 on a 200-hectare pilot plot on black soils (Luvic Chernozems).

Given the specific nature of farms focused on the production of commercial crops, the presence of fallow land in crop rotation, and the lack of opportunities to use domestically produced manure, measures have been taken to ensure carbon sequestration and deposition in arable soils or to reduce its losses, starting in 2025.

We collected the legacy soil data and fresh soil samples from the 0-30 cm layer. Two sample strategies were used: standard agronomic methods - divided into polygons according to GOST R 58595, and a randomly stratified scheme for subsequent geostatistical analyze. Soil analysis were carried out at the local RUSOLAN laboratory, part of the global network of soil laboratories (GLOSOLAN), to respond to the need for harmonizing soil analytical data and support evidence-based decision making for sustainable soil management.

Ground-based field monitoring is conducted throughout the season, and the farm is sequentially introducing green manure (GM) into the grain crop rotation as a catch and fallow crop. The farm is also transitioning to an organo-mineral plant nutrition system, supplementing the existing mineral nutrition system with small-scale organic granular fertilizers (FYM). For the fields under study, a crop rotation in 2025-2029 was assumed: fallow to sorghum (GM), winter wheat +GM+FYM, soybeans, winter wheat +FYM. Forecast of stock dynamics was made using the RothC model until 2030, Mg C ha-1.

Calculation of C input based on the adopted crop rotation and the planned crop yields according to the technological maps shows that the existing crop rotation is insufficient to maintain long-term C reserves in each field at the lower productivity quartile level; it is necessary to provide an additional average long-term annual input of 0.2-0.7 Mg C ha-1. To achieve median values, it is necessary to provide an additional average long-term input of 0.5-0.9 Mg C ha-1, and the upper quartile – 1-1.5 Mg C ha-1. This can be achieved both through the proposed changes in crop rotation and through the application of organic fertilizers. Accordingly, an increase in soil C reserves can be expected with C input exceeding these values.

# Assessment of water resources carrying capacity and identification of obstacle factors in the Songnen Plain based on a combined weighting-matter-element extension model

**Lei Wang, Liang Jin, Jifeng Liu and Dan Wei***

[1] *Institute of Plant Nutrition, Resources and Environment, Beijing Academy of Agricultural and Forestry Sciences, Beijing 100097, China;*
*wd2087@163.com

**ABSTRACT**

Understanding water resource carrying capacity (WRCC) is necessary to identify informed water resource conservation measures for regional development and sustainable growth. The WRCC system comprises socio-economic, natural ecological, and water resource subsystems. We propose a framework that integrates a WRCC indicator system, combined weighting-based matter-element extension model, and an obstacle degree model for the dynamic evaluation of WRCC. For Songnen Plain, China, we report that the WRCC in most areas was overloaded or transitioning toward overload from 2012 to 2017, but that conditions optimized from 2018 to 2021, except in the Heihe area. Optimal WRCC conditions occurred in the central Songnen Plain region, but poorer conditions occurred in northern and southern regions. From 2013–2021, the natural ecological subsystem carrying capacity exceeded that of water resource and socio-economic subsystems, and performed best in the Changchun area; the Tsisihar area socio-economic subsystem had the highest carrying capacity and was balanced from 2018–2021. The coupling coordination degree among urban subsystems reached a high level or above in all cases, accounting for 94.44%. From 2012–2021, the obstacle degree of the socio-economic subsystem plummeted from 97.8% in 2012 to 40.57% in 2018, only to rebound sharply to 94.91% by 2021, those of the water resource subsystem from 57.54% to 56.70%, and those of the natural resources subsystem, from 66.8% to 46.23%. WRCC was primarily influenced by socio-economic and water resource subsystems. Dominant obstacle factors shifted from agriculture to socio-economic structure, with key limiting indicators including water yield modulus, water consumption per 10,000 yuan of GDP, Spatially, the obstacle factors exhibited differentiated spatial association patterns. efficiency of water resource development and utilization, and wastewater discharge. These results and insights provide a framework to facilitate integrated assessments of WRCC at various spatial scales.

## ABSTRACT

Global black soils are critical to the terrestrial carbon cycle and essential for quantifying global carbon sink capacity. However, SOC sequestration assessments often rely on short-term data and linear assumptions, failing to reflect long-term accumulation trends under organic fertilization. To address this, we conducted a meta-analysis integrating long-term (>20 years) data from 9 black soil sites across 4 global regions to evaluate the impacts of fertilization on SOC sequestration potential. Three treatments were examined: no fertilizer (CK), chemical fertilizer (CF), and combined organic and chemical fertilization (O+CF). Our results showed that SOC exhibited a net depletion under the CK treatment, while the O+CF treatment significantly increased SOC sequestration. Under the O+CF treatment, long-term additional C input drove SOC sequestration to exhibit a non-linear temporal change eventual saturation, with levels of 39.44 (US), 108.81 (Canada), 49.64 (Russia), and 82.42 (China) Mg $ha^{-1}$. Saturation times differed by site: ~80 years (US), ~30 years (Russia), 45 years (Canada), and 50 years (China), all stabilizing at an annual growth rate <0.001%. Management practices (duration and C input) were key drivers, with saturation triggered at a cumulative C input of 83.63 Mg C $ha^{-1}$ across the global black soils region. At saturation, global black soils' potential SOC sequestration was ~1.31 (US), 0.97 (Canada), 13.12 (Russia), and 38.77 (China) Pg C, with global application of organic fertilization to these soils capable of offsetting ~0.05% of annual global soil C emissions (~90 Pg C). This study highlights the unique value of long-term field datasets. Accurately quantifying SOC sequestration potential and its environmental drivers in global black soils is vital for climate change mitigation and sustainable agriculture.

## ABSTRACT

Off-season croplands, defined as the period between harvest and subsequent sowing, play an underrecognized role in land–atmosphere interactions. In major black soil (Mollisol) regions, research has primarily focused on crop productivity and carbon dynamics, leaving the biogeophysical implications of post-harvest field conditions largely unexplored. Crop residue cover, a core practice of conservation agriculture, is well known for its soil and agronomic benefits, yet its large-scale biogeophysical climate effects remain largely unquantified and absent from climate assessments. Here, we present a spatiotemporally continuous, satellite-derived dataset of post-harvest residue cover across the world's four major Mollisol regions from 2000 onward. Leveraging this dataset, we quantify the biogeophysical role of off-season croplands in modulating land surface energy balance, with a focus on shortwave radiative forcing driven by albedo enhancement. Our results show that residue-covered off-season croplands consistently reduce net shortwave radiation across Mollisol regions, generating a measurable and spatially coherent cooling effect. When aggregated across space and time, this biogeophysical signal translates into non-negligible radiative forcing offsets, which we further express in $CO_2$-equivalent units to facilitate comparison with other climate mitigation strategies. This study provides the first global-scale assessment of the biogeophysical climate mitigation potential of residue-covered off-season croplands in Mollisol regions. By explicitly linking conservation-oriented land management to land surface radiative processes beyond the growing season, our findings highlight the importance of incorporating off-season surface dynamics into Earth system models and underscore the role of agricultural management as a nature-based climate solution extending beyond crop production periods.

# The impact of conservation agriculture on functional microorganism-driven organic nitrogen mineralization and plant–microbe interactions in black soil regions

**Shuangyi Li [1*], Zhongju Jia[1]**

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, China.*

## ABSTRACT

The organic nitrogen synthesis and mineralization processes mediated by functional microorganisms are central to achieving efficient nitrogen use in sustainable agriculture. In intensive agricultural systems, long-term and excessive application of mineral nitrogen fertilizers not only intensifies nitrogen losses but also leads to the degradation of functional microbial communities and their metabolic activities, reduces soil organic nitrogen storage and supply capacity, and diminishes plant–microbe interactions—collectively impairing both agroecosystem health and economic sustainability. Conservation agriculture is widely recognized as one of the most effective strategies for promoting sustainable land use, currently implemented on over 9% of global croplands. By integrating straw retention and reduced tillage, this approach modulates functional microbial composition and activity, enhances the synthesis and mineralization of soil organic nitrogen, improves nitrogen fertilizer use efficiency, and strengthens plant–microbe synergies to support stable and high crop yields. However, due to the inherent complexity of soil systems and the unculturability of most microorganisms, the shifts in core functional microbial communities driving organic nitrogen cycling under conservation agriculture remain poorly characterized, and the nature of plant–microbe interactions in this context is still largely unknown.

This study aims to elucidate how conservation agriculture influences functional microorganism-driven organic nitrogen mineralization and plant–microbe interactions through a controlled soil incubation with isotopic labeling followed by a pot experiment. We employed two tillage practices—conventional tillage (CK): complete removal of straw without return, followed by rotary tillage at 30–40 cm depth before spring sowing and direct seeding using a no-till planter; and strip tillage (RT): retention of maize straw on the surface after autumn harvest, with strip clearing and shallow tillage (10–20 cm) prior to spring sowing using a row-cleaning implement, followed by direct seeding. These treatments were applied across two soil layers—surface (0–20 cm) and subsurface (20–40 cm)—and four nitrogen fertilizer rates: zero nitrogen (0N), low nitrogen (60 kg N/ha, 60N), medium nitrogen (120 kg N/ha, 120N), and high nitrogen (240 kg N/ha, 240N). Soils were collected in October 2023 from a long-term conservation agriculture demonstration site established in 2017 in Gaojia Village, Lishu County, Jilin Province, representing both tillage systems at the two depths. After sieving through a 4-mm mesh for homogenization, soils were pre-incubated for 90 days at constant temperature with 15N-labeled $NH_4Cl$ and glucose to enrich microbial biomass-derived organic nitrogen. Following incubation, soils were leached with $CaCl_2$ solution and distilled water to remove residual inorganic nitrogen and substrates, then used in a maize growth pot experiment. Using Raman-activated cell sorting, nanoscale secondary ion mass spectrometry (NanoSIMS), microbial metagenomics and metatranscriptomics, and root metabolomics, we assessed the effects of conservation agriculture on organic nitrogen mineralization efficiency and mineral nitrogen utilization, characterized the active microbial communities involved in organic nitrogen cycling, and deciphered plant–microbe interaction responses.

Results from 15N isotope tracing revealed that, compared to CK, strip tillage increased organic nitrogen mineralization in surface soils by fourfold. Consequently, maize plants exhibited significantly higher uptake of mineralized organic nitrogen and greater biomass accumulation. Total plant nitrogen uptake increased with rising inorganic nitrogen inputs, yet the proportion derived from mineralized organic nitrogen peaked at 60N and declined thereafter. Microbial community and network analyses showed that, relative to CK, strip tillage significantly reduced bacterial abundance in both 0–20 cm and 20–40 cm layers while increasing fungal abundance and enhancing bacterial–fungal interactions. Integration of mineralization data with microbial profiles highlighted the critical role of fungi in driving organic nitrogen turnover under conservation agriculture. NanoSIMS analysis confirmed that active microorganisms in strip-tilled soils responded more sensitively to exogenous mineral nitrogen. Moreover, the turnover rate of microbial-derived organic nitrogen was significantly accelerated under RT. Under nitrogen-deficient conditions (0N, 60N), both treatments induced strong immobilization of microbial-derived organic nitrogen due to nitrogen limitation. However, under sufficient nitrogen supply (120N, 240N), active microorganisms in strip-tilled soils preferentially assimilated exogenous inorganic nitrogen, leading to net mineralization of microbial-derived organic nitrogen. Single-cell Raman sorting coupled with metagenomic sequencing identified key active taxa involved in organic nitrogen cycling in black soils, including members of Firmicutes, Proteobacteria, Bacteroidetes, and Actinobacteria. Notably, the extent of organic nitrogen mineralization was negatively correlated with the relative abundance of these taxa, which were significantly enriched under strip tillage. Root metabolomic analysis further demonstrated that strip tillage markedly enhanced root exudation, particularly of shikimate and phenylpropanoid derivatives, terpenoids, alkaloids, and fatty acids. These compounds showed significant correlations with active functional microbial taxa and exhibited stronger plant–microbe interaction networks under RT. Collectively, these findings identify the key functional microbial groups governing organic nitrogen cycling in black soils and underscore that conservation agriculture enhances plant–microbe functional coordination, thereby improving the turnover and mineralization efficiency of soil organic nitrogen. This study provides mechanistic insights into plant–microbe nitrogen cycling under conservation agriculture, with practical implications for sustainable nutrient management.

# Transferring Global Pedogenon Insights for Soil Security in Australia

**Wartini Ng [1*], Quentin Styc[1], and Alex McBratney[1]**

*[1] School of Life and Environmental Sciences & Sydney Institute of Agriculture, Faculty of Science, The University of Sydney, New South Wales 2015, Australia*

*wartini.ng@sydney.edu.au

**ABSTRACT**

Soil is an inherently complex and diverse system. Assessing the capacity and condition, the biophysical dimensions of soil security, requires a robust framework to evaluate soil change over time. Pedogenon concept provides such a framework by defining soil classes based on homogeneity in soil-forming factors at a specific References time, rather than similarity in current soil properties.

This study compares two major applications of the pedogenon concept: a national-scale map for Australia and a recently developed global pedogenon map, both at 90m resolution but derived from different input datasets. The Australian pedogenon map was derived using a total of 27 environmental covariates which were representative of the scorpan factors with varying original resolution of 80 – 270m, and clustered via k-means algorithms. In contrast, the global pedogenon map integrates 22 environmental covariates with a coarser resolution ranging from 90 – 55,000m resolution. These covariates are then subjected to dimension reductions using principal component analysis (PCA) and non-metric-multidimensional-scaling (NMDS) for continuous and categorical variables respectively prior to clustering with k-means algorithm.

The comparison will evaluate the degree of similarity between the two maps and examine how differences in input data and processing methods influence soil security assessments within Australia. A key objective is to develop a method for remapping locally produced pedogenon classes, such as those from the Australian map, onto the legend of the global pedogenon map. This will support scalable and harmonised soil assessments across national and global contexts, improve comparability, and enable integration of pedogenon-based evaluations for soil capacity and condition.

# Implementing the Soil Security Framework to Assess National Soil Governance: The Case of France

**J-C. Itey**[1]*

[1] *IUCN WCEL SoilSAL SG, Paris, France*

*julie.celia.itey@gmail.com

**ABSTRACT**

The soil security framework apprehends soil sustainability across five dimensions: capacity, condition, capital, connectivity, and codification (Evangelista et al., 2024). France provides a revealing case study of how national governance systems can advance several dimensions of the soil security framework, while remaining weak in others. In the last two decades, France has made significant progress in assessing two of the five soil security dimensions: soil condition and capacity. National monitoring programs and technical frameworks allow measurement of soil quality, ecosystem functions, and potential productivity, providing a strong foundation for evidence-based decision-making. Recognition of soils as a form of natural capital is emerging but remains limited. Mechanisms to account for soil degradation, preserve soil stocks, or incentivize restoration are non-existent or insufficient. Gaps are even more pronounced in the codification and connectivity dimensions. French law does not provide a unified definition or legal status for soil, leading to fragmented and partial protection across urban, agricultural, and environmental regulations. Case law and judicial expertise show inconsistent reasoning, limited transparency, and restricted public access (Baysse-Lainé et al., 2025). The French case study highlights a global need for coherent legal definitions and norms for soil protection. Without shared concepts, translating knowledge of soil capacity, condition and capital into operational laws and policies remain inconsistent. An international convention on soil security could help align national frameworks, like France's, with a common normative structure, needed to support more effective and consistent soil governance.

# A soil security perspective: Reframing soil indicators for effective governance

**Sandra J. Evangelista[1*], Alex McBratney[1]**

[1] *School of Life and Environmental Sciences, The University of Sydney, Sydney, Australia*

*sandra.evangelista@sydney.edu.au

**ABSTRACT**

When assessing soil, biophysical properties often dominate discussions of indicators, informing us about immediate physical aspects. However, most soil health indicators are broad and general, failing to differentiate between multiple soil functions that would more accurately represent the true condition of soil. Consequently, soil health discussions are frequently framed within agricultural contexts, emphasising productivity and human needs while overlooking soil's intrinsic ecological roles that extend beyond biomass production.

From a soil security perspective, assessing soil condition requires a more comprehensive approach. This framework emphasises soil multifunctionality, provision of multiple services, and resilience against diverse threats, providing a more complete understanding of how secure a soil is in its physical state. Critically, soil security extends beyond biophysical domains to incorporate socioeconomic and political dimensions that influence how soil is valued, managed, and protected. These five dimensions, Capacity, Condition, Capital, Connectivity, and Codification, must all be fulfilled for soil to be considered secure. Assessing these dimensions across soil's various roles requires appropriate indicators and contextual interpretation.

This paper proposes indicator classes guided by the soil security framework to move from narrow agricultural-focused soil health concepts toward holistic understandings of soil that recognise diverse soil functions, services and the broader societal intersections with soil necessary for ongoing protection against threats.

Additionally, the paper aims to identify and discuss potential indicators that characterise the intrinsic nature of soil itself independent from its roles. Recognising and quantifying these intrinsic indicators would draw attention to the need to conserve and protect the soil not only for utilitarian functions but also as unique, irreplaceable entities within the biosphere.

In developing soil monitoring policies, there is a need for a collective understanding on how indicators are defined and interpreted. This means moving beyond vague "soil health" concepts to explicitly specify what the indicator is used to measure whether for biophysical or other dimensions of soil. Soil policy cannot rely on ambiguous metrics that fail to articulate what aspect of soil they actually indicate if we want to make a lasting impact with how soil is governed.

# A Pedogenon Approach to Delineating Soil Districts across Europe

**Quentin Styc[1*], Julio Pachon[1], Wartini Ng[1], and Alex McBratney[1].**

[1] *Sydney Institute ofAgriculture & School ofLife & Environmental Sciences, The University ofSydney, NSW 2006, Australia*

*Quentin.styc@sydney.edu.au

**ABSTRACT**

With the recent adoption of the Soil Monitoring and Resilience Law by the European Parliament, the establishment of soil districts has become crucial to address soil degradation, which affects approximately 70% of Europe. Soil districts are defined as management zones that account for soil and environmental variability while remaining practical to implement, ideally at the administrative level.

Building on the recent proposal by Wadoux et al. (2024) to map soil districts in several European countries, an important question arises regarding the continuity and consistency of these districts across national borders. In parallel, soil districts have already been delineated in Australia using the pedogenon framework. This approach is based on mapping areas with similar quasi-stable soil-forming factors, defining soil geographical units not by the spatial variation of their properties - which may be sensitive to human activities - but by the spatial variation of environmental drivers. The underlying assumption is that similar soil-forming conditions lead to similar soils.

In Australia, soil districts were mapped by assessing similarities among pedogenons while applying spatial constraints to ensure the resulting units are both representative of soil diversity and practical for management decisions (Styc et al., 2025). The present study aims to replicate this methodology using the recently developed global pedogenon map (Francos et al., 2025), focusing on its application to Europe. Particular attention will be given to the challenges posed by the continent's intensive land use and management practices.

# A Decade of Soil Security: From Concept to Global Action

**Alex McBratney, Sandra Evangelista, Julia Feeth, Nicolas Francos, Anilkumar Hunakunti, Daniel Irving, Thilini Jayasekara, Wartini Ng, Julio Pachon, Daniel Park, Amin Sharififar, Quentin Styc & David Watt**

*Aroura, Soil & Soil Security Think Tank* *

alex.mcbratney@sydney.edu.au

**ABSTRACT**

A decade after the conception of *Soil Security*, we can now clearly see how this once-aspirational idea has matured into a global framework placing soil at the centre of sustainability discourse. The Soil Security framework - built around five interlinked dimensions of *capacity, condition, capital, connectivity, and codification* - has evolved into a practical and dynamic tool connecting soil functionality to human prosperity and planetary health. It has deepened our understanding of how *pedogenons, genosoils,* and *phenosoils* interact to sustain soil resilience and ecosystem performance.

This presentation celebrates the *scientific, policy,* and *practical advances* achieved under the Soil Security paradigm over the past ten years. It will illustrate how the framework has begun to influence soil policy principles, guide governance strategies, and inform on-the-ground assessment across diverse climatic, economic, and management contexts.

Looking ahead, the next phase of Soil Security demands translation from concept to coordinated *national* and *regional strategies* that are both effective and affordable. Innovations in *digital soil assessment, proximal sensing, soil phenotyping,* and *data-driven governance* now make it possible to link local measurements with global indicators in real time - enabling low-cost, field-based monitoring and more responsive management.

As we enter the next decade, the opportunity lies in uniting *science, policy,* and *communities* under a shared ambition: to secure the world's soils as *living infrastructure* fundamental to food, water, and climate security, and the maintenance of biodiversity and ecosystem function. The long-term vision is bold yet achievable - *a global convention on soil security*, underpinned by actionable national strategy.

**ABSTRACT**

Climate change is one of the most significant global challenges, with far-reaching impacts on the environment, economy, and society. Elevated temperatures, altered precipitation patterns, and extreme weather events affect terrestrial ecosystems, especially soils, a vital yet often overlooked natural resource. Changes in these climate variables can significantly alter soil properties, reduce functional capacity, and ultimately threaten soil security, which is a concept that integrates the sustainable management and protection of soils to maintain ecosystem resilience and human well-being.

This ongoing study applies the Soil Security Assessment Framework (SSAF) proposed by Evangelista et al. (2023) to evaluate how climate change affects soil security across New South Wales, Australia. The SSAF quantifies and maps the ability of soils to perform functions across each of the five dimensions (capacity, condition, capital, connectivity, and codification) of soil security. Here, only the capacity and condition dimensions are assessed. A baseline period (1971-2000) was used to model soil indicators and functions over time, which provides a foundation for forecasting future changes under projected climate scenarios.

Using the genosoil (inherent capacity) and phenosoil (current state) concepts, spatial layers of key soil indicators, including soil organic carbon, pH, cation exchange capacity, and bulk density, were generated through digital soil mapping with a Quantile Regression Forest model. The model achieved satisfactory performances, with $R^2$ values of about 0.6 for most indicators. Based on the genosoil and phenosoil layers, soil functional capacity and condition were assessed for the baseline period.

The next stage will predict changes in soil capacity and condition under future climate scenarios to identify emerging threats to soil security. These outcomes will contribute to the development of adaptive soil management strategies, inform policy decisions, and support the long-term goal of sustaining soil security in ongoing climate challenges.

**ABSTRACT**

Soil governance plays a critical role in securing soils globally, a necessity accounted for under the codification dimension of the Soil Security Assessment Framework (SSAF). While soil policy encompasses principles and actions adopted by governing bodies to protect soil functions and services, soil governance has historically been neglected compared to water and atmospheric governance. Policy is codified into binding actions through laws and regulations. However, the codification dimension, defined as quantifying and monitoring policies and legislation related to soil security, is currently hindered by a lack of standardized quantification tools. The absence of quantitative metrics undermines efforts to secure soils at national and international levels, especially since existing legislation is often complex and lengthy and may focus narrowly on threats such as pollution or erosion, lacking comprehensive coverage of the 23 soil roles defined in the soil security framework.

This paper presents a novel framework for quantifying the completeness of soil security regulation for Australia, designed for integration with the other SSAF dimensions. The analysis employs semantic text comparisons between the 23 defined soil security roles (functions and services) and a corpus of Australian legislation and court decisions.

The methodology leverages Large Language Models (LLMs) to encode textual data into vector representations, using cosine similarity metrics to measure the semantic distance between legal texts and soil security roles. To ensure the retrieved documents are specifically relevant to soil, a composite similarity score is calculated, assigning 80% weight to the soil security role similarity and 20% to the similarity with an extended definition of soil policy. Expert validation, using a modified intercoder reliability method, was applied to the most similar documents to assign a binary score (relevant/not relevant) based on whether the document explicitly or implicitly referred to a given soil activity.

We demonstrate how the approach highlights role-specific coverage, reveals gaps and overlaps across jurisdictions, and supports prioritisation of legal review. The workflow is open, scalable, and designed to integrate with other SSAF dimensions, providing a foundation for longitudinal monitoring of soil-relevant governance. Using specific case studies, we discuss the further steps needed to constrain the spatial component of legislation, another aspect underrepresented in research.

This application of advanced text analysis opens new avenues for quantifying the SSAF codification dimension. By providing quantitative metrics for policy completeness, this framework can help stakeholders measure interventions, guide research questions, and highlight where legislation needs improvement, especially when soil agency may be subjectively interpreted or overlooked.

**ABSTRACT**

Despite its enormous importance and contributions, soil has been historically undervalued and often overlooked. To address this gap, the Soil Security Assessment Framework was recently developed to provide a comprehensive approach for quantifying the multifaceted roles of soil, including its functions, services, and resilience toward threats, across the five dimensions: capacity, condition, capital, connectivity, and codification. Together, these roles and dimensions operationalise soil security by translating soil's biophysical, socio-economic, and governance contributions into comparable metrics. Building on the Soil Security Assessment Framework, Aroura: the Soil Security Think Tank, was recently established to develop principles and policy recommendations aimed at securing soil globally. In this context, the promotion of a Global Convention to Secure Soil stands as an essential instrument to translate growing awareness into binding global cooperation; ensuring that soil is recognised, valued, and safeguarded as the living foundation of all terrestrial systems. By recognising and preserving soil diversity, preventing loss of functionality and services, decreasing threats to soil integrity, and ensuring the sustainable use of soil, an international treaty to secure soils would elevate soil's visibility on the global stage. This presentation outlines Aroura's aspirations and a practical pathway towards achieving a Global Convention to Secure Soil.

**ABSTRACT**

This study presents the development of a global pedogenon map, which classifies soil units based on similarities in their formation processes while excluding anthropogenic effects, at a high spatial resolution of 90 m. Designed for use by scientists, land managers, and policymakers, this map classifies distinct soil units —called pedogenons—based on key soil-forming factors, including parent material, climate, soil organisms, relief, and inherent soil properties. This study employs a combination of principal component analysis (PCA), non-metric-multidimensional-scaling (NMDS), and an unsupervised classification technique (K-means clustering) to capture the full range of soil formation processes across diverse landscapes of the world yielding an unbiased, globally applicable classification. The global pedogenon map enables soil capacity and condition monitoring on a global scale. This foundation is crucial for future identification of "least disturbed soils" to serve as a References for any soil around the globe. By integrating this dataset with broader environmental data, the global pedogenon map supports global efforts to enhance soil security and monitor environmental changes.

## ABSTRACT

Soil security lies at the heart of resilient agricultural production, climate adaptation, and ecosystem sustainability, yet soils globally are under mounting pressure from degradation, land-use change, and climate extremes. Addressing this challenge demands integrated national strategies that embed soil in policy, economics, social governance, and knowledge systems. We present a robust vision for national soil security by refining five generic policy frameworks: Integrated soil security monitoring and assessment, soil-centric land use planning, economic valuation of soil services, comprehensive soil threat prevention and restoration, and stakeholder engagement and stewardship. We propose that an effective national soil security strategy should establish harmonised monitoring systems using advanced indicators to inform policy and practice at all levels. Land use planning should be reoriented to recognise soil as a critical natural capital asset, supported by zoning and regulatory mechanisms that prevent conversion of high-value soils and incentivise regenerative practices. Embedding economic valuation in policy through mechanisms such as payment for soil services can align market incentives with public goods, and thereby foster investment in soil conservation. Prevention and restoration frameworks should integrate climate - smart technologies, locally adapted regenerative practices, and targeted interventions against erosion, salinisation, and nutrient decline. Finally, governance and stewardship models—anchored in participatory, adaptive, and equity-driven approaches—are critical for sustaining momentum, ensuring accountability, and leveraging collective action. Together, these policy pillars chart a pathway for nations to transition from siloed, reactionary responses to proactive, anticipatory stewardship, with soil security concept as a foundation for food security, biodiversity, and climate resilience. Scholarly evidence and recent international initiatives underscore the urgency and practicality of this integrative approach, setting a new standard for soil security strategy at the national scale.

# European Union advances in soil protection with the Soil Monitoring Law, the Mission Soil and the Carbon farming

**Panos Panagos**[1*]

[1] *European Commission, Joint Research Centre (JRC), Ispra, Italy*

*panos.panagos@ec.europa.eu

**ABSTRACT**

In Europe, soil health is facing emerging challenges that require innovative solutions and policy interventions. We acknowledge that 62% of the European Union (EU) soils are not in healthy condition, while we face serious challenges such as climate change, food security, biodiversity loss, and socio-economic pressures. The severity of these issues is evident in the fact that soil erosion is unsustainable for around ¼ of the EU territory, carbon stocks in soils are declining, nutrients are depleting, and emerging contaminants can pose a serious threat to soil and human health. The costs of soil degradation in the EU may reach up to 70 Billion Euros per year, highlighting the urgent need for action. To address these challenges, the EU has put in place many policies for agro-environmental protection since 2000, including soil protection. The European Green Deal, launched in 2020, has set an ambitious roadmap to make the EU the first carbon-neutral continent with a modern, competitive, and resource-efficient economy.

This increased focus on soil health has led to the development of new policies and initiatives, such as the recent adopted Soil Monitoring and Resilience Law, which aims to establish a common framework for monitoring and assessing soil health. After a two-year legislative process, the Soil Monitoring Law has been definitively approved by the European Parliament in October 2025. The Law will establish a comprehensive and harmonized, yet flexible, framework for monitoring soil health, with criteria for healthy soils, and establish non-binding, sustainable targets for each soil descriptor. The EU Soil Observatory will support the implementation of the law through a range of actions, including the development of the EU Soil Health Portal, updating the LUCAS Soil Module, and the provision of technical guidance documents. The Law marks a significant step towards implementing effective soil protection policies in the EU and has put the aspirational target of achieving healthy soils by 2050. Furthermore, the Soil Mission, which aims to set up 100 Living Labs to promote sustainable land and soil management in urban and rural areas, will play a crucial role in achieving the objective of healthy soils by 2050. With an estimated investment of nearly €1 billion until 2028, funded research projects under the Soil Mission are expected to reverse soil degradation through action on the ground, underpinned by the development and monitoring of a set of indicators. In addition to these initiatives, the Carbon Removals and Carbon Farming (CRCF) regulation is the first EU volunteer framework for certifying carbon removals and carbon farming. This regulation will monitor, report, and verify carbon removals, soil emission reduction, and biodiversity benefits, providing a new opportunity for farmers and other stakeholders to contribute to climate change mitigation.

**ABSTRACT**

Governance frameworks are stakeholder operated interacting instruments and processes (Kooiman, 2016) performing various functions. Functions can include *inter-alia*, defining e.g., sustainable agricultural terms, metrics, outcomes, potentially connecting consumers to sustainable agricultural practices, and verifying 'sustainable' information displayed on food labels. Verification can both update relevant soil metrics and 'sustainably farmed' food label representations, based on how soil responses to agricultural practices. Food labels can encourage transformative change (Parker et al., 2021), increasing demand for sustainable agricultural products.

This paper examines Australia's food label governance framework, focusing on the regulation of undefined sustainable agricultural claims. It explores what protects consumers from false 'sustainably farmed' claims and considers how consumers and all stakeholders could be better connected to sustainable agricultural practices through revising the labelling governance framework structure.

Consumers cannot know or easily access information to ensure the sustainability of agricultural produce. Certification schemes can connect consumers to farming practices, promoting the importance of soils. In Australia, generally, soils are not part of certification schemes. Further, soil sustainable agricultural practices that benefit soil health are not communicated to consumers via food labels.

This paper argues a revised overarching food label governance structure can ultimately better connect consumers (and all agri-food stakeholders) with sustainable agricultural practices promoting greater recognition of, and demand for, sustainable Australian agricultural produce.

*yangjay@kangwon.ac.kr

**ABSTRACT**

Jeju Island (1,846 km²), located at the southernmost tip of Korea, has long remained geographically and culturally isolated from the mainland, fostering distinctive cultural identities and agricultural practices. Even within the island, marked regional variations in customs had been closely linked to its pedogenic diversity. While most of Jeju's soils are volcanic, the narrow belts of the upper northern and far western zones possess dark brown non-volcanic soils that are relatively fertile, supporting crops such as rice, garlic, cabbage, and barley—forming historically prosperous communities. In contrast, the rest regions, dominated by volcanic ash soils, exhibit low fertility and bulk density but high organic matter, cation exchange capacity, phosphate adsorption, and porosity, giving rise to poorer agricultural settlements. Cultural expressions have mirrored this soil divide. Weeding songs in fertile zones are short and cheerful, whereas those in infertile volcanic areas are longer and plaintive. Dolmens and ancient relics occur exclusively in fertile soil regions, and ancestral rites differ according to land inheritance systems shaped by soil productivity. Likewise, seeding practices—furrow sowing versus broadcasting—reflect soil constraints and adaptation. These patterns demonstrate that soil characteristics profoundly shape cultural landscapes, reinforcing the nexus between soil genotype and societal phenotype. However, modern management—through fertilizers, pesticides, and mechanization—has homogenized soil productivity ("phenosoils"), eroding traditional soil-linked cultural diversity. This study underscores the vital connection between soil security and cultural heritage.

* penny.wensley1@gmail.com

**ABSTRACT**
**Individual Presentation or as a Panel Contributor**

It is more than a decade since the concept of Soil Security was developed as a new soil-centric, scientifically based, interdisciplinary framework for addressing multiple global challenges. Since 2013, its proponents have committed significant effort to its promotion, through specialised forums and publications. The establishment in 2024, of a new Global Soil Security Think Tank, Aroura, has accelerated this promotional effort and supported the production of a number of new papers and outreach products, to help explain and gain acceptance of the concept. While progress has been made and aspects of the soil security construct are drawing greater attention in some quarters, we are a long way from achieving the paradigm shift required to change national and international policy approaches to soil.

Currently the dominant paradigm understood and accepted by the majority of soil stakeholders and influencing the development of soil policy and strategies at the local, national, regional and and international level, is that of soil health. Soil health is recognised within the soil security concept as soil condition, i.e. only one of the dimensions of soil requiring policy attention. But with the level of attention to soil health growing, an even greater advocacy effort will be needed to convince policy makers to embrace the more comprehensive concept of soil security.

Thinking about this challenge, I am reminded of the famous expression, dating back to the 1700's "first catch your hare'. There are many explanations of its origin, and quite a number of variations ("first catch your fish/first catch your carp/first catch your stag"), but most attribute it to an instruction in a recipe by Hannah Glasse, the writer of an early cookery book-"The Art of Cookery. Made plain and Easy", published in 1747. Some argue it came from a medieval latin treatise, which included the phrase "and the common folk say that you must first catch your stag and after it has been caught, skin it"

Whatever its origins, it became a catch cry and is used to this day, to suggest the need to act methodically, step by step, to achieve an objective.

There are myriad/multiple goals built into the approach advocated by the designers of soil security, but the fundamental objective here is to gain acceptance of the concept of soil security, as THE, not A, basis for soil policymaking.

But even that isn't the first step.

As a long-standing advocate for soil and someone who has spoken often in national and international forums about the challenge of soil advocacy, I believe we have not yet reached the threshold of 'soil awareness' or 'soil consciousness", in the wider community that is necessary to "sell' the more sophisticated and strategic idea of soil security to policy-makers.

There remains an enormous task of advocating for soil before real traction can be achieved for soil security. 'First catch your hare' means, in the first instance, ongoing/intensified effort to achieve one of the key missions of the IUSS since its founding, "to promote global understanding of and engagement with soils and their protection'. It is no coincidence that the IUSS Strategic Plan 2021-2030 elevated this broad aim into a more purposeful, simple goal and made its number one strategic objective the "improvement of soil consciousness'. Halfway through the life of the Plan, it remains as urgent and vital a task as ever.

I do acknowledge that gains have been made- that the subject of soil is moving up policy agendas. I spoke at length about this at the Soils for our Future' Conference in Winnipeg in July, 2025, in a keynote address entitled 'The Changing Landscape for Soil Advocacy' and if time permits in this session, I will be happy to elaborate.

On this subject, I was interested to see that at this 23rd World Congress of Soil Science, there is a session entitled *'Soil Literacy for all: transforming global awareness into engagement and impact through collective action".* We all need to contribute to expanding 'soil literacy/soil consciousness" but doesn't the References to 'transforming global awareness'' also cause us to recall the 'first catch your hare' phrase? How can we talk about transforming global awareness into engagement and impact through collective action, if we haven't yet achieved global awareness of the value of soil, of the services it provides and the need to protect this precious resource?

I am not preaching pessimism. Just being realistic about getting in place the foundations for policy change.

And I should add that even though I argue the need for a broader soil advocacy effort to underpin the campaign to advance soil security, these actions can be taken in parallel- the one reinforcing the other. There are many avenues and new opportunities emerging for this to happen, at the national level, in regional fora and multilateral settings. I will be pleased to identify these in my presentation.

# Development of a Canadian Soil Strategy

**ABSTRACT**

The Soil Conservation Council of Canada is working collaboratively with numerous stakeholders to develop a Canadian Soil Strategy. The Strategy will be an **agriculture industry-led** framework and plan for collective action to maintain and enhance the agricultural soils in Canada, with an immediate view (by 2030) and longer-term view (by 2050). Some current work on the strategy are setting major objectives, identifying goals and priority actions for the agriculture industry and expanding current activities, while reducing duplicative efforts and increasing efficiency. A desired outcome of the strategy is to foster the agriculture industry's long-term commitments towards soil health.

The ongoing development of the strategy has involved seeking partners to help lead the development as well as sourcing resources to assist in the work required to generate a well thought out and comprehensive strategy. Work to date has focused on engagement with multiple stakeholder to gather input on what components/topics should be included in the strategy, reviewing similar strategies from other national jurisdictions, examining existing resources that highlight the need for a coordinated
national strategy.

This talk will highlight some of the successes and challenges that have come about during the initial phase of the strategy development, provide a summary of what stakeholders have been said is required in the strategy and a brief highlight of the current contents of the strategy.

# Climate change intensifies phosphorus limitation in rice systems

**Yu Wang[1*], Hao Chen[1], Jiahui Yuan[1], Lian Song[1], and Chunwu Zhu[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*E-mail: wangyu@issas.ac.cn

**ABSTRACT**

Phosphorus (P) availability is emerging as a critical but underrecognized constraint on rice production under climate change. Although elevated atmospheric $CO_2$ can stimulate crop growth, its long-term effects on soil P supply remain uncertain, particularly when warming occurs simultaneously. Here we synthesize evidence from long-term free-air $CO_2$ enrichment experiments and a decade-long field manipulation combining elevated $CO_2$ with in situ warming in a typical paddy-upland rotation system to examine how climate change alters P bioavailability in rice soils. Across experiments, soil available P showed little change initially but declined substantially over time, decreasing by more than 20% under long-term $CO_2$ enrichment alone and by 32-54% under warming or combined $CO_2$-warming treatments. These declines were accompanied by higher soil C:P ratios and increasing transfer of P into less bioavailable forms. Mechanistically, elevated $CO_2$ promoted organic P accumulation and enhanced P removal through harvest, whereas warming further intensified P depletion by strengthening Fe–organic carbon associations and microbial immobilization, despite initially stimulating P mineralization. Together, these aboveground-belowground processes reduced the capacity of soils to replenish plant-available P under sustained climate forcing. The results show that climate change can progressively weaken the soil P supply base required to sustain rice production, and that warming may intensify this risk beyond the effect of elevated $CO_2$ alone. These findings highlight an emerging challenge for future food production and underscore the need for adaptive nutrient management to maintain yield stability under changing climatic conditions.

# Climate Change Effects on Rice Yield, Nutritional Health and the Free-Air $CO_2$ Enrichment Platform Innovation

**Chunwu Zhu[1*], Chuang Cai[1], Lian Song[1], and Dongming Wang[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*E-mail: cwzhu@issas.ac.cn

**ABSTRACT**

Rice paddies sustain more than half of the world's population, yet their responses to climate change remain a major uncertainty for future food security and human health. Based on long-term free-air $CO_2$ enrichment (FACE) experiments, we synthesized recent progress in understanding how elevated $CO_2$ reshapes rice productivity, grain quality and paddy ecosystem research capacity. First, we found that indica rice shows a 2- to 3-fold stronger yield response to elevated $CO_2$ than japonica rice. This contrast is mainly explained by the ability of indica rice to maintain nitrogen uptake, avoid photosynthetic down-regulation, and build a sufficient carbon sink in panicles. These findings led to a new conceptual framework in which enhanced nitrogen acquisition promotes carbon gain and high yield under elevated $CO_2$, enabling more accurate assessment of global rice yield responses and their spatial heterogeneity. Second, elevated $CO_2$ was shown to decrease key nutrients in rice grains while increasing grain arsenic accumulation. Mechanistic evidence indicates that nutrient dilution and altered plant water and nutrient transport reduce mineral concentrations, whereas elevated $CO_2$ enhances arsenic mobilization and bioavailability in flooded soils. These changes may aggravate hidden hunger and arsenic-related health risks among rice-dependent populations. Third, related work demonstrated that the $CO_2$ fertilization effect on rice yield is not necessarily sustained over multiple generations. Using FACE experiments, together with DNA methylation and transcriptome analyses, the study showed that multigenerational maternal $CO_2$ exposure alters rice nitrogen uptake, biomass and yield responses, highlighting the need to incorporate long-term $CO_2$ exposure into crop models. Finally, to overcome limitations of previous FACE platforms, we developed a third-generation FACE facility that can simultaneously simulate elevated $CO_2$ and whole-ecosystem warming under open-field conditions. This platform provides critical experimental capacity for evaluating rice production, nutrition and ecosystem resilience under future climate scenarios. Together, these advances support climate-smart strategies to increase rice yield, safeguard grain quality and reduce health risks in a high-$CO_2$ world.

# From Soil to Grain: Organic Farming Improves Micronutrient Bioavailability

**Xiaopeng Gao[1*], Jing Hou[1], and Martin Entz[2]**

[1] *Department of Soil Science, University of Manitoba, Canada*

[2] *Department of Plant Science, University of Manitoba, Canada*

*Xiaopeng.gao@umanitoba.ca

**ABSTRACT**

Zinc (Zn) and iron (Fe) are essential micronutrients for human health, yet their deficiencies remain widespread globally. Agronomic biofortification of crop grains through improved farming practices offers a sustainable solution to enhance dietary micronutrient intake. This presentation combines findings from a long-term field experiment and a global meta-analysis to assess how organic and conventional farming systems influence Zn and Fe concentrations and bioavailability in crops.

Field data were obtained from the Glenlea Long-Term Crop Rotation Study (2011–2020), Canada's oldest continuous comparison of organic and conventional farming. Two fully phased crop rotations—annual (wheat–flax–oat–soybean) and annual-perennial (wheat–flax–alfalfa–alfalfa)—were evaluated. Organic farming significantly increased grain Zn concentration in most years, while Fe concentration remained unchanged. Grain Zn was also higher in the annual-perennial rotation in seven of ten years. Phytate concentrations were ~35% lower in the annual-perennial rotation under organic management, leading to reduced phytate/Zn and phytate/Fe molar ratios and improved micronutrient bioavailability. However, these nutritional benefits were associated with lower grain yield due to limited phosphorus (P) availability in organic systems, particularly following alfalfa. Compost addition improved yield but increased phytate levels, reducing Zn/Fe bioavailability.

To contextualize these results globally, a meta-analysis of 54 peer-reviewed studies (322 paired observations) compared organic and conventional systems across cereals, legumes, and vegetables. Organically grown crops contained on average 14.2% higher Zn concentrations (95% CI: 9.7–19.0%, $p < 0.001$), while Fe concentrations were generally similar, except under wet conditions (>850 mm annual precipitation), where Fe increased by 14.5%. However, organic systems showed a 24.7% lower yield (95% CI: –31.2 to –17.6%, $p < 0.001$), particularly in cereals grown in arid regions.

Together, these findings demonstrate that organic and diversified crop systems can enhance Zn bioavailability and, under specific conditions, Fe content, but often at the expense of productivity. The results highlight the need for integrated nutrient management—particularly phosphorus optimization—to balance the trade-off between crop yield and nutritional quality. Further research on micronutrient bioavailability mechanisms is essential for developing farming systems that advance both food security and human nutrition.

# Mycobacterium vaccae: The Interconnection between Soil Health and Human Health

**Winfred Espejo[1*], Camila Espinoza-Mendoza[1], Mauricio Schoebitz[1], José Celis[2], and Marco Sandoval[1]**

[1]*Department of Soils & Natural Resources, Facultad de Agronomía, Universidad de Concepción, Chillán, Chile*

[2]*Department of Animal Science, Facultad de Ciencias Veterinarias, Universidad de Concepción, Chillán, Chile.*

*winfredespejo@udec.cl

**ABSTRACT**

*Mycobacterium vaccae* is a non-pathogenic saprophytic bacterium widely distributed in soils rich in organic matter. Its study has gained relevance due to its role in the interconnection between soil health and human health, within the conceptual framework of Planetary Health. This systematic review analyzed scientific publications (2000–2025) retrieved from databases such as PubMed, Scopus, Web of Science, and Cochrane, selected under PRISMA criteria and evaluated using validated methodological quality tools.

In soil environments, human exposure to *M. vaccae* occurs primarily through inhalation of soil particles, dermal contact, and indirect ingestion, being more frequent in rural settings and reduced in urban areas, where a "microbial deficit" has been observed. The identified immunological effects include the promotion of regulatory T cells and the reduction of systemic inflammation (Xiao et al., 2024). In the neurobiological context, exposure to M. vaccae enhances serotonin production, reduces neuroinflammation, and increases stress resilience (Ghosh, 2024). Animal studies and preliminary clinical trials report benefits in anxiety, depression, asthma, and atopic dermatitis (Ghosh, 2024).

Public health implications highlight the need to restore soil biodiversity and promote contact with natural environments through biodiverse green spaces and regenerative agricultural practices. Climate change, pollution, and soil degradation threaten M. vaccae populations, with potential adverse consequences for global health.

In conclusion, *M. vaccae* represents a key microorganism at the soil–human interface, with growing evidence supporting its immunological and neurological benefits. Preserving its natural habitat and ensuring adequate exposure to beneficial microorganisms should be integrated as preventive and well-being strategies in the 21st century.

## ABSTRACT

Conservation tillage combined with legume-based crop rotations (CT-LB) has gained global recognition as a climate-smart agricultural practice for its potential to enhance soil organic carbon (SOC) sequestration. However, the synergistic effects and underlying mechanisms by which CT-LB promote SOC accumulation remain unclear. This study conducted a global meta-analysis, utilizing data from 86 field trials across 78 publications, to examine interaction effects of CT and LB on SOC sequestration. Results showed CT and LB individually increased SOC by 5.25% and 2.21%, while CT-LB led to a synergistic 9.76% increase compared to traditional tillage with non-legume rotation (TT-TL). SOC enhancement under CT-LB was strongly correlated with total nitrogen (TN, $R^2$=0.73), soil aggregates >0.25mm ($R^2$=0.89), alkaline phosphatase ($R^2$=0.89), and light fraction organic carbon ($R^2$=0.94). Mechanistically, CT-LB improved SOC through: (1) increasing TN (+18.28%) and lowering C:N ratio (-12.22%) to enhance residue input and decomposition, (2) stimulating microbial and enzyme activity (+15–20%), and (3) promoting aggregation (+14.5%) that physically protects carbon. Site-specific conditions strongly influenced outcomes: warmer regions with initially low TN (<1 g/kg), low SOC (<10 g/kg), and high bulk density (>1.3 g/cm³) showed the most positive effects. Sub-group analysis confirmed that CT-LB significantly improved SOC particularly under compacted soils, lower fertility, and higher mean annual temperature/precipitation, while responses in cold regions (<9°C) were negligible. Across scenarios, CT-LB could increase global SOC sequestration by 0.06–0.19 Mg $ha^{-1}$ $yr^{-1}$ in the 0–20 cm layer if widely adopted. The integration of legume root systems and microbial secretions further facilitated micro- to macro-aggregate formation, encapsulating SOC against degradation. Discussion emphasized that while CT alone can sometimes elevate bulk density and limit nodulation, its combination with LB offsets such drawbacks by improving soil porosity, nutrient cycling, and microbial necromass stabilization. Importantly, the synergistic effect was larger than the sum of individual practices, underscoring the interactive benefits of combining reduced soil disturbance with legume diversification. Limitations included reliance on replication-based meta-analysis due to missing variance data, and conversion factors for SOC/BD in some studies, which may reduce precision. Nonetheless, this comprehensive synthesis demonstrates that CT-LB represents a practical, scalable strategy for enhancing SOC, mitigating climate change, and sustaining soil fertility. Conclusion: adopting CT-LB can substantially increase SOC storage, particularly in nutrient-poor, compacted, or warm environments, and should be prioritized within global conservation agriculture expansion.

## ABSTRACT

Balancing food security with environmental sustainability is a central challenge for large agrarian economies undergoing rapid structural change. China provides a critical case, having experienced a pronounced northward shift of grain production and intensifying domestic grain trade over the past four decades. Using provincial data from 1980–2020, we quantify how interprovincial grain flows redistribute land, water use, nitrogen pollution, and greenhouse gas (GHG) emissions between producing and consuming regions, and we assess future trajectories to 2060.

We combine a cost-optimization trade model (CHINAGRO) with provincial statistics on grain production, consumption, and socio-economic variables to simulate interprovincial flows of rice, wheat, and maize. We then estimate embedded virtual cropland, virtual water, nitrogen losses ($NH_3$, NOx, $NO3^-$), and net GHG emissions ($CO_2$, $CH_4$, $N_2O$ minus soil and biomass carbon sequestration). Fixed-effects panel models and structural equation models are used to identify climatic and socio-economic drivers, and an SSP2-based scenario to 2060 is coupled with a nitrogen–carbon credit framework to explore environmental tax and subsidy transfers.

From 1980 to 2020, interprovincial grain trade in China increased more than fivefold, while production shifted from south to north. This reorganization transferred environmental burdens—virtual cropland, blue–green water use, and nitrogen pollution—from increasingly urbanized southern consumers to northern producers. Despite these pressures, net GHG emissions embedded in traded grain declined by ~41%, driven by the expansion of relatively low-emission maize systems and cropland carbon sinks in northern regions. Projections indicate that by 2060 northern China will further consolidate its role as the national "granary", with trade volumes and associated virtual resource transfers continuing to rise; however, embedded nitrogen and net GHG emissions are projected to increase as trade expands.

Under a stylized nitrogen–carbon credit scheme, we estimate that grain-consuming regions would need to transfer on the order of US$81 billion annually by 2060 to internalize production-stage nitrogen and GHG externalities. The findings highlight the importance of integrating domestic trade, spatial production shifts, and environmental accounting when designing eco-compensation, agricultural modernization, and dietary transition policies.

## ABSTRACT

Zinc (Zn) and selenium (Se) are essential trace elements for human health. However, approximately 17.3 % and 50–100 million people worldwide are at risk of Zn and Se deficiency, respectively, primarily due to low concentrations of these elements in staple foods. Importantly, projected future rises in atmospheric $CO_2$ concentrations will increase carbohydrate content while decreasing protein content in C3 crops, further reducing Zn concentration in wheat grains. Foliar application is an effective agronomic strategy to improve human micronutrient nutrition, but the interaction mechanisms during Zn-Se co-application and their impact on the co-biofortification of grains remain unclear.

This study integrated field and pot experiments with subcellular fractionation, transcriptomics, and proteomics to analyze the Zn-Se interaction mechanisms across multiple scales: organ allocation, subcellular distribution, and molecular regulation. It also investigated the response of grain proteins to Zn-Se accumulation under Zn-Se co-biofortification. The research revealed: First, compared to Se application alone, Zn-Se application reduced grain Se content by 37.5 %, indicating an antagonistic interaction between the two elements. Concurrently, the allocation proportion of Se in leaves increased by 7.8 %. Subcellular distribution showed Zn driven Se sequestration in leaf cell walls and soluble fractions. The addition of Zn reversed the grain Se concentration and the leaf-to-sheath translocation factor from positive to negative correlation. Transcriptome analysis indicated that co-application regulated the expression of genes involved in Zn/Se/S/P-related transport and metabolic pathways, forming a regulatory network that likely drives Se subcellular compartmentalization and impedes its translocation to grains. Second, despite the antagonistic interaction, optimizing the application concentration (0.4 % $ZnSO_4 \cdot 7H_2O$ + 0.0021 %–0.0024 % $Na_2SeO_3$) effectively compensated for this antagonism, enabling Zn-Se co-biofortification while ensuring grain Se content remained below the toxic threshold (<1.0 $mg \cdot kg^{-1}$). The biofortified grains achieved an organic Se proportion as high as 96.7 %, and both whole grain products and milled flour could meet the estimated daily Zn and Se intake requirements for adults. Proteomic analysis further revealed that differentially expressed proteins in Se metabolism, S metabolism, and amino acid metabolism pathways collectively responded to Zn-Se accumulation in grains. Furthermore, foliar application upregulated the expression of reactive oxygen species scavenging related genes (e.g., *SOD*, *GST*), enhancing the antioxidant capacity of wheat. Additionally, the potential ecological risk index (RI) for the incorporation of Zn-Se enriched straw was less than 150, indicating a low risk level.

In summary, this study elucidates the multi-scale mechanisms of Zn-Se antagonism and provides a theoretical foundation and molecular targets for optimizing Zn-Se co-biofortification technology. This approach integrates directly into conventional wheat production, ensuring yield without high cost or specialized equipment. It aligns with the United Nations' second Sustainable Development Goal of ensuring global food security and improving nutrition by 2030, offering a technical pathway and theoretical support to address nutritional security challenges under global change.

# Occurrence, Properties and Sustainable Management of Degraded Upland Soils Under a Changing Climate in the Philippines

**Victor B. Asio***

*Department of Soil Science, Visayas State University*

*Baybay City, 6521 Leyte, Philippines*

*Email: vbasio@vsu.edu.ph

**ABSTRACT**

Soil is a multifunctional resource, but humans have focused almost exclusively on managing soil for biomass (food) production, thereby causing rapid soil degradation and reducing its ability to provide the multifunctionality that underpins human and planetary health (Kopittke et al., 2025). Soil degradation is a major ecological problem that impacts environmental health and food security in the Philippines. This is particularly true for many upland areas where the poorest Filipino farmers, who are also the most vulnerable and most food insecure, are living and farming (Roa, 2007). Soil degradation has not only decreased crop productivity on these lands but also caused environmental problems such as soil erosion, floods, siltation in lowlands and water bodies, and the drying up of drinking water sources. Uplands, which comprise about 60 percent of the country's land area, are defined as undulating and steep lands that range in elevation from near sea level to about 1000 m elevation. This definition is geomorphological and clearly separates the flat lowlands from the elevated uplands (Asio et al., 2024).

As in other SE Asian countries, the major processes of soil degradation in the Philippines are water erosion, chemical degradation, and physical degradation. Water erosion is primarily caused by agricultural practices, particularly overgrazing and deforestation; chemical degradation is almost exclusively the result of improper management of cultivated arable lands; and physical degradation is mainly due to agricultural activities. The major factors that cause soil degradation include deforestation, overgrazing, agricultural practices, industrial activities, mining, and waste disposal. The increased frequency of strong typhoons due to climate change significantly contributes to soil degradation, aggravating the effects of the wet tropical climate with an annual rainfall ranging from about 1,000 mm in the south to more than 4,000 mm in mountainous areas, particularly along the eastern coast of the archipelago (Asio et al., 2009; Asio et al., 2024).

Degraded upland soils in the Philippines can be grouped into three types based on the landforms where they occur: a) the fragile young soils from recent volcanic materials (mostly Andisols and Inceptisols) on higher elevations and rugged topography; b) the highly weathered but more resilient soils (Ultisols) on the more stable slopes on the lower elevations; and c) the poorly to moderately developed soils (mostly calcareous) on sedimentary hills along coastal plains (Inceptisols and Mollisols). Degraded upland soils have several physical and chemical fertility problems that limit their use for crop production, the most common among which are strongly acidic/alkaline pH, low organic matter content, low nutrient status, and shallow solum. The typical plant species in marginal and degraded uplands that can be used as indicator plants are Cogon grass (*Imperata cyclindrica*), Bugang or Talahib (*Saccharum spontaneum*), Carabao grass (*Paspalum conjugatum*), Hantutuknaw (*Melastoma malabathricum*), and Guava (*Psidium guajava*), which is almost always present in marginal uplands.

Agroforestry is widely considered the sustainable form of land use for marginal and degraded upland soils. An innovative form of agroforestry, which the Philippine government has formally endorsed to rehabilitate degraded lands, is *Rainforestation Farming*, which is the planting of native tree species available in the locality together with food crops (Asio, 2017). Contour farming, although not widely practiced by upland farmers, is another technique effective in conserving rainwater and reducing soil losses from surface erosion. Contour farming practices are classified into vegetative barriers and physical barriers. Vegetative barriers include contour hedgerows, natural vegetative strips, contour fences, and contour composting, while physical barriers include contour furrows, contour bunds, contour rock walls, and bench terraces. Fertilization with a combination of chemical fertilizers and manure, especially chicken manure, is widely practiced in many areas, particularly where poultry farms are located (Asio et al., 2024).

*adriano.sofo@unibas.it

## ABSTRACT

The continuous use of synthetic fertilizers and pesticides has led to serious environmental and health concerns, including soil degradation, biodiversity loss, and pollution. In this context, bio-composts derived from organic waste are increasingly recognized as sustainable alternatives that enhance soil fertility and microbial activity. However, their potential role in the dissemination of antimicrobial resistance (AMR) remains poorly understood.

This study evaluated the effects of two bio-compost formulations (pelleted and powdered) on soil microbial communities and the occurrence of antibiotic-resistant bacteria (ARBs), adopting a One Health approach that integrates human, animal, and environmental health perspectives. Experiments were conducted in an *ex-situ* pilot system consisting of three tanks containing untreated soil, soil plus pelleted bio-compost, and soil plus powdered bio-compost. Samples were collected over one year (T0–T4) and analyzed using molecular and cultivation-based approaches.

DNA quantification and 16S rRNA sequencing revealed an overall increase in bacterial biomass following bio-compost application, reaching up to $1.1 \times 10^6$ ng DNA/kg soil. Taxonomic analysis showed that bacterial groups such as *Paenibacillus*, *Brevibacillus*, and *Corynebacterium*, originating from the compost, became dominant over time, partially replacing native soil taxa. Despite these compositional shifts, the treatments did not significantly alter the abundance of ARBs. Resistant isolates were identified through cultivation on selective media containing ampicillin or trimethoprim, followed by susceptibility testing to ten antimicrobials. Although trimethoprim-resistant strains were detected in the bio-composts, no significant increase in ARB populations was observed in treated soils compared with controls.

These findings, interpreted within the One Health framework, indicate that bio-compost application enhances microbial proliferation and soil biological quality without promoting AMR spread in the short term. Nevertheless, the detection of resistant strains within compost underscores the importance of continuous AMR surveillance across interconnected ecological and agricultural systems. Understanding these soil–microbiome–health interactions is essential for ensuring the safety, sustainability, and resilience of bio-based fertilization practices in the face of global change and food security challenges.

## ABSTRACT

Climate change increasingly threatens global wheat production, with rising temperatures and shifting precipitation patterns reducing yields. Understanding future spatiotemporal patterns of and key climate drivers of wheat yield is critical for sustainable development. However, previous studies often overlooked complex nonlinear relationships among multiple climate factors. Here, we combined APSIM-wheat with Random Forest-SHAP to capture both the wheat growth process and complex, non-linear relationship and threshold effects between yield and climate factors. A comprehensive dataset consisted of 15 national long-term experiments located in three major wheat production regions of China was used for this purpose. APSIM models showed strong predictive accuracy across all regions. Using the validated crop models, we projected future wheat yield and analyzed the response to extreme climate events under various scenarios. Results indicated that wheat production would stagnate or decline in the mid- to long term, varying by climate scenarios and regional condition. Yields ranged from 4.0-7.2 t ha-1 under low-emission and 2.5-6.5 t ha-1 under high-emission scenarios. In the long term, the gap between low- and high- emissions scenarios was expected to widen. Under high-emissions scenarios, yields in Northwest China decreased by 30-40 % by 2099 due to heavy precipitation and cold extremes, making it the most vulnerable areas. In Yangtze River Basin, yields decreased by 19-36 % as hot extremes and heavy precipitation, while in North China Plain, they decreased by 17-25 %, mainly from hot extremes. Extreme climate events had significant nonlinear and threshold effects on yields. This study emphasizes the need for greater consideration of region-specific strategies and provides a foundation for targeting management practices to maintain food security and enhance long-term resilience to future multiple climate disasters.

# Towards Sustainable Rice Cropping Systems in a Changing Climate

**Kees Jan van Groenigen**[*1]

[1] *Department of Geography, University of Exeter, United Kingdom*

*kj.vangroenigen@exeter.ac.uk

**ABSTRACT**

Agriculture's environmental footprint is expected to expand as population, income, and demand for resource-intensive foods rise. Climate change further compounds these pressures by threatening crop yields while accelerating greenhouse gas emissions. Rice production exemplifies this tension: paddy systems feed over half of the global population yet generate nearly one-fifth of agricultural methane emissions, a gas with around 27 times the warming potential of $CO_2$. In this talk, I will present recent work on management and breeding strategies designed to sustain rice yields while lowering emissions. Drawing on field experiments, modelling, and global data syntheses, I will examine how water management, cultivar choice, and fertilizer regimes together shape methane and nitrous oxide fluxes in paddy ecosystems. I will emphasize the strong role of biophysical and socioeconomic context, underscoring the need for region-specific recommendations rather than one-size-fits-all solutions. I will then highlight evidence that integrated practices (including improved irrigation, straw management, and machinery) could raise global yields and deliver considerable social and economic benefits, but may paradoxically increase area- or yield-scaled emissions if implemented without parallel investments in mitigation. Finally, I will outline approaches to future-proof rice systems, including strategies to capture the $CO_2$ fertilization effect and reduce vulnerability to climate extremes. Together, these findings illustrate both the potential and the limits of current mitigation pathways, and the challenge of reconciling food security with climate goals.

**ABSTRACT**

Sorted patterned ground represents a morphological soil surface characteristic associated with a polygenetic origin. Among the proposed mechanisms, differential frost heaving caused by repeated freeze-thaw cycles in soils influenced by the permafrost active layer or subjected to seasonal freezing is considered the most possible, while other processes are mainly theoretical. This study investigated the genesis and preservation of patterned ground in the upper Majella Massif (Central Apennines, Italy) through integrated analyses of soil and air temperatures, as well as soil morphological, mineralogical, and physicochemical properties. Mean annual ground surface and winter equilibrium temperatures suggested that permafrost was absent at a depth <2 m, although this does not exclude the presence of a deep, relict form of a shallow permafrost in past climatic phases. Therefore, the observed patterned ground may be features originating from shallow permafrost during ancient climatic phases, which have been preserved by mechanisms affecting the superficial soil horizons. Principal Component Analysis revealed that the preservation of relatively larger patterned ground is primarily controlled by soil texture and mineralogy, particularly the content of 2:1 clay minerals which enhance water retention and promote frost heave. The results suggested that preservation is confined to the uppermost soil horizons, where freeze-thaw cycles induce miniature (diameter of the sorted circle is 3 to 7 cm) patterned ground development. In addition, wind-driven snow redistribution, which leads to patchy snow cover and limited thermal insulation of the soil, contributes to the preservation of permafrost. Under these conditions, freezing of water-saturated soil may generate sorting of rock fragments, and repeated superficial freeze-thaw cycles result in the formation of the miniature patterned ground. This study highlights how past environmental conditions, soil properties, ongoing freeze-thaw processes, and local microclimatic factors interact to shape patterned ground in mid-latitude mountain environments.

# The link between soil security and one health

**Damien J. Field*, Tom Swan, and Alex McBratney**

[1] *Sydney Institute of Agriculture, The University of Sydney, Sydney, Australia*

*E-mail Address of Presenting Author

(damien.field@sydney.edu.au)

**ABSTRACT**

Soil provides multiple and diverse functions (e.g., the provision of food and the regulation of carbon), which underpin the health of animals, humans, the environment and the planet. However, the world's soils face existential challenges. To this end, the concept of Soil Security was developed. In parallel, the concept of One Health likewise works across the human–animal–environment interface, highly relevant for the goals of Soil Security. In this review, we evaluated the roles which both the Soil Security and One Health concepts have served in the literature between 2012 and 2023 and explore the potential linkages between both concepts. We outline that both concepts are used in disparate fields, despite considerable overlap in aims and objectives. We highlight the Soil Health concept as a potential connector between Soil Security and One Health. Overall, we argue that both Soil Security and One Health are highly complementary fields of scientific inquiry with solid leverage for translation into policy and practice. However, there is a need to define One Health dimensions, as has been done for Soil Security. We advocate for a biosphere-focused framework to collectively make progress toward the 2030 Sustainable Development Goals and other global existential challenges.

# Global wheat soil metagenomes reveal dryland cropping systems as microbial genomic hotspots

**Jiayu Li[1], Matthew Denton[1], and Yi Zhou[1*]**

*[1] School of Agriculture, Food and Wine, The University of Adelaide, Waite Main Building, Waite Campus, Urrbrae, SA, 5064, Australia*

*E-mail Address of Presenting Author: yi.zhou@adelaide.edu.au

**ABSTRACT**

Wheat is one of the most important grain crops globally and is unique among major cereals in that it is extensively cultivated across both irrigated and rainfed agroecosystems. This wide environmental distribution provides a valuable yet underexplored opportunity to investigate how contrasting water management shape soil microbiomes at a global scale.

We first assembled a global wheat soil dataset comprising 145 sites from 22 countries, representing both irrigated and rainfed production systems. Comparative metagenomic analyses revealed that cropping environment (irrigated versus rainfed) was the second most important factor influencing both taxonomic and functional diversity of soil microbiomes, following geographic location. Notably, rainfed wheat soils harboured a substantially greater number of unique microbial genes than irrigated soils, suggesting enhanced genomic diversification under long-term water limitation.

Building on these global patterns, we focused on Australian rainfed wheat systems, which represent the largest rainfed wheat-growing region in the world. We established an Australian wheat soil bank consisting of samples collected across the continent. Deep metagenomic sequencing (~4Tbp data) generated a comprehensive gene catalogue containing 337 million non-redundant genes, more than double the size of the current global soil gene catalogue (159 million genes, Bahram et al 2018). Remarkably, fewer than 10% of genes overlapped between the two catalogues, highlighting the exceptional genomic novelty and functional uniqueness of Australian rainfed wheat soils.

Functional profiling revealed strong associations between microbial genes linked to plant drought resilience and site-level annual rainfall, indicating microbial adaptation to long-term water limitation and potential roles in crop stress tolerance. Soil pH across Australian dryland wheat systems exhibited a relatively narrow range (5.6–8.3) yet showed significant positive correlations with both taxonomic and functional diversity of the soil microbiome. These patterns align with observations from global native soils (Bahram et al 2018), where pH is a dominant driver of microbial diversity, and the native systems span a much wider pH range (2.5–7.5).

Collectively, this study demonstrates that long-term rainfed wheat systems harbour highly distinctive and functionally specialized soil microbiomes shaped by water availability and soil physicochemical constraints. Dryland cropping soils as a globally significant reservoir of microbial genomic novelty and provide a foundation for leveraging soil microbiomes to enhance drought resilience and sustainability under future climate change.

# Optimizing Mineral Nutrition to Improve Soybean Yield and Quality under Elevated $CO_2$

**Zhichang Chen[1*], Zaoli Zhang[1], and Qian Dong[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*zcchen@issas.ac.cn

**ABSTRACT**

The rapid rise in atmospheric carbon dioxide ($CO_2$) concentration is a principal driver of global climate change. Since the Industrial Revolution, anthropogenic activities have continuously elevated atmospheric $CO_2$ levels, generally enhancing crop productivity through the $CO_2$ fertilization effect. Legumes often exhibit a stronger yield response to elevated $CO_2$ ($eCO_2$) than cereals, primarily because symbiotic nitrogen (N) fixation alleviates N limitations, enabling legumes to better exploit the increased carbon availability. However, meta-analyses indicate that the actual yield enhancement of soybean under $eCO_2$ conditions is substantially lower than model projections, suggesting that its yield potential in future $CO_2$-enriched environments remains constrained. Emerging evidence points to limitations in non-N mineral nutrients as key factors restricting legume growth and symbiotic nitrogen fixation under $eCO_2$. Supporting observations include consistent declines in soybean seed concentrations of essential micronutrients such as iron and zinc under $eCO_2$. Moreover, effective nodule development and nitrogen fixation in soybean require adequate supplies of multiple mineral elements, including magnesium, iron, and sulfur. Taken together, these findings suggest that improving the availability of non-N nutrients in agricultural soils may represent a promising approach to further enhance soybean yield and nutritional quality in future high-$CO_2$ environments.

# Characteristics of paddy soil: specifics in dynamics in organic carbon cycling

**Tida Ge, Zhnke Zhu, Liang Wei, Shuang Wang, Jianping Chen**

*State Key Laboratory for Quality and Safety of Agro-Products, Ningbo University, Ningbo, 315211, China*

## ABSTRACT

Rice paddy ecosystem has the dual functions of carbon (C) source and C sink. Therefore, it is of great significance for ensuring China's food security and achieving the goal of "C neutrality", by controlling the C sequestration and greenhouse gas mitigation of paddy soil. In recent years, research focused on the process and mechanism of soil organic carbon (OC) turnover in paddies has been carried out all over the world. This review summarized the process and mechanism of soil C sequestration in paddies from the aspects of sources, transformation, stabilization, and regulation technics of OC, and propose strategies to deal with the "C neutrality". The main source of soil OC was rice straw, root, rhizodeposits, microbial assimilation C and organic fertilizer. After the input of exogenous organic materials into soil, the decomposition and mineralization were first controlled by the dissolution process of OC. The microbial mineralization of the dissolute OC was closely related to soil moisture condition, nutrient content and its stoichiometric ratio, microbial activity, and other factors. Apart from emitted soil OC, the remaining part of inputs was mainly anabolized to form living microorganisms and microbial residues, which were finally fixed in soil protecting by aggregate, organo-mineral colloidal complex, and necromass (amino sugar). Paddy soils in China have significant effect on C sequestration. In the recent 40 years, research data showed that the soil OC content of the subtropic paddy soil has been increased by 60% under the implementation of multiple managements such as irrigate and fertilizer application and straw returning. It had positive effect on achieving "C neutrality" by adopting the managements of increasing C sequestration and mitigating greenhouse gas emission. These managements included optimizing the combination irrigate and fertilizer application and straw returning, establishing an ecological compensation mechanism for C emission reduction, and promoting the inclusion of the rice farming system into the "C trading market". Therefore, it is necessary to clarify the mechanism of C sequestration function in paddy fields, improve the accuracy of accounting and forecasting C neutrality, accelerate the development of C neutralization technology in paddy field in future research, which provide scientific and technological support for achieving the "C neutrality" strategic goal in advance.

# Deciphering the Role of Ethylene Signaling in Endoplasmic Reticulum Stress Response and Crop Resilience

**Chuanfa Liu[1*], Renfang Shen[1,2], and Ping Lan[1,2,3]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China*

*E-mail Address: liucf@issas.ac.cn

**ABSTRACT**

Global climate change-induced adversities such as high temperature, drought, and salinity severely threaten crop productivity and food security by triggering endoplasmic reticulum (ER) stress—a condition where the protein folding capacity of the ER is overwhelmed, activating a conserved unfolded protein response (UPR) to restore cellular homeostasis. Failure of this response can lead to cell death. While the phytohormone ethylene is implicated in regulating ER stress responses, the underlying molecular mechanisms remain elusive. Our previous work identified a complex interplay between ethylene signaling and the key ER stress transducers bZIP28/bZIP60, which mediate the UPR. Genetic analysis using multiple mutants including *bzip28/60 ctr1-1*, *bzip28/60 ein2-5*, and *bzip28/60 ein3 eil1* revealed that ethylene signaling components CTR1, EIN2, and EIN3/EIL1 modulate plant sensitivity to ER stress, both in concert with and independently of bZIP28/60. To dissect the ethylene-specific regulatory network, we performed transcriptomic profiling of WT, *bzip28/60*, *ein3 eil1*, and *bzip28/60 ein3 eil1* seedlings under ER stress. Comparative analysis of differentially expressed genes (DEGs) confirmed that bZIP28/60 primarily control the upregulation of most ER stress-responsive genes. Gene Ontology (GO) enrichment analysis in WT highlighted significant induction of processes including stress response, signaling transduction, and programmed cell death, while processes like translation and photosynthesis were suppressed. Importantly, we identified a subset of ER stress-responsive DEGs dependent on EIN3/EIL1, which were enriched in similar stress- and cell death-related pathways. Cluster analysis pinpointed a group of genes potentially coregulated by ethylene and ER stress pathways, showing expression patterns consistent with EIN3/EIL1-dependent regulation under stress. From this cluster, we identified key candidate genes—including *ORE1/ORS1*, *DIN2*, *SEN1*, *bZIP1*, *ABI1*, *NYC1*, and *NYE1*—with known roles in senescence, energy metabolism, stress adaptation, and chlorophyll degradation. These genes were validated as ER stress-inducible via quantitative real time-PCR. Our findings propose a dual model whereby ethylene fine-tunes ER stress responses: (1) through EIN3/EIL1 interaction with bZIP28/bZIP60 during UPR, and (2) via a parallel, bZIP28/60-independent pathway that modulates cell death and stress adaptation. This study provides novel targets for enhancing crop resilience against climate-associated abiotic stresses, contributing to the sustainable soil–plant systems under changing environments.

# Effects of Quinoa Cultivation on Greenhouse Gas Emissions and Soil Properties in Different Saline-Alkali Ecosystems

**Hongna Cui**[1*]

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Changshu National Agro-Ecosystem Observation and Research Station, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China.*

*Hongnacui@issas.ac.cn

**ABSTRACT**

Saline-alkali soils is an important globally distributed ecologically fragile area, and the coupling relationship between vegetation restoration and carbon cycle processes has become a research hotspot in global change studies. Quinoa is a high-biomass crop with cold resistance, drought resistance, and salt-alkali tolerance, exhibiting great potential for application in the ecological restoration of Saline-alkali soil. However, the carbon allocation mechanism and greenhouse gas emission (GHGs) characteristics of quinoa under different saline-alkali environments remain unclear. This study was conducted in the Saline-alkali soils of Inner Mongolia and Dongying. The in-situ GHGs fluxes in quinoa-cultivated plots and non-cultivated plots (control) were monitored using the field static dark chamber method. Meanwhile, soil samples were collected to analyze soil chemical properties, including pH, total nutrients, water-soluble salts, dissolved organic carbon, available nitrogen and so on. The aim of this study was to reveal the influence mechanism of quinoa cultivation on GHGs and soil fertility in Saline-alkali soils. The results showed that: 1) Quinoa cultivation significantly increased greenhouse gas emissions in Saline-alkali soils. Compared with the control, the global warming potential was increased by up to 30.99%. However, there was no positive correlation between greenhouse gas emissions and quinoa biomass, and the plot with the highest biomass was not the one with the highest emissions; 2) Quinoa cultivation significantly improved the soil nutrient status of Saline-alkali soils. The contents of total soil nutrients were significantly increased, and the content of soil water-soluble salts was effectively reduced, alleviating the degree of soil salinization; 3) Correlation analysis indicated that GHGs were mainly regulated by soil pH, total nitrogen, available nitrogen, and dissolved organic carbon contents, and changes in soil chemical properties were the key factors driving the variations in greenhouse gas emissions. This study is the first to systematically clarify the carbon cycle effects and soil improvement potential of quinoa in different saline-alkali ecosystem, providing a scientific basis for the synergistic management of vegetation restoration and greenhouse gas emission reduction in Saline-alkali soils, and enriching the theoretical research on the carbon cycle of saline-alkali ecosystems in arid and semi-arid regions.

## ABSTRACT

Industrial development, urbanization, and agricultural activities have significantly increased anthropogenic atmospheric heavy metal pollution, with metals mainly adhering to fine particulate matter ($PM_{2.5}$, $PM_{10}$), which is transported over long distances via atmospheric deposition, ultimately contaminating plant leaves and soils, thereby polluting terrestrial ecosystems. Studies have shown that atmospheric deposition is the primary source of heavy metal accumulation, particularly lead (Pb), in leafy vegetables near urban and industrial areas, with Pb on $PM_{2.5}$ entering plant leaves and inhibiting crop productivity. In the context of global warming, the frequency, duration, and intensity of heatwaves (HW) in terrestrial ecosystems are increasing. Heat stress leads to stomatal opening for heat dissipation, which may further promote the infiltration of $PM_{2.5}$ into plant tissues, exacerbating crop yield loss and amplifying health risks through the food chain.

Our results demonstrate that, under HW conditions, atmospheric $PM_{2.5}$-Pb exposure significantly reduces lettuce yield and nutritional quality, including soluble sugars, soluble proteins and amino acids. In contrast, $PM_{2.5}$-Pb exposure or heat stress alone did not adversely affect lettuce (*Lactuca sativa* L.) yield or induce stomatal closure. However, under heatwave conditions, $PM_{2.5}$-Pb markedly decreased stomatal conductance and net photosynthetic rate. The combined effects of HW and $PM_{2.5}$-Pb further triggered dynamic stomatal closure and reactive oxygen species accumulation, leading to chloroplast deformation and impaired photosynthetic activity. Metabolomic analyses elucidated the molecular mechanisms by which $PM_{2.5}$-Pb regulates stomatal closure under heatwave stress and highlighted the consequent losses in lettuce yield and nutritional quality driven by stomatal dysfunction.

Collectively, these findings underscore that climate change can indirectly intensify human health risks transmitted through the food chain by amplifying the ecotoxicity of existing pollutants. Increasingly frequent HW may therefore render current pollution regimes more damaging, imposing a “double hit” on crops during critical growth stages and threatening the stability and resilience of global food systems. Addressing these emerging challenges requires moving beyond isolated approaches to climate mitigation or pollution control, and instead adopting an integrated “climate–pollution–health” framework to safeguard crop productivity and human health under a changing climate.

**ABSTRACT**

There is an urgent need for sustainable economic transitions in response to global warming and climate change impacts. Despite its role in global food security, agriculture significantly contributes to greenhouse gas (GHG) emissions. Quantifying GHG emissions from agricultural systems is primordial to support climate change mitigation strategies and the transition toward low-carbon food production systems. The wheat carbon footprint is primarily driven by nitrogen fertilisation, field emissions, and soil management. However, a conventional Life Cycle Assessment (LCA) approach does not account for soil characteristics, attributes and special variability. The soil is treated as a static background condition, failing to account for spatial variability in soil attributes and their influence on carbon dynamics, productivity, and GHG emissions. This limitation constrains the identification of effective mitigation pathways and weakens the robustness of carbon-footprint baselines in agricultural assessments. The Low-Carbon Wheat Program (LCWP) in Brazil is a science-based research, development, and innovation initiative aimed at promoting climate-smart and regenerative practices across wheat production systems. The program integrates soil and crop management, sustainability indicators, and life cycle assessment within a harmonised framework focused on reducing greenhouse gas emissions and improving environmental performance. The framework integrates chemical, physical, and biological soil attributes, as well as soil carbon dynamics, into Life Cycle Assessment (LCA). The LCWP framework posits soil as a central analytical component of LCA rather than a contextual descriptor, enabling a more realistic representation of soil-driven processes within environmental assessments. Soil quality is characterised using chemical, physical, and biological indicators, which are integrated into management quality indices to represent soil functioning and conservation status. In parallel, soil organic carbon dynamics are explicitly modelled using RothC. This approach aims to establish a robust site-dependent carbon footprint baseline and promote the mitigation and removal of GHG through improved soil management and climate-smart production strategies. Moreover, the framework is designed to support measurement, reporting, and verification (MRV) requirements and to align with the findable, accessible, interoperable, and reusable (FAIR) data principles, thereby enabling scalability across regions and management contexts. This framework provides a structured basis for supporting decision-making in research, policy design, and value-chain strategies to accelerate the transition to low-carbon wheat systems.

# Green recycling food waste management – a comparative case study in China

**Yu Liu**[1], **Gang Wang**[1]

[1] *College of Land Science and Technology, China Agricultural University, Beijing, China*

**ABSTRACT**

Food waste is the world's dumbest environmental problem, accounting one-fifth of food getting wasted globally and with about ten percent of greenhouse gas emissions come from food waste worldwide. It has been a major challenge threatening global food security and environmental sustainability. Food waste recycling and repurposing are promising for lowering the environmental and economic burden of discarded food, facilitating agroecosystem sustainability. In this study, the economically developed and populous Taihu Lake region of China was selected as a research pilot to conduct life cycle assessment of food waste treatment scenarios in the region. Typical treatment scenarios are incineration, aerobic composting, and anaerobic digestion. The results showed that aerobic composting had the best environmental efficacy in most of the impact categories, including global warming, terrestrial acidification, freshwater eutrophication, human health, freshwater ecosystems, and terrestrial ecosystems. Anaerobic digestion ranked first in particulate matter absorption and photochemical ozone synthesis. Incineration has the worst results in all environmental impact categories. On the economic level both incineration and anaerobic fermentation resulted in higher costs, whereas aerobic composting was able to achieve an economic benefit of 96.07 CNY/t.

## ABSTRACT

The interactive effects of elevated $CO_2$ ($eCO_2$) and warming—two core drivers of global change—on terrestrial ecosystem services remain systematically underexplored. Our study synthesizes 2,619 observations from 257 studies across global cropland, grassland, and forest ecosystems to address this gap. Unlike previous analyses that often rely on unpaired factors, we exclusively included studies with paired factorial designs (encompassing control, warming, $eCO_2$, and their combined treatment). Our methodology yielded results that stand in clear contrast to those of earlier research. For instance, while both factors individually increased root biomass and soil respiration, their interaction reduced root biomass and showed no significant effect on soil respiration—a counterintuitive result likely stemming from unpaired factors comparisons, which our design avoids. Our results indicate that $eCO_2$ generally exerts positive effects on ecosystem services, largely compensating for the negative impacts of warming, leading to an overall positive net effect. Specifically, $eCO_2$ enhanced crop yield and plant productivity by improving water use efficiency and photosynthetic rates. While warming alone potentially stimulated photosynthesis, it did not translate into significant yield benefits and even risked reducing productivity. Under interaction, the positive effects of $eCO_2$ compensated for the negative impacts of warming, resulting in significant yield increases. Furthermore, $eCO_2$ improved soil health and climate mitigation by enhancing water use efficiency, soil biodiversity, nutrient cycling, carbon sequestration, and plant nitrogen uptake while reducing reactive nitrogen losses. In contrast, warming had negligible overall effects on these aspects, and the interactive effects consistently aligned with the influence of $eCO_2$ alone. Critically, we found that the interaction between warming and $eCO_2$ is not simply additive, as often assumed. Instead, it shows as synergistic or antagonistic effects on key indicators like grain yield and carbon sequestration. This key finding provides new theoretical support for refining climate models and machine learning predictions.

## ABSTRACT

As plants assimilate micronutrients from the soil, they serve as the primary conduit through which these elements enter the food chain. Zinc is a vital micronutrient that is indispensable for the physiological and metabolic processes of plants, animals, and humans. Although required in trace amounts, zinc deficiency is widespread in Indian agricultural soils, primarily due to intensive cropping systems, imbalanced application of macronutrient fertilizers, and inadequate incorporation of organic matter. These factors have adversely affected fodder productivity and nutritional quality, thereby influencing zinc status in livestock and humans. Adopting a **One Health** perspective, this study investigates zinc fertilization mediated changes in the soil–plant–animal continuum. A field-cum-animal study was conducted at Coimbatore district, Tamil Nadu, India, using a fodder crop under four nutrient management treatments *viz*., NPK control, NPK + 25 kg $ZnSO_4$ $ha^{-1}$ applied as basal, NPK + 0.5% $ZnSO_4$ foliar spray applied thrice at 10-day intervals, and NPK + 25 kg $ZnSO_4$ $ha^{-1}$ applied as basal combined with 0.5% $ZnSO_4$ foliar spray applied thrice at 10-day intervals. Dairy cow animals of uniform age were identified for the study. The fodder crop was grown and was fed to selected dairy cows continuously @ 20 kg/animal/day. The required amount of green fodder grown in each treatment plot was fed to the selected animals for 15 days for attaining stabilization. After the stabilization period, the milk sample was collected from dairy cows fed with and without zinc enriched super Napier fodder at weekly intervals for 5 weeks. The results of the experiment revealed that, application of NPK along with 25 kg of soil application of $ZnSO_4$ + 0.50% Foliar spray thrice at 10 days interval significantly improved the fodder yield by 12.5%, zinc content by 17.5% over NPK besides sustaining the Zn availability and improved the fodder quality. Feeding the dairy cows with Zn enriched fodder improved the milk Zn content by 9.6%. These findings support the effectiveness of zinc enrichment through combined soil and foliar zinc application as a practical solution to combat zinc deficiencies across the food chain. The findings offer important insights into the transfer and bioavailability of nutrients, particularly zinc, across the soil–plant–animal continuum and provide a practical framework for applying the One Health approach in agriculture, demonstrating how targeted micronutrient management can simultaneously enhance soil fertility, fodder quality, livestock nutrition, and ultimately human health outcomes.

**ABSTRACT**

Coastal wetlands are referred to as “blue carbon” sinks due to high primary production and C storage capacity. However, ongoing degradation of these ecosystems reduces coastal carbon sequestration, threatening cultivated land availability and food security. Therefore, it is necessary to restore these degraded soils to ensure sustainable food production using eco-friendly technologies. Biochar and its by-product, pyroligneous acid (PA), have raised wide interests because of their multiple benefits in soil improvement. In this study, a wood waste derived biochar (WBC), composted biochar product (CBC), and PA were applied into a coastal saline soil collected from the Yellow River Delta to investigate the response of a commercial crop, okra (*Abelmoschus esculentus*) to their individual or combined applications using a 120-day pot experiment. Compared with the un-amended treatment, the WBC and CBC significantly increased the total biomass and pod yield of okra by 144%, 229%, 149%, and 392%, respectively. Similarly, PA increased the pod yield by 128%, but with little effect on the total biomass of okra. Compared with individual PA application, the co-application of PA and WBC or CBC significantly increased the biomass and pod yield of okra by 107%, 229%, 157% and 261%, respectively. Moreover, these amendments application increased the content of soluble protein and flavone of the pods, suggesting the improved nutritional quality. The increased plant growth and pod yield were mainly attributed to the enhanced nutrients availability (e.g., $NO_3^-$-N, Olsen-P) and improved soil properties (e.g., pH, exchangeable sodium). Additionally, increased microbial abundance and diversity, along with a shift in the rhizosphere bacterial community toward beneficial taxa, were identified as key factors driving these positive outcomes. Our findings demonstrate that co- application of biochar and PA is a practical and promising strategy for restoring productivity in degraded coastal soils, thereby supporting soil health and food security.

## ABSTRACT

**Background and Objectives**: Current research on elevated $CO_2$ ($eCO_2$) largely focuses on aboveground responses in simplified monocultures, neglecting critical belowground biotic interactions and the ecological reality of diurnal $CO_2$ fluctuations. This study addresses this gap by investigating the tripartite interaction between asymmetric day-night $eCO_2$ regimes, arbuscular mycorrhizal fungi (AMF) inoculation, and intercropping of nitrogen-fixing (fababean) and non-fixing (wheat) species.

**Methods**: Wheat (*Triticum aestivum*) and fababean (*Vicia faba*) were cultivated in monoculture and intercropping within controlled-environment chambers. Plants were subjected to inoculation with or without the AM fungus *Funneliformis mosseae* under four asymmetric $CO_2$ regimes: ambient ($aCO_2$; 400/450 ppm, day/night), daytime $eCO_2$ ($DeCO_2$; 550/450 ppm), nighttime $eCO_2$ ($NeCO_2$; 400/600 ppm), and full day-night $eCO_2$ ($D+NeCO_2$; 550/600 ppm). Key growth and physiological parameters were analyzed at harvest.

**Results**: Elevated $CO_2$ consistently increased the root-to-shoot biomass ratio and soluble sugars while decreasing tissue N, P, and K concentrations, leaf gas exchange, chlorophyll, soluble protein, and free amino acids. The physiological sensitivity to $eCO_2$ followed a distinct hierarchy: **$DeCO_2$ > $D+NeCO_2$ > $NeCO_2$ > $aCO_2$**. In contrast, the synergistic benefits of AMF colonization on host plants were maximized under **$D+NeCO_2$**, followed by $DeCO_2$ and $NeCO_2$.

**Conclusions**: The AMF–$eCO_2$ interaction differentially modulates plant performance in a host-specific and cropping pattern-dependent manner. Our findings demonstrate that **daytime $CO_2$ elevation drives physiological shifts, while synergistic plant-AMF benefits are greatest under sustained (day+night) $eCO_2$.** This underscores the necessity of integrating key biotic symbionts with ecologically realistic, asymmetric $CO_2$ scenarios to accurately forecast and manage agroecosystem productivity under future atmospheric conditions.

**Keywords:** Fababean, monoculture, mycorrhization, $N_2$-fixation, winter wheat

**ABSTRACT**

Plant uptake of elements (essential and beneficial, of unknown utility, or harmful) is a process that can vary seasonally due to fluctuations in environmental factors. Factors such as climate and human activity affect the bioavailability of soil elements and their absorption by plants, influencing the abiotic and biotic phenomena in the soil and the physiology of plants, both of which can be only partially interpreted.

Previously, Ruggiero et al. (2022) proposed multielement composition as an indicator of origin for the Sorrento Lemon (Femminello cv. Ovale di Sorrento) of Protected Geographical Indication (PGI). The PGI area (Sorrento Peninsula and Capri Island, southern Italy) is relatively small and has a rather homogeneous soil origin. However, significant seasonal variations in the concentrations of some elements have already been observed, making multielement signature less effective to distinguish local production from the others.

The research focuses on the multielement variability of Sorrento Lemon PGI. The accumulation of elements in lemons was observed in parallel with their bioavailability in the soil over two years (2024-2025) of production during fruit growth (autumn-winter that is a highly dynamic period for elements in the fruit and soil). This was done to identify the elements in mature fruit expected to be subject to minimal seasonal variability. This enables the identification of the elements most suitable for authenticating Sorrento Lemon PGI production and for preventing fraud related to its geographical origin.

Thus, to assess such variability, in a PGI lemon orchard of the municipality of Massa Lubrense, the bioavailability of more than forty elements was monthly assessed in soil, and in lemon sampled from autumn to winter at developmental stages: green, yellow-green, and yellow. The element bioavailability in the orchard was studied together with pedoclimatic characteristics and availability of water in the soil. The study of the element accumulation in lemon was supported by observing the evolution of the qualitative and biometric characteristics of the fruit during growth. The readily and potentially bioavailable elements in soil were extracted according to methods used in environmental analyses. All analyses were conducted using accredited methods. Elements were determined by ICP-MS, MS/MS, and OES. Data were statistically processed using univariate and multivariate methods.

# Integrated Physiological and Microbial Mechanisms Underlying Cold Tolerance in Japonica Rice: From Root Function to Rhizosphere Ecology

**Jia Yan[1*], Zhao Hongwei[1] and Ma Huimiao[1]**

[1] *Key Laboratory of Germplasm Enhancement, Physiology and Ecology of Food Crops in Cold Region, Ministry of Education, Northeast Agriculture University, Harbin, China*

*E-mail Address of Presenting Author
(jiayan@neau.edu.cn)

**ABSTRACT**

**Background and Objectives:**
Cold stress is a major abiotic constraint limiting rice productivity, particularly in high-latitude and high-altitude regions. While the detrimental effects of low temperature on above-ground physiology are well-documented, a comprehensive understanding integrating root system responses, rhizosphere microbial dynamics, and their collective impact on yield formation remains elusive. This research program systematically investigated the multi-faceted impacts of low-temperature stress, specifically low water temperature (Tw), on japonica rice. The objectives were to: (1) quantify the effects of low Tw during reproductive growth on photosynthetic production, nitrogen (N) uptake, and yield components; (2) elucidate the relationships between root physiological traits, phytohormone signaling, and panicle development under cold stress; (3) characterize the shifts in root morphology, physiology, and rhizosphere microbial communities (diversity, composition, and function) induced by low-temperature treatment at different growth stages (tillering, booting, combined); and (4) identify key microbial genes and pathways associated with cold response and their links to plant performance.

**Methods:**
Field experiments were conducted over multiple years (2015-2024) in Harbin, a cold-temperate region of Northeast China. Two japonica rice cultivars with contrasting cold tolerance—DN428 (moderately tolerant) and SJ10 (susceptible)—were used. A split-plot design was employed with low-Tw treatment as the main factor and variety as the sub-plot factor.
*Reproductive Stage Low-Tw Stress:* Plants were subjected to 17 °C Tw for durations of 3-15 days during reproductive growth (panicle initiation). Measurements included photosynthetic parameters (net photosynthetic rate Pn, leaf area index LAI, chlorophyll content), N concentration and uptake in different tissues, yield components, root vitality, xylem sap rate, root absorption surface area, antioxidant enzyme activities, and phytohormone (ABA, IAA, GA3, ZR) levels in roots, leaves, and panicles. Anther ultrastructure and pollen fertility were examined via microscopy.
*Multi-Stage Low-Temperature Treatment* : Treatments were applied at: Tillering stage (T1, 15 °C, 7 days), Booting stage (T2, 17 °C, 7 days), and a combination of both (T3). Controls (T0) received normal irrigation. Root morphological traits (length, surface area, volume), physiological activity (oxidation activity, xylem sap rate), root N accumulation, and biomass were measured. Rhizosphere soil was sampled at key stages for analysis of pH, organic matter (OM), total N (TN), total P (TP), available P (AP), and available K (AK). Metagenomic sequencing was performed on soil DNA to profile microbial community diversity, composition, and functional potential. Weighted Gene Co-expression Network Analysis (WGCNA) was used to identify gene modules and hub genes correlated with root traits and soil nutrients.

**Key Results:**
*Reproductive Stage Impact*: Low Tw during reproductive growth severely impaired N uptake, which decreased linearly with treatment duration. This led to reduced LAI and Pn, inhibiting normal panicle development. A significant decrease in seed setting rate and grain weight were the primary causes of yield loss. Despite increased spike N concentration at maturity, grain N yield declined (by 4 –47%). The cold-tolerant DN428 maintained higher N utilization efficiency and harvest index under stress than SJ10.
*Root-Panicle Relationships under Cold Stress*: Low Tw disrupted pollen development and reduced fertile pollen percentage. It significantly decreased the number of surviving panicle branches and spikelets, with a greater
impact on secondary than primary structures. DN428 maintained better anther development and panicle size. Its stronger cold tolerance was associated with higher root levels of zeatin (ZR) and auxin (IAA), which helped sustain root antioxidant enzyme activity (SOD, POD, CAT), vitality, and absorption surface area. This facilitated photosynthetic material transfer to support spikelet formation.
*Root and Rhizosphere Response to Multi-Stage Cold*: All low-temperature treatments (T1, T2, T3) significantly suppressed root morphological and physiological traits, with the combined T3 treatment having the most severe effect. DN428 consistently exhibited smaller declines than SJ10. Cold stress altered rhizosphere properties, increasing OM, TN, and TP but decreasing AP and AK. Microbial alpha diversity (Shannon index) was most significantly reduced at the full heading stage. Beta diversity analysis showed distinct shifts in microbial community composition under stress, especially for T3.
*Microbial Community and Functional Shifts*: Low-temperature treatment altered the relative abundance of key bacterial phyla (e.g., *Arthrobacter, Gemmatimonas*). *Actinomycetota* and *Euryarchaeota* were positively associated with positive root traits, while *Thermodesulfobacteriota* showed negative correlations. AP and AK were dominant drivers of microbial community structure. Metagenomic functional profiling indicated changes in pathways like "Carbon metabolism" and "Two-component system." Network analysis revealed that cold stress simplified microbial co-occurrence networks, particularly in SJ10.
*Identification of Key Genetic Elements*: WGCNA identified gene modules significantly correlated with root traits and soil nutrients. The MEbrown module, positively associated with root oxidation activity, contained hub genes *lacZ* (K01190, β-galactosidase), *fucK* (K00879, L-fuculokinase), and *rafA* (K07407, α-galactosidase), implicating galactose and pentose phosphate pathways in the cold response.
*Integrated Pathways to Yield Loss*: Structural equation modeling revealed variety-specific mechanisms. In DN428, yield loss under T2/T3 was primarily driven by cold-induced downregulation of key microbial functional genes (e.g., *lacZ, rafA, fucK*), leading to impaired rhizosphere nutrient cycling and subsequently suppressed root physiology and N accumulation. In SJ10, yield loss was more associated with a broader collapse of rhizosphere microbial community structure and diversity (reduced alpha diversity), which directly limited soil AP availability and root activity.

**Conclusions:**
This integrated research demonstrates that low-temperature stress impacts rice through a cascade of interconnected physiological and ecological disruptions. The cold-tolerant cultivar DN428 employs a strategy centered on maintaining root hormonal homeostasis and physiological activity, allowing for relative stability in panicle development. Its yield loss under severe cold is closely linked to the suppression of specific microbial functional genes critical for carbon and energy metabolism. In contrast, the susceptible SJ10 suffers from a more generalized degradation of rhizosphere microbial community structure and function, leading to a sharper decline in nutrient bioavailability and root performance. These findings highlight that enhancing cold tolerance in rice requires an integrated "gene –microbe –root function" approach. Future strategies should aim not only at improving plant intrinsic cold tolerance but also at fostering resilient rhizosphere microbiomes capable of maintaining metabolic activity and nutrient cycling under low-temperature stress.

**ABSTRACT**

Nucleotides constitute an important pool of organic phosphorus in natural environments, and their hydrolysis represents a crucial geochemical process that links biological activity and phosphorus cycling. Iron and manganese minerals, which are widely distributed and highly reactive, can catalyze the dephosphorylation of nucleotides, thereby influencing phosphorus cycling. In this study, the dephosphorylation of nucleotides by a series of manganese oxides was systematically evaluated, identifying α-$MnO_2$ as the most effective catalyst. Further investigation into the reactivity of α-$MnO_2$ toward nucleotides with different phosphorus stoichiometries revealed that acidic conditions promoted the dephosphorylation of adenosine triphosphate (ATP) and adenosine diphosphate (ADP), whereas adenosine monophosphate (AMP) remained resistant to dephosphorylation. High-performance liquid chromatography (HPLC) and attenuated total reflectance Fourier-transform infrared (ATR-FTIR) spectroscopy were employed to track the stepwise hydrolysis products and to elucidate the key interfacial complexation between nucleotides and the α-$MnO_2$ surface, thereby clarifying the catalytic mechanism of phosphoanhydride bond cleavage. These findings provide new insights into the abiotic transformation of organic phosphorus and highlight the potential role of manganese oxides in triggering phosphorus cycling under environmental conditions.

**Key words**: nucleotides; manganese oxides; phosphorus cycle; dephosphorylation

**ABSTRACT**

Sulfate fertilization reduces arsenic (As) uptake in rice, but its dose-dependent mechanisms under flooded-drained conditions remain unclear. A pot experiment with sulfate doses revealed that 100 mg $kg^{-1}$ sulfate addition created the strongest reducing conditions, driving peak sulfate consumption and sulfide production. This enhanced FeS formation, sequestering As in solids and lowering porewater As. Consequently, grain As decreased by 48% at 100 mg $kg^{-1}$ sulfate addition, versus 26% at 200 mg $kg^{-1}$ sulfate addition. Thus, an intermediate sulfate dose optimizes microbial sulfate reduction and FeS-mediated As immobilization, minimizing grain As accumulation.

# Legacy soil information in the Northern Regions of Ghana: Implications for Integrated Soil Fertility Management (ISFM)

**E. Yeboah[1*], A.S. Owusu Ansah[2], and J.K. Gyamfi[3]**

*1 (Soil Microbiology Division, CSIR-Soil Research Institute, Kumasi, Ghana)*
*2 (Soil Genesis and Classification Division, CSIR-Soil Research Institute, Kumasi, Ghana)*
*3(Soil Genesis and Classification Division, CSIR-Soil Research Institute, Kumasi, Ghana)*
* eyeboah5@hotmail.com

**ABSTRACT**

**Introduction**

Soil fertility remains a challenge in Ghana and other sub-Saharan African countries. The major farming systems in the region are characteristically low input and rely heavily on inherent soil organic matter. Ghana has one of the lowest fertiliser application rates in the sub-region. This situation is worse in the northern part of Ghana (Debpuur et al., 2021) where the low-productive soils have negatively impacted on crop yields of smallholder farmers. Integrated soil fertility management (ISFM) practices which is premised on combining organic resources and inorganic fertilisers to combat soil fertility decline in combination with improved germplasm has been introduced as a credible technology for restoring soil fertility. This study was carried to provide basis for implementation of Integrated Soil Fertility Management in the Upper East, Upper West, North East and Northern Regions of Ghana.

**Materials and methods**

A total of 34 demonstration fields were delineated from 17 districts within the Upper East, Upper West, North East and Northern Regions. The polygon coordinates of the demonstration fields were taken using Geographic Position System (etrex 30 GPS). It was imported in the ArcMap 10.7.1 and edited into polygon features. These shapefiles were used for extraction of aggregated soil information (from 1980 to 2016) Google Earth Engine (GEE) and www.Soilhive.ag.

**Discussion**

The soil chemical properties obtained from legacy soil data indicate the low soil primary macro nutrients including organic carbon in the thirty-four communities of the four regions. The generally low primary macro nutrients of the intervention districts and communities require external source of nutrients for good crop growth indices and ultimately improved yields.

**Conclusion:**

The soil chemical properties of the project intervention districts are low in primary macro nutrients and external inputs in the form of organic and chemical fertilizers are needed to improve and sustain soil fertility. The concept of ISFM to improve soil fertility is therefore a justified management practice.

## ABSTRACT

Vietnam's fruit sector faces persistent constraints—including variable fruit quality, suboptimal yields, and stagnant farmer incomes—that limit competitiveness in high-value export markets. This study evaluates whether soil-health-based farm management, supported by improved diagnostics and targeted interventions, can enhance fruit production, quality, and sustainability across major tropical fruit systems. The work was conducted within the multi-year project Improving Quality of Tropical Fruit Vietnam, initiated in 2019 under the Vietnam Farmers' Union, which functions as a Living Lab to co-develop and demonstrate scalable solutions with farmers, advisors, and local authorities.

The central research question was: Can integrated soil health diagnostics and tailored nutrient management measurably improve fruit yield, quality, and shelf life in Vietnam's tropical fruit systems? To address this, crop- and site-specific baseline management plans were established across several provinces and updated annually. A dedicated soil testing laboratory was created, applying two complementary broad-spectrum analytical approaches: Near Infrared Spectroscopy (NIRS) and 0.01 M $CaCl_2$ soil extractions (1:10 soil:solution), followed by ICP-AES or ICP-MS for quantification of plant-available nutrients. NIRS calibrations were developed using large international datasets and validated prior to routine use. In Vietnam, NIRS prediction of soil organic carbon (SOC) showed excellent agreement with References measurements ($R^2$ = 0.96; RPD = 4.8; RMSEP = 0.13), with similarly strong performance for N-total, soil organic matter, clay content, and effective cation exchange capacity (ECEC). Measurements included plant-available macro- and micronutrients, bioavailable heavy metals, SOC, pH, soil texture, and water quality, complemented by monitoring of crop protection residues in soil and fruit. Diagnostic results revealed widespread soil acidity and low plant-available calcium and phosphorus as key constraints. Management interventions—such as optimized liming, vermicompost application, and calcium–phosphorus blends—were tailored accordingly. These interventions led to increased mango yields, reduced fertilizer costs, and improved fruit nutrient profiles (higher Ca, lower N). Mango shelf life improved by 4–10 days, and no pesticide residues were detected in mango fruits in the final project year. Water quality was generally adequate, though elevated iron levels and localized salinity posed risks for irrigation and production.

Overall, the findings demonstrate that soil-health-based management, combined with improved fertilization, water management, and integrated pest control, can substantially enhance fruit yield, quality, and shelf life in tropical systems. These improvements strengthen export potential to markets such as Europe, the USA, and Japan, while supporting farmer livelihoods and sustainability goals. The Living Lab approach provides a replicable model for Vietnam's wider fruit sector, and the broad-spectrum soil testing framework offers a robust basis for monitoring progress toward relevant Sustainable Development Goals (SDGs).

# Reduced Protein Content under Elevated $CO_2$ Enhances Perfluorooctanoic Acid Bioaccumulation in Wheat

**Hongyan Guo[1], Fan Jiang[1*], and Wenchao Du[2]**

[1] *School of Environment, Nanjing University, Nanjing, China*

[2] *School of Environment, Nanjing Normal University, Nanjing, China*

*fanjiang@smail.nju.edu.cn

**ABSTRACT**

Perfluorooctanoic acid (PFOA) contamination in agricultural soils poses a persistent and growing threat to food safety and human health. However, how rising atmospheric $CO_2$ concentrations reshape PFOA bioaccumulation in wheat, a major global staple crop, remains unknown. Here, we systematically examined the impacts of elevated $CO_2$ ($eCO_2$) on the fate of PFOA in soil–wheat systems under environmentally relevant contamination levels. Elevated $CO_2$ significantly reduced protein content and root protein exudation in wheat, thereby disrupting protein-mediated immobilization of PFOA in the rhizosphere and leading to an 8.8–12.4% increase in whole-plant PFOA accumulation.

At the root–soil interface, protein depletion impaired the formation of PFOA–protein complexes, compromising the protective function of the root epidermis. Simultaneously, cytosolic protein concentrations in roots declined markedly by 32.1–53.1%, substantially limiting intracellular sequestration of PFOA. As a result, PFOA translocation from roots to grains increased by 55.4–59.3%. These combined processes ultimately elevated PFOA concentrations in wheat grains by 12.2–29.4%, significantly amplifying the potential risk of human dietary exposure.

Collectively, our findings reveal that $eCO_2$-induced protein depletion across the soil–plant continuum drives a previously unrecognized enhancement of PFOA bioaccumulation in wheat. This study highlights the compounded risks arising from interactions between legacy soil contaminants and ongoing climate change, underscoring the necessity of integrating climate-driven physiological responses of crops into future soil pollution risk assessments and food safety management strategies.

## ABSTRACT

Human activities, particularly fossil fuel combustion, deforestation, and other land-use changes, have driven a substantial increase in atmospheric $CO_2$ concentrations, from 315 ppm in 1958 to 430 ppm in 2025[1]. Projections suggest these levels could reach 800 ppm by the end of the century[2]. Elevated atmospheric $CO_2$ ($eCO_2$) often stimulates photosynthesis in C3 plants and enhances carbon assimilation[3]. $eCO_2$ generally increases carbon input into soils, affecting both the production and consumption of nitrous oxide ($N_2O$)[4], the third most important greenhouse gas. However, the net impact of $eCO_2$ on $N_2O$ emissions from global cropland is uncertain, and the underlying drivers are poorly understood.

Here, we present integrated experimental and meta-analytical evidence showing that soil pH fundamentally regulates $N_2O$ responses to $eCO_2$. We show that the stimulatory effect of $eCO_2$ increases with soil pH, driven by two complementary mechanisms: greater carbon-fueled $N_2O$ production and reduced $N_2O$ consumption as soils acidify. By incorporating the $CO_2$–pH interaction, our ensemble of top-performing meta-analysis models projects that $eCO_2$ will increase $N_2O$ emissions from global croplands by an average of 3.1%, substantially lower than previous estimates (+29%)[5]. Our findings resolve key discrepancies in literature and provide a mechanistic framework to improve climate model projections and guide targeted mitigation strategies in agroecosystems under future atmospheric conditions.

## ABSTRACT

Urban soils host highly diverse microbial communities and serve as a critical biological interface linking environmental change to human health under the One Health framework. However, conventional DNA-based surveys cannot distinguish active, dormant, or dead microorganisms, potentially leading to overestimation of pathogen risk and obscuring the ecological processes governing zoonotic pathogen dynamics. Resolving the activity status of soil microbes is therefore essential for identifying true pathogen risk hotspots. Here, we characterized urban active soil microbiomes using PMA-enabled sequencing across 203 soil samples collected from 24 Chinese cities, spanning gradients of urbanization intensity, land-use types (arable land, urban forests, and parks), and climate conditions. By focusing on metabolically active microbial fractions, we examined how urbanization, land use, and environmental factors jointly shape the spatial patterns of potential zoonotic and priority pathogens in urban soils. Active microbial diversity was consistently 30–50% lower than total DNA-based diversity, yet showed pronounced compositional and ecological divergence, indicating that a limited subset of fast-responding taxa dominates real-time microbial activity. Urban soils harbored diverse active zoonotic pathogens, with distinct pathogen assemblages associated with different land-use types. Urbanization markedly increased the activity, detection frequency, and richness of rodent-associated pathogens, particularly within urban park soils, where detection rates approached saturation in megacities. Pathogen risk patterns were jointly driven by soil physicochemical properties, especially nitrogen forms, and urban socio-ecological intensity, while higher active microbial diversity was associated with reduced pathogen risk. Together, these findings demonstrate that active soil microbiomes, rather than total microbial presence, govern urban pathogen ecology, mediating the effects of climate and urbanization on zoonotic risk. By explicitly incorporating microbial activity, this study provides a mechanistic basis for microbiome-informed urban planning and targeted interventions aimed at enhancing urban resilience to emerging public health threats.

## ABSTRACT

Understanding and predicting nitrogen (N) losses across diverse agroecosystems is essential for designing more sustainable management strategies. However, N losses vary substantially across soils, climates, and management practices, and occur through multiple pathways including leaching, runoff, and gaseous emissions. This spatial and temporal complexity makes robust quantification challenging and limits the transferability of management recommendations across regions. Process-based agroecosystem models provide a mechanistic framework for simulating soil–plant–atmosphere interactions and nitrogen transformations. Yet their application at broader scales is often constrained by intensive parameterisation requirements, structural uncertainty, and difficulties in calibration and validation across heterogeneous datasets. As agricultural monitoring expands and multi-source data become increasingly available, machine learning (ML) presents new opportunities to enhance predictive performance. This presentation explores how ML approaches can complement, rather than replace, mechanistic modelling. We assess key limitations in current process-based simulations of agricultural N losses and demonstrate how ML can enhance parameterisation, identify hidden patterns, and improve predictive performance across regions. We propose a hybrid modelling framework that integrates biogeochemical process understanding with data-driven learning, aiming to deliver more accurate, scalable, and decision-relevant tools for sustainable N management.

**ABSTRACT**

Managing soil health (SH) within agricultural fields sustains high yields while preserving essential ecosystem services. However, agriculture often focuses on soil chemistry (SC), while physical (SP) and biological (SB) aspects are neglected, compromising soil functions. In this study, we integrate these three dimensions to assess whether SH can explain yield variability and guide management decisions. In two commercial sugarcane fields in Southeast Brazil (42 and 40 ha), we delineated high- and low-yield zones from two years of yield and ancillary data, carrying a targeted soil sampling (15 and 9 samples) at 0–10, 10–20, 20–40 cm. Principal component analysis (PCA) was used to evaluate yield variability in relation to 32 soil attributes, selecting a minimum dataset. Using the Soil Management Assessment Framework (SMAF), we generated SC (pH, potassium), SP (clay, bulk density) and SB (organic carbon, β-glucosidase activity) indices and integrated them into a soil health index (SHI) ranging from 0 (poor) to 1 (excellent). PCA showed that SC had the 12 most influential attributes for PC1, while SP had the six highest loadings of PC2. SB contributed marginally, supporting a hierarchy of influence of chemical > physical > biological. The SHI revealed mixed patterns, with high-yield zones showing higher values in only 66% of cases. However, decomposing the index provided valuable and consistent insights across both fields, that are presented jointly. SC indices ranged from 0.39–0.77–0.97 (minimum–mean–maximum), SP from 0.64–0.78–1.00, and SB from 0.08–0.19–0.35. High-yield zones had higher SC indices in 100% of cases. Spatial analysis showed that physical patterns were less limiting and more uniform across zones than SC and SB. In contrast, SB presented noisy and limiting patterns, lacking spatial structure. These findings relate to field management practices: (i) SC is routinely monitored and adjusted with lime and fertilizers; (ii) SP is accounted by controlled traffic, annual sugarcane straw input and soil preparation during replanting every 4–6 years; (iii) few actions address SB, as soil organic carbon maintenance is challenging in tropical conditions and enzymatic assessments remain uncommon. In practice, these fields appear unable to benefit from a healthy biological fraction, as they currently receive no management attention. Yield depends almost entirely on SC, which may limit resilience under adverse environmental conditions. Our results highlight that SHI assessments can guide management priorities, yet requiring careful interpretation of outcomes, since uniform or unmanaged dimensions can introduce noise and mislead decisions. Broadly, agriculture must shift toward an integrated and spatial management of SC, SP and SB to sustain the continued provision of soil functions, protecting this fragile yet vital resource for the planet.

[4] *RSPB, Scotland*

*j.brook.22@abdn.ac.uk

**ABSTRACT**

Limited data exists from broad-scale surveys that assess the threat of soil structural degradation using multiple metrics, especially across multiple time-points. This was addressed by combining visual, physical and isotopic data to identify signatures of structural degradation on nine agricultural fields across three river catchments in Scotland, with sampling undertaken in September 2024, and repeated in February 2025. In each of the nine fields, three replicate samples were collected from each of: field margins, in-field locations, and areas with visible degradation to the soil surface. Intact soil cores were collected at depths of 2-7cm and 30-35cm, as well as disturbed bulk soil samples. The qualitative Visual Evaluation of Soil Structure (VESS) was combined with quantitative measurements of penetration resistance, dry bulk density, water retention characteristics and saturated hydraulic conductivity. These conventional soil physical tests were supplemented by the novel results of a rapid compaction assay and the new trial of using stable water isotopes to analyse signatures of soil pore water. For the September sampling, topsoil bulk density of in-field soils were 26.7% denser than field margins, and only 2.2% less dense than the visibly degraded locations. The February sampling showed similar results, with in-field samples 16.42% denser than the field margins, and only 0.84% less dense than visibly degraded locations. These results were also reflected in saturated hydraulic conductivity. A substantial seasonal reduction in soil structural health was found across all field locations, with bulk density for in-field and visibly degraded locations increasing by 35.7% and 37.9% respectively between September and February. Preliminary $\delta 2H$ and $\delta 18O$ data revealed a negative correlation with increasing bulk density, which may reflect different soil water storage and flow in compacted soils, and suggesting a potential alignment between stable isotope signatures and soil physical properties that could provide an indicator of soil compaction.

## ABSTRACT

Sustainable agriculture hinges on plant–soil–microbe cross-talk that drives nutrient cycling, stress resilience, and biodiversity. Microbe-rich root zones, the rhizosphere and rhizosheath, are dynamic hotspots that sustain nutrient turnover and plant growth.

In a two-year field study in Caselle in Pittari (Salerno, Italy), we tested how management shapes soil biological (enzymatic activities, 16S rRNA profiles) and physico-chemical properties. We ran two trials: (1) wheat under organic amendment (SUST) versus mineral fertilization (CONV); and (2) pollinator-friendly mixes (Eco-plus, Rustico) aligned with EU CAP eco-schemes. In both trials, an unmanaged control (CTRL) with spontaneous vegetation was included. Samples were collected from bulk soil, rhizosphere (rp), and rhizosheath (rs) at pre-sowing and flowering.

An initial overall survey showed that time was the dominant driver: all enzymes peaked at flowering, indicating stronger microbial stimulation during active growth. Space also mattered: rp and rs diverged from bulk soil, reflecting strong root filtering. In trial 1, PERMANOVA detected no significant differences among CONV, SUST, and CTRL, yet NMDS revealed clear early spatio-temporal structuring. Dehydrogenase activity (DHA) was higher in rp than in bulk soil ($p < 0.05$), marking intensified plant–microbe metabolism. SUST increased labile C in bulk soil, and shifts in micronutrients paralleled changes in microbial communities. Diversity, enzyme rates, and organic matter covaried positively, but plant stage explained most separation, with biodiversity highest at flowering. In trial 2, PERMANOVA detected significant effects of plant mixes ($p < 0.05$). Rustico showed markedly higher DHA and urease than Eco-plus (both $p < 0.001$), demonstrating that plant traits strongly shape microbial responses. Sites with high enzymatic activity often exhibited lower microbial diversity, suggesting that functionality was concentrated in dominant taxa—efficiency over richness.

Overall, time is the primary driver of soil microbial activity, with functional peaks tracking crop stages and shaping soil performance. The Rustico mix stands out by boosting above-ground biodiversity while amplifying below-ground microbial processes. Thus, soil-health assessment should look beyond management labels and explicitly integrate temporal variability and distinct root-associated microenvironments. Practically, deploying diverse plant mixes, reducing mineral inputs, and continuously monitoring spatio-temporal patterns are key to safeguarding soil ecosystem services.

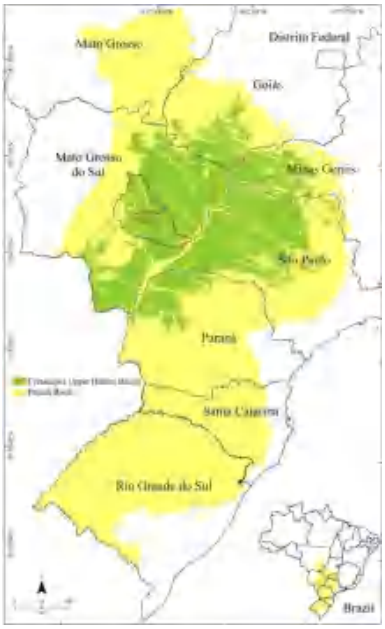
# Arenization in the Bauru Basin, Mato Grosso do Sul, Brazil

**Viviane Capoane[1*] and Robert A. Burrow[2]**

[1] *Universidade Estadual de Mato Grosso do Sul, Campo Grande, Brasil)*

[2] *Universidade Federal de Santa Maria, Rio Grande do Sul, Brasil*



*capoane@gmail.com, bobburrow@gmail.com

## ABSTRACT

Arenization is a form of physical soil degradation characterized by the reworking of unconsolidated or weakly consolidated sandy deposits, resulting in the constant mobility of sediments and difficulty in vegetation establishment. Although widely studied in the southwestern region of Rio Grande do Sul, a state in the south of Brazil, where its natural origin and intensification by human activities are well documented, the phenomenon remains poorly understood in the Bauru Sedimentary Basin, especially in its western portion. In Mato Grosso do Sul, a state in the center-west of Brazil, arenization is often confused with desertification, which reinforces the need for studies that consider its genesis, dynamics, and environmental conditioning factors. This study aimed to map and analyze the evolution of sand fields in the Pardo River watershed, in Mato Grosso do Sul. Mapping was performed using the Brightness Index 2 (BI2) derived from Sentinel-2 images from the dry season of 2023. Validation was carried out by comparing the BI2 from the rainy season. Satellite images were processed using the SNAP software. The results revealed arenization foci of different dimensions and extensive degraded areas vulnerable to arenization. In the Pardo River basin, the mapped foci totaled 17,834.34 hectares, with areas ranging from less than 1 to 376.41 hectares. The arenization process occurs in different slope compartments, such as the base, slope, and interfluves, where natural vegetation has been suppressed and the soil depleted by poorly managed production processes. The physical and chemical characteristics of Quartzipsamments, such as low organic carbon content, are associated with high rates of surface exposure and weakened load-dependent structures, leading to degradation. Over time, exposed surfaces have become more vulnerable to the action of water and wind, promoting the formation and expansion of sand fields. The region's climatic conditions facilitate the advance of arenization foci, with different agents acting in distinct periods. During the rainy season, the impact of raindrops on deforested areas, low biomass production (forage), and overgrazing stand out as factors contributing to soil degradation. In the dry season, wind acts as a transporter of particles loosened by rain. This interaction between biotic factors (low plant biomass production) and abiotic factors (rocks, soils, wind, and rain) plays a crucial role in the arenization process in the Pardo River watershed. In the foci, due to the continuous supply of sand, wind acts as a dune-shaping agent throughout the year. Considering that the expansion of eucalyptus plantations occurs predominantly on sandy soils such as Quartzipsamments, in areas of degraded pastures, silviculture conceals the severity of environmental degradation. The recent land-use changes in the eastern portion of Mato Grosso do Sul–from degraded pastures to eucalyptus monocultures indicate that climate change has been largely overlooked in the state. In the southern Cerrado of Mato Grosso do Sul, where the dry season is already well defined, ongoing climate change and the global aridification process are expected to intensify aridity, prolong droughts, and aggravate environmental and socioeconomic impacts.

## ABSTRACT

**Introduction:** The Nitrogen (N) footprint (NF) is a key indicator of N issues through the involvement of stakeholders along the life cycle, and virtual N factors (VNFs) for foods are crucial to calculate food production NF. N loads from agricultural land account for a large proportion of the overall NF and are greatly influenced by production activities; however, research evaluating the impacts of agricultural activities on VNF and NF has been insufficient. The objective of this study is to calculate and compare crop yields, VNF, and NF under the current scenario and four scenarios developed based on stakeholder input. The analysis examines the impacts of these scenarios, derived from interviews with producers and policymakers, on VNFs and NFs, providing knowledge that aligns with regional needs and supports decision-making for N management.

**Method**: The target region is Mikasa City, Hokkaido, Japan, with four major crops: onion, rice, soybean, and wheat. The study period was 2000–2022. Soil and Water Assessment Tool (SWAT) 2012 Rev. 692 used to incorporate cold-region adaptation (SWAT-FSP, Mihara et al., 2024) and paddy functions (based on modified SWAT-PADDY, Tsuchiya et al., 2018). To account for parameter uncertainty in SWAT, 100 parameter sets were selected that showed a good fit between simulated and observed streamflow, sediment/TN loads, and crop yields. Annual averages of crop yields and N dynamics (precipitation N, N fixation, denitrification, volatilization, plant uptake N, river runoff N, leaching N, yield N and residual N) were calculated with these parameters. The N-Calculator method developed by Leach et al. (2012) was modified and used for VNF and NF calculation. First, VNF was calculated using statistics of N fertilizer for new input, SWAT outputs for cultivation/harvest stages and other inputs, and Shibata et al. (2014) for processing/market stages. Second, NF was calculated by multiplying each crop's VNF by its consumption N, derived from crop yield N of SWAT outputs and utilization rates by Shibata et al. (2014). Based on interviews with agricultural stakeholders in Mikasa City in 2024, four scenarios related to their farming activities of high local interest were developed (Fertilizer reduction, Organic fertilizer, Residue removal, Cover crop). Each scenario was first simulated in SWAT to estimate crop yields and N dynamics, and these outputs were then fed into the N-Calculator to calculate VNFs, and NFs.

**Results and Discussion**: The calculated crop yields, VNFs, and resulting NFs varied across the four scenarios compared to the baseline. The cover crop scenario decreased the VNFs and the corresponding NFs for all four crops without decreasing yields. Fertilizer reduction scenario decreased VNFs and NFs while maintaining onion yield. Organic fertilizer scenario showed a trade-off where both yield and VNF decreased for rice and wheat, and decreased NF. Residue removal scenario increased VNF for rice, soybean, and wheat and increased NFs, while yields remained unchanged. Notably, cover crop scenario decreased VNFs and NFs for all crops and residue removal scenario increased VNFs and NFs for all crops, therefore N flow diagrams for these two scenarios were compared. In the cover crop scenario, leaching and runoff at the cultivation stage decreased for all crops. This result was driven by two key processes represented in SWAT: (1) altered soil erosion calculations due to increase land cover (reducing runoff N), and (2) cover crop uptake of inorganic N in non-cultivation season (reducing leaching N). In the residue removal scenario, for rice, soybean, and wheat, the amount of N in removal residues exceeded the N load resulting from the in-field N losses (i.e., leaching and runoff). This occurred because residue N, which was returned to the field in the baseline scenario, was instead removed from the field, manifesting as an increase in VNF. Furthermore, because organic matter was not returned to fields, the tendency toward soil N consumption intensified for all crops, suggesting a risk of compromising long-term productivity. These analyses demonstrated that bottom-up assessment using the SWAT model not only quantifies known phenomena such as "cover crops retain soil N and suppress runoff and leaching," but also visualizes how decisions at harvest, such as “residue removal”, impact N loads (VNF and NF) across the entire food system.

# Long-Term Land-Use Change in a Mediterranean Agroforestry System: Assessing and Restoring Soil Health in Apple Orchards of Pelion, Greece

**E. Evangelou[1*], A. Grammenou[1], M. Tziouvalekas[1], C. Pankou[1], P. Maletsika[2] G. Thalasinos[2], G. Nanos[2] and V. Antoniadis[2]**

[1] *Institute of Industrial and Forage Crops, Hellenic Agricultural Organization Dimitra, Larisa, Greece*

[2] *Department of Agriculture Crop Production and Rural Environment, University of Thessaly, Volos, Greece*

**ABSTRACT**

The apple cultivation in the mountainous region of Pelion (Central Greece) is a critical economic driver, providing essential socio-economic benefits and promoting rural retention. Historically, this expansion involved the conversion of forest ecosystems to orchards. This study aims to evaluate the long-term impact of this land-use change on soil health and test effective mitigation strategies for degradation. To achieve this, we are monitoring physical, chemical, and biological soil health indicators under field conditions across land uses representing successive intensities of change: intact native forest, productive, actively cultivated orchards, and abandoned orchards. The soils primarily exhibit an acidic pH (ranging from 5.02 to 7.0) and range in texture from loamy sand to clay loam. Preliminary findings show significant differences in soil organic carbon (SOC) concentration, with the forest plots containing nearly three times the concentration found in the orchards (1,5% -2%), which is expected to broadly influence overall soil function and health. To assess mitigation potential, a Randomized Complete Block Design is implemented in four active farms (blocks), comparing three management strips: 1) Local Farmer Practice (Positive Control), 2) Green Fertilization (legumes/grass cover crops), and 3) Manure Addition. An adjacent chestnut forest plot serves as land-use control. This paper will present the 1st year results of soil health scoring derived from a comprehensive suite of soil quality indicators, including; Physical Indicators (soil texture, bulk density, aggregate stability, infiltration rate, water holding capacity); Chemical Indicators (total N, SOC, C/N ratio, nutrient availability, electrical conductivity, pH); and Biological Indicators (microbial biomass C, 24h C mineralization potential, and permanganate oxidizable carbon (POX-C). The study aims to identify management options that can enhance soil health, thereby supporting the long-term sustainability and economic viability of apple cultivation in this sensitive Mediterranean mountain system.

**Key words:** soil health scoring; physical, chemical, biological soil health indicators;

**ABSTRACT**

Adaptive soil and water management practices are essential to mitigate the impacts of climate change, such as drought and heat stress, which are increasingly threatening Belgian agriculture and its productivity. Among these, organic mulching has been studied extensively, but rarely comprehensively. On a loamy sand soil in Belgium, three one-year field studies (2023–2025) under conservation agriculture examined the effects of organic mulch type and dose on potato (Solanum tuberosum L.) growth, soil temperature, soil water tension, nitrogen dynamics, and soil microbiome. In 2024 and 2025, the subsequent yields of summer maize (Zea mays L.) and summer wheat (Triticum aestivum L.) grown in rotation with potato were also measured, along with plant-available nitrogen. The study period covers contrasting weather conditions, with an early dry summer in 2023, a wet season in 2024, and a dry summer in 2025. Organic mulches enhanced soil water retention by reducing evaporation and improving infiltration, while also buffering soil temperature, which increased crop productivity. The type and dose of mulch stimulated microbiome communities differently and, in some instances, modified the nitrogen balance, resulting in variable effects on crop yield. Overall, grass mulch provided the most consistent benefits across different environmental conditions, still enhancing maize yield in the subsequent summer season when the initial nitrogen input was high (i.e., a higher dose). In contrast, woodchips and miscanthus negatively affected the nitrogen balance through soil nitrogen immobilization and slow mulch mineralization. This resulted in a reduced yield of potatoes under woodchips, as well as lower subsequent yields of wheat under both woodchips and miscanthus mulch. This study highlights that mulching effectiveness is influenced by the interplay between mulch characteristics and crop-specific requirements under different environmental conditions, underscoring the importance of comprehensive studies in understanding adaptive strategies.

# A Mixed-Methods Approach to Study Land Management and Soil Health in Urban Soils

**Chengcheng Feng[1*], Slava Vasenev[1], Ingrid Lubbers[1], and Jetse Stoorvogel[1,2]**

[1] *Department of Environmental Sciences, Wageningen University & Research, Wageningen, The Netherlands*

[2] *Department of Environmental Sciences, Open University, Heerlen, The Netherlands*

*chengcheng.feng@wur.nl

**ABSTRACT**

Urbanization is accelerating worldwide. In the Netherlands urban areas are projected to exceed 17% of its territory by 2040. Urban development often involves the construction of Technosols—man-made soils whose properties and functions are shaped by human activities. As key components of urban green infrastructure, these constructed Technosols contribute to essential ecosystem services such as flood mitigation and carbon sequestration. Most urban soils that remain unsealed occur within urban green spaces, including public parks and private gardens, where soil performance depends on both initial soil construction and subsequent management. These management decisions interact with edaphic biota, which strongly influence soil functioning. Among soil biota, earthworms play a particularly important role, especially during early-stage constructed Technosol development. As ecosystem engineers, earthworms influence urban soil functions through burrowing and casting, altering soil structure and enhancing nutrient cycling. Understanding how earthworm activity interacts with Technosol construction and management is therefore essential for supporting soil-based ecosystem services.

This research focuses on Wageningen, known as the “City of Life Sciences”, and adopts a mixed-method approach across both private and public urban green spaces. It combines (1) a survey to explore spatial variation in soil properties and management practices in private gardens, and (2) a field-plot experiment to observe dynamics in soil functions and ecosystem service delivery under realistic urban conditions.

The survey identified environmental (parent material, land cover) and anthropogenic (management intensity, gardener characteristics) factors associated with variation in soil properties. To date, 88 responses have been collected and soil samples have been taken from +30 private gardens. More than half of respondents expressed interest in soil biodiversity, highlighting the potential for citizen engagement in urban soil stewardship. The ongoing field-plot experiment simulates urban soil constructions to assess the effects of topsoil depth, vegetation type and anecic earthworms on soil ecosystem services delivery. Early observations indicate treatment-related differences in soil temperature, moisture dynamics and greenhouse-gas emissions.

By analyzing how management practices and earthworm abundance affect ES delivery—particularly regulating and supporting services— this research offers insights into how ecological and social factors co-shape urban soils. The results aim to foster greater public engagement, inform sustainable management strategies, and explore the potential of earthworm-based approaches to enhance ecosystem services in urban environments.

**ABSTRACT**

Despite wine is a leading agricultural product worldwide, vineyard soils are among the most eroded, often compacted, poorly structured and low in biodiversity. Conversely to many other crops, high-quality wines are generally obtained by subjecting the plants to a certain amount of stress to ensure the biosynthesis of desired secondary metabolites. This originates terroirs, i.e., specific areas where climatic, pedological and cultural conditions converge towards a particularly appreciated product. As a result of the ongoing climate change, areas of moderate stress are becoming unsuitable for high-quality wine production.

In Italy, in the Piedmont region, more than 40,000 ha are dedicated to viticulture. Here, three main grapevine black-berry varieties are cultivated (Barbera, Nebbiolo, and Dolcetto) with several local appellations (the highest being DOCG). The land is fragmented into terroirs, with Barbera vines spread over the whole region, Dolcetto grapevines localized in the south-eastern areas and Nebbiolo clustered in the northern and southernmost parts.

In the framework of the LivingSoiLL project, our research objectives were: i) to assess soil health in vineyards of the most common black-berry varieties by a soil health index (SHI) and ii) to evaluate the relationship between soil health and terroir, especially in the context of climate change.

We extrapolated topsoil data (0-30 cm) under vineyards from the regional soil database (over 2,800 points) and calculated a SHI following the Cornell assessment of soil health (CASH) taking into account some indicators of chemical fertility (N, P, CEC, pH, and available micronutrients), physical characteristics (BD, field capacity, permanent wilting point, AWC) and OM content as a proxy of biological functioning. For each indicator, cumulative distribution functions were calculated using both the soils of the whole region and specific varieties as References populations. An additive normalized SHI score was calculated for each DOCG.

The Piedmont vineyard soils are characterized by an average sand content of 30%, OM content of 15 g/kg, and BD of 1.4 kg/dm$^3$; over 70% of the soils are classified as Entisols. Most DOCG appellations are characterized by a dominant USDA soil order. Soil properties do not differ sharply among the different appellations, although some northern DOCGs have higher sand content (over 50%) and lower CEC values. One of the southernmost appellations, instead, showed low soil OM content, low AWC, and high BD, resulting in the lowest SHI values. In general, SHI scores were higher in the eastern part of the region where DOCG wines are produced from Dolcetto grapevines.

In conclusion, we highlighted the appellations that have a lower SHI and may struggle to cope with extreme events (such as droughts), while appellations with higher OM content and a better soil health are at lower risk of degradation under the ongoing climate forcing.

## ABSTRACT

Truffle-based agroforestry systems are increasingly recognized for their potential to enhance soil health, biodiversity, and rural economies in Mediterranean regions. However, despite their environmental and socio-economic relevance, current practices remain fragmented, technically challenging, and highly variable in productivity. The European PRIMA project Truffle Agroforestry Innovate & Empower (TAIE) aims to address these challenges by developing and validating innovative agroforestry models tailored to truffle (Tuber spp.) and desert truffle (Terfezia spp.) cultivation. Operating across Italy, Spain, Türkiye, and Morocco, the project integrates multidisciplinary research, field experimentation, value chain analysis, and stakeholder engagement.

The TAIE project establishes five demonstration sites that reflect diverse climatic and pedological conditions, where truffle cultivation will be combined with complementary practices, such as aromatic plant intercropping, animal grazing, and beekeeping. These integrated approaches are expected to increase soil organic carbon, improve nutrient cycling, and enhance ecosystem resilience. The project also adopts advanced field monitoring tools and precision agriculture techniques to optimize irrigation, detect plant stress, and support decision-making. Soil health will be assessed through indicators aligned with the proposed EU Directive on Soil Monitoring and the "A Soil Deal for Europe" mission, including microbial activity, carbon pools, and structural stability.

The TAIE project also investigates economic barriers, socio-cultural constraints, and emerging market opportunities within truffle value chains. Certification schemes, branding strategies, and producers' willingness to adopt agroforestry practices will be analyzed to support innovative business models and strengthen rural livelihoods. A dedicated ICT platform will facilitate knowledge exchange among researchers, producers, and policy makers, while tailored learning materials and capacity-building actions will support gender-inclusive community empowerment.

As TAIE is currently at an early stage of implementation, project partners are working on the completion of baseline surveys, the harmonization of methodological protocols across demonstration sites, and the refinement of the experimental design to ensure comparability and robustness of the forthcoming results. In the medium term, the project is expected to generate measurable improvements in key sustainability indicators related to soil health, ecosystem functionality, and landscape resilience. Moreover, TAIE aims to strengthen stakeholders' readiness to adopt innovative agroforestry solutions, while increasing the visibility of Mediterranean truffle-based systems as a viable and climate-resilient land-use strategy. The project aspires to serve as a References framework for future policies, bridging scientific innovation with practical, locally adapted solutions.

**ABSTRACT**

Soil salinization is a significant challenge that declines agricultural productivity, especially in coastal regions. This study examines the impact of soil amendments, irrigation regimes, and subsurface drainage on wheat yields in coastal saline-alkali soils. The research tests various amendments, including bio-organic fertilizer, biochar, and calcium lignosulfonate, to enhance soil quality and improve crop performance. Field experiments were conducted to evaluate the effectiveness of these strategies under different irrigation regimes, including intermittent and controlled irrigation. Additionally, subsurface drainage systems were assessed for their ability to mitigate soil salinity and improve water use efficiency. Our findings highlight the synergistic impact of combining soil amendments and efficient irrigation strategies on enhancing wheat yield under a subsurface drainage system, thereby improving soil health and optimizing water management in saline-alkali soils. This research aims to provide sustainable solutions for the reclamation of saline soils and contribute to improving food security in coastal regions, thereby helping to achieve the UN Sustainable Development Goals (SDG2: Zero Hunger).

## ABSTRACT

Against the backdrop of increasingly severe global cropland soil degradation, soil health assessment has emerged as a core approach to ensuring sustainable utilization of soil resources and is crucial for mitigating degradation and restoring soil fertility. Addressing the limitation that existing soil health assessments are predominantly static evaluations lacking consideration of the matching relationship between soil inherent potential and human management activities, this study draws on social-ecological system theory to innovatively construct an integrated Genoform-Management-Phenoform (G-M-P) framework for cropland soil health assessment. Building on this foundation, the Soil Health Rubik's Cube (SHRC) diagnostic model was developed and applied to spatiotemporal dynamic analysis of Northeast China from 2000 to 2020. The study found that: (1) soil genoform endowment spatially exhibits a decreasing pattern from plains to periphery; (2) agricultural "management" intensity shows a "high in the south, low in the north" pattern and fluctuated downward from 0.26 to 0.12 during the study period; (3) based on the SHRC model, 36 G-M-P coupling types were identified, among which GH–MM–Q4 and GH–ML–Q4 are the most representative dominant types in Northeast China's croplands, accounting for 8.37% and 5.58%, respectively. The G-M-P framework proposed in this study breaks through the static limitations of traditional assessments and provides a new scientific perspective and decision support for sustainable management and policy-making of cropland soils in Northeast China and globally.

1. Introduction

Soil is the core of the Earth's critical zone, the foundation for maintaining terrestrial ecosystem functions, and the cornerstone of food security for human society ( Liu et al., 2025). However, under the dual pressures of global climate change and agricultural intensification, cropland soil degradation has become a global challenge, directly threatening the achievement of the United Nations Sustainable Development Goals (SDGs), particularly "Zero Hunger" (SDG 2) and "Life on Land" (SDG 15). Therefore, how to scientifically diagnose and effectively curb the degradation trend of cropland soils has become a major scientific issue in the fields of regional sustainable development and national food security.

Soil health assessment has evolved from the single concept of "soil fertility" to "soil quality" integrating physical, chemical, and biological attributes, and ultimately deepened to "soil health" emphasizing ecosystem functions(Doran et al., 2015;Bünemann et al., 2018; Rinot et al., 2019). The Comprehensive Assessment of Soil Health (CASH) system in the United States, the LANDMARK project in the European Union, and China's cultivated land fertility survey have established relatively mature assessment frameworks, which typically quantify the current state of soil based on minimum data sets (MDS) and multifunctionality assessments (Moebius-Clune et al., 2016; Karlen D L et al., 2019a;Garg et al., 2025; Ren et al., 2024).

Although existing studies derive comprehensive health indices through weighting and summing soil inherent properties and human management, they completely ignore the crucial matching relationship between them. Consequently, they fail to answer a series of critical questions: Are superior fertile soils activated by appropriate management? Or are they overexploited? Or underutilized? Are low-potential soils being over-developed? If the understanding of soil health remains at the level of attribute aggregation, it cannot touch upon the relational core that drives evolution. The root of this limitation lies in the failure to understand cropland as a coupled Social-Ecological System (SES). A truly scientific soil health assessment must diagnose whether the core relationship between "genoform and management" is matched.

This study takes cropland in Northeast China from 2000 to 2020 as a case study area, aiming to: 1) characterize the spatiotemporal patterns of resource baseline genoform and human utilization management; 2) analyze soil phenoform through functions and stresses; 3) identify matching patterns by coupling "Genoform-Management-Phenoform" and propose adaptive management zones.

2. Materials and Methods

**2.1 Study framework**

Cropland systems are essentially semi-natural, semi-artificial composite systems. Social-Ecological System (SES) theory provides us with a theoretical foundation for fundamentally understanding and analyzing cropland soil health (Schlüter et al., 2017) . To apply social-ecological system theory to this study, we mapped the cropland soil system of Northeast China to the core analytical units of SES theory (Fig. 1).

This study constructed the Genoform-Management-Phenoform (G-M-P) analytical framework, advancing the concepts of soil "genotype" and "phenotype" ( Droogers et al., 1997; Rossiter, 2021; McBratney A et al., 2014; McBratney Alex B et al., 2019). In the G-M-P analytical framework, Genoform corresponds to the resource system in SES, referring to the intrinsic and relatively stable attributes of soil, which are inherent variables in the system. "Management" corresponds to the combined effects of governance systems and actors in SES, referring to human interventions applied to soil, which are external variables in the system. Phenoform corresponds to the output state of resource units in SES, representing the observable comprehensive performance of soil health resulting from the interaction between Genoform and Management.

**2.2 Study area**

Northeast China primarily comprises three provinces: Heilongjiang, Jilin, and Liaoning, with geographic coordinates spanning from 118°53′E to 135°05′E longitude and 38°43′N to 53°33′N latitude (Fig. 2). The region covers a total area of approximately 790,000 km², is rich in soil types, and serves as an important agricultural production and ecological functional zone in China.

**2.3 GPI Indicator Selection and Index Construction**

Drawing on the comprehensive consideration of soil-forming factors in soil classification systems such as the Classification System for the Third National Soil Survey of China (Trial Version), the USDA Soil Taxonomy, and the World References Base for Soil Resources, this study constructed the Genoform Potential Index (GPI). Climate indicators including mean annual precipitation (PRE), mean annual potential evapotranspiration (PET), and accumulated temperature ≥10°C (GDD), terrain indicators, soil attributes including soil texture (TEX), soil depth, and coarse fragment content (CF), as well as hydrological indicators such as water table depth (WTD) were selected to assess the GPI.

**2.4 MII Indicator Selection and Index Construction**

To quantitatively assess the management intensity of human activities on cropland soils in the study area, this study integrated five key dimensions to construct the Management Intensity Index (MII) system: chemical fertilizer input, chemical regulation input, mulching material input, water resource input, and energy input (Li et al., 2025). Specifically, chemical fertilizer input included N application rate, $P_2O_5$ application rate, and $K_2O$ application rate; mulching material input included plastic film usage; water resource input included irrigation quota; and energy input included diesel consumption for agricultural machinery and agricultural electricity consumption.

**2.5 Classification of Phenoform**

Soil phenoform represents a comprehensive assessment of soil health status from two dimensions: the functions performed by the soil system and the stresses it experiences. Functions aim to quantify the actual capacity of soil to provide agroecosystem services such as production, carbon sequestration, water regulation, and biodiversity maintenance. Stresses evaluate the degree of degradation including wind erosion, water erosion, drought, and salinization. Based on the entropy weight method, the Function Index and Stress Index were quantified separately, and according to the four-quadrant method, the FRI and DRI indices were classified into four soil phenoforms: Ideal Healthy type, Degraded type, Potential Overdrawn type, and Low-efficiency Conservative type.

**2.6 SHRC Diagnostic Model**

This study constructed the Soil Health Rubik's Cube (SHRC) diagnostic model. The SHRC diagnostic model integrates three dimensions: G, M, and P (Fig. 3). Both G and M were classified into three types based on their values—low, medium, and high—while P was classified into four types. Once the three-dimensional attributes of a spatial unit are determined, it can be precisely positioned into a specific cell within the Rubik's Cube space. Each cell represents a unique combination pattern.

3. Results

**3.1 Spatial Distribution Pattern of GPI**

The spatial distribution characteristics of nine key indicators of cropland GPI in Northeast China are shown in Fig. 4(a).

Based on the comprehensive evaluation of the above indicators, the study obtained the spatial classification results of cropland soil genoform potential in Northeast China (Fig. 4b). High GPI croplands exhibited characteristics of large-scale contiguous distribution, with their extent highly consistent with the geographic location of plains. Medium GPI croplands were mainly distributed around the periphery of high-potential areas, forming an agricultural production belt transitioning from plains to mountainous and hilly regions. Low GPI croplands were primarily distributed in the hilly areas of the southwestern part of the study area.

Quantitative statistical results indicated (Fig. 4c) that Northeast China possesses superior overall cropland resource endowment, with high and medium GPI croplands accounting for more than 86% of the total area. In Heilongjiang Province, high GPI croplands accounted for 61.78%, while low GPI croplands represented only 3.58%. Jilin Province was dominated by medium genoform potential croplands, accounting for 55.08%. Liaoning Province had a relatively high proportion of low genoform potential croplands, reaching 40.78%.

**3.2 Spatiotemporal Evolution Characteristics of MII**

Although MII fluctuated over time, its spatial distribution pattern remained relatively stable, with high-intensity areas concentrated in the central and southern plains, while the northern and eastern regions consistently remained low-intensity zones. The study analyzed the changes in the proportional structure of MII levels across different regions during the study period (Fig.5(b)). Quantitative analysis of regional average MII also confirmed the temporal variations across different provinces (Fig.5(c)). The overall average MII in Northeast China declined from 0.26 in 2000 to its lowest point of 0.08 in 2010, then rose to 0.19 in 2015, and finally decreased to 0.12 in 2020.

**3.3 Evolution of Soil Phenoform: Function, Stress, and Phenoform**

Soil functions showed overall improvement (Fig. 6). Spatially, functions exhibited a general pattern of "high in the north, low in the south", which was largely consistent with the distribution of genoform potential.

Ecological stresses intensified significantly, and risk types underwent shifts (Fig. 7). Wind erosion and drought risks declined, but water erosion intensity and salinization degree increased markedly. Spatially, water erosion in eastern Liaoning Province, salinization along the coast, and drought in the west formed compound stresses; western Jilin Province faced dual pressures from wind erosion and salinization.

During the study period, the area proportion of "Ideal Healthy" type (high function, low stress) cropland significantly declined from 38% to 27%. Meanwhile, two unsustainable phenoform types expanded dramatically: the area proportion of "Potential Overdrawn" type (high function, high stress) increased more than threefold, surging from 4.32% to 18.58%; the area proportion of "Degraded" type (low function, high stress) also rose significantly from 15% to 24%.

**3.4 Diagnosis of Genoform-Management-Phenoform (G-M-P) Coupling Patterns**

Based on the Soil Health Rubik's Cube (SHRC) model, spatiotemporal dynamic diagnosis was conducted on 36 types of "Genoform-Management-Phenoform" (G-M-P) coupling patterns in Northeast China from 2000 to 2020, revealing the complex evolution and significant spatial differentiation of regional cropland health patterns (Fig.9). GH–MM–Q4 and GH–ML–Q4 are the most representative dominant types in Northeast China's croplands, accounting for 8.37% and 5.58%, respectively, widely distributed in the Sanjiang and Songnen Plains and their northeastern forest-agriculture transition zones, characterized by the stable conversion of high potential into Q4 phenoform under relatively moderate input intensity. GM–MH–Q2 and GH–MH–Q2 are the fastest-expanding types over the past two decades, accounting for 6.17% and 3.48%, respectively, primarily concentrated along the Liaoning coast, central mining and industrial corridor, and western Jilin plains, presenting an imbalanced state of "high input but limited function and intensified stress"; the third category is the overdrawn types of GH–MM–Q1 and GM–MH–Q1 , accounting for 3.82% and 2.42%, respectively, characterized by the coexistence of high function and high stress, typically occurring in scenarios of mountain development and peri-urban intensive utilization, driven by processes such as water erosion or salinization.

4 Discussion

**4.1 From Attribute Integration to Relational Diagnosis: Methodological Innovation**

Existing studies often integrate various attributes into a single index, which tends to misidentify high yield but high-risk units as healthy. In contrast, this study constructed a diagnostic Rubik's Cube by integrating soil genoform potential (GPI), human management intensity (MII), and phenoform (P), enabling the identification of high yield but high-risk phenomena. For example, in sloping croplands and coastal salinization-sensitive areas, high-intensity inputs sustain relatively high production but simultaneously significantly elevate water erosion and salinization risks, causing units to shift from "Ideal Healthy" type to "Potential Overdrawn" type. Therefore, this study elucidates when, where, and why phenoform differences occur.

**4.2 Zoning Management Strategies and Policy Implications Based on G-M-P**

Optimization and enhancement zones such as GH–MM–Q4 and GH–ML–Q4 are widely distributed in the central-northern Heilongjiang plains, serving as the core food security zone of Northeast China. Through conservation tillage, precision fertilization, organic amendments, and other technologies, soil carbon stocks and biodiversity can be enhanced while maintaining high yields, creating model sustainable agricultural areas. Restoration and rehabilitation zones such as GM–MH–Q2 and GH–MH–Q2 are concentrated in coastal Liaoning, central regions, and western Jilin. Measures including fertilizer and pesticide reduction, cropping structure adjustment, fallow rotation, and irrigation-drainage system restoration should be implemented to break the "high input-high stress" vicious cycle, reduce stress, and restore functions. Early warning and monitoring zones such as GH–MH–Q1 and GM–MH–Q1 are distributed in mountain reclamation areas and peri-urban intensive use zones. Monitoring and early warning systems should be established, development intensity controlled, soil and water conservation strengthened, and ecological restoration on sensitive areas guided to prevent sharp deterioration of soil health. Potential activation zones such as GM–ML–Q3 are scattered in northwestern Heilongjiang and other marginal areas, serving as strategic reserve zones. Under strict ecological risk assessment, production potential should be activated in an orderly manner through scientific planning and moderate inputs, avoiding the pattern of development followed by remediation.

**4.3 Limitations and Prospects**

(1) Lack of dynamic tracking of genoform evolution. This study treated GPI as a relatively stable inherent attribute, but long-term human management activities can actually cause gradual changes in soil genoform. For example, sustained organic amendments can improve soil texture and depth, while excessive reclamation leads to soil erosion and organic matter loss, thereby altering the soil's inherent potential. Future research should quantify the long-term modification effects of different management practices on soil genoform maps.

(2) The causal mechanisms between management and phenoform still require further investigation. The current study identified the spatial patterns of G-M-P coupling types, but the causal pathways of "which management combinations under which genoform backgrounds lead to which phenoform transitions" have not been fully revealed.

(3) Insufficient scale conversion and refined diagnostic capability. This study achieved soil health diagnosis at the regional scale, but its application at the field scale still requires optimization.

# Effects of Land-use Variation on Soil Infiltration Capacity and Preferential Flow in Typical Low Hilly Area

**Linlin Chu[1*], Rong Ma[2], and Dan Chen[3]**

*Affiliation of Linlin Chu, Rong Ma, and Dan Chen (College of Agricultural science and Engineering, Hohai University, Nanjing, China)*

*chull@hhu.edu.cn

**ABSTRACT**

Large-scale vegetation rehabilitation introduced in low-hilly areas to decrease soil erosion disasters is an important method. Consequently, it is worth paying attention to the influence of soil infiltration capacity that results from the changing of land use types. To date, few studies have been conducted on the mechanism of how changes in land usage influence soil permeability or preferential flow development. The dye tracer method and indoor experiments were adopted in the present study to quantitatively analyze the differences in physicochemical properties of soils, their impact on preferential flow development and soil permeability in paddy fields, dry land, and forest land. It was found that forests and dry lands have a greater soil penetration capacity than paddy fields, with the stable infiltration rates at 0–20 cm and 20–40 cm depths being greater by 43.52–73.15% and 129.41–529.41%, respectively. The preferential flow development differs depending on land usage patterns, forest land has the less value the stained area ratio (20%) and matrix flow depth(2.15 cm) and the greatest value of the preferential flow ratio(84.93%), length index(10.11), stained variation coefficient(0.91) and peak number(19.40), compared with dry land and paddy fields. The result of variance analysis shows that soil bulk density and moisture content have inhibitory effects on preferential flow development and infiltration capacity and that greater porosity and organic matter content promote infiltration and preferential flow. These findings are important for understanding the hydrological mechanisms taking place in soils and are of assistance in agricultural land management.

*chull@hhu.edu.cn

**ABSTRACT**

The ecological construction in coastal saline-alkali areas urgently needs to be explored in terms of water-salt regulation management and functional irrigation. In this paper, the extremely severe saline soil in the eastern coastal area of the North China Plain was selected for vegetation rehabilitation by drip irrigation. Through two-year field experiments, the spatial and temporal soil salinity-water dynamics of three land use types (LUTS) under two irrigation strategies (IIS) were systematically studied. The results revealed: (1) The soils in the understory grassland and shrub land root zones remained stable for desalination, with the average ECe decreasing to 0.69 dS/m and 0.71 dS/m under autumn irrigation at surface, and 0.66 dS/m and 0.85 dS/m under winter irrigation. And a slight salt accumulation occurred in the bare land in stage IV. (2) The soil surface moisture increased, and the bulk density decreased significantly with drip irrigation. The final moisture of understory grassland and shrub land was 3.85 and 2.97 times that of the bare land layer at 0-10 cm, 2.55 and 1.97 times at 10-20 cm, and 1.61 times and 1.47 times at 20-40 cm, respectively. (3) Due to quick salt rinsing, Salix matsudana and Hibiscus maintained a high survival rate, and the germination of understory vegetation further increased the vegetation coverage. Meanwhile perennial understory herbs gradually became the dominant species, which positively effects on the maintenance of soil low-salt environment. (4) There were significant differences in SWC and ECe between autumn and winter irrigation treatment during stage I and stage II, indicating that irrigation strategies only impact on soil water-salt movement in the early stage. While there was no significant difference between understory grassland and shrub land, indicating that the research about the effects of vegetation cover type on water-salt transport should take a longer time scale.

*[5] Trijunção Farm (Agricultural Manager's office, Jaborandi, Brazil)*

*flavia.santos@embraapa.br

**ABSTRACT**

Brazil has approximately 100 million hectares of pastures with medium to low vigor, a situation that is even more critical in sandy soils due to their chemical, physical, and biological fragility. To address this problem, the Brazilian government issued a decree aiming to restore around 40 million hectares of degraded pasture by 2023, and the introduction of integrated systems has emerged as a viable technology to achieve this goal. In 2019, a research initiative was launched by Embrapa at Fazenda Trijunção, located in western Bahia, Brazil, to study the management of a sandy soil, plant, and animal components through the implementation of the Low carbon beef (LCBB) protocol, under integrated crop-livestock production system. For the soil component, samples were collected at depths of 0–10 cm, 10–20 cm, and 20–40 cm to measure the soil health (specifically in the 0–10 cm layer) (Mendes et al., 2024) and carbon sequestration (CS). The study evaluated the LCBB protocol against a LCBB control, that represents the conventional system or extensive pasture (low input), and the natural Cerrado (Cer) as a baseline. Carbon sequestration was found to be higher in the LCBB (13.55 and 11.77 Mg $ha^{-1}$) compared to the LCBB control (10.89 and 9.48 Mg $ha^{-1}$) and to the Cerrado (8.64 and 9.61 Mg $ha^{-1}$) in the 0–10 cm soil layer for 2019 and 2023, respectively. In the 10–20 cm soil layer, no significant differences were observed among the three systems. However, in the 20-40 cm soil layer, the Cerrado exhibited greater CS than the LCBB and LCBB control systems, but only in 2023, with no significant differences observed between the latter two. No significant differences were observed between 2019 and 2023 within each system. Results from 2019 indicated that both, LCBB and LCBB control, showed a critical soil health condition, with scores falling between the “getting sick” and “unhealthy” classes, respectively. This condition reflected the history of extensive use and low organic matter inputs typical of extensive pastures in Brazil. In the 2023 sampling, the recovery trend was consolidated in LCBB, classifying the soil as “healthy,” while the LCBB control remained in the “getting sick” condition, with no significant changes since 2019. These results indicate a progressive gain in organic carbon and an improvement in nutrient storage in the LCBB area. The higher forage and meat production observed in the LCBB (data not presented) further supports the potential of the LCBB protocol as effective solutions for restoring degraded pastures.

## ABSTRACT

Farming systems in the southwestern United States are facing intense challenges due to recurrent droughts and land degradation. Agricultural producers are actively seeking methods to enhance soil health and improve soil resiliency against drought. A long-term soil health study was initiated at the Leyendecker Plant Science Research Center in Las Cruces, New Mexico, USA, to investigate the impact of management practices on soil health indicators in a corn silage (*Zea mays* L.) cropping system. Tillage methods tested on the plots every year were conventional, strip tillage, and no-tillage. Cover crop treatments imposed on the plots every year include no cover crop (NC); single species cover crop (SC), [triticale (*x Triticosecale* Wittmack), and multiple species cover crops (MC), [a mixture of triticale, barley (*Hordeum vulgare*), Austrian winter pea (*Pisum sativum* L.), and daikon radish (*Raphanus sativus*)]. Soil amendment treatments consisted of a compost-biochar blend, applied only once at two rates (0 and 33.6 Mg/ha). The biochar made from lodgepole pine (*Pinus contorta* Douglas ex Loudon) was 10% of the blend. The treatment combinations were replicated four times, and the plots were maintained under the same treatments. Multiple physical, chemical, and biological soil measurements were assessed. After four years, significant main treatment effects were observed for many of the soil indicators measured. Two-way and three-way interactions were mainly not significant for the indicators. The compost-biochar amendment resulted in a 16% increase in soil organic matter (SOM). It increased several plant nutrients in the soil, including Olsen phosphorus by 76%, potassium by 9%, zinc by 56%, iron by 12%, and copper by 7%. The amendment application also resulted in a slight but significant reduction in pH. The SC cover crop treatment had the highest total microbial (TM), total bacterial (TB), total fungal (TF), and arbuscular mycorrhizae fungi (AMF) biomasses compared to MC and NC. Compared to the NC treatment, the SC increased TM by 30%, TB by 30%, TF by 75% and AMF by 66%. Furthermore, the cover crop treatment (both SC and MC) increased the soil aggregation by an average of 11% and soil water infiltration by an average of 33% compared to the NC treatment. No-tillage treatment had 7.5% more SOM than the strip tillage treatment, but it was not statistically different from the conventional tillage. The impacts of reduced tillage were not shown for many of the indicator measurements, probably due to the longer time it takes for its benefits to become apparent. This study demonstrates that using cover crops and organic amendments could provide quicker benefits for soil health improvements in irrigated arid agroecosystems.

# Dynamic of soil organic carbon and phosphorus for different technological options in the Peruvian Amazon

**Vega-Ravello, R.[1], Alegre, J.[1]*, La Torre, B.[1], García, S.[1], Loli, O.[1], and Dueñas, A.[2]**

[1] *Soil Science Department, Universidad Nacional Agraria La Molina - UNALM, Lima, Peru*

[2] *Horticulture Department, Universidad Nacional Agraria La Molina - UNALM, Lima, Peru*

*E-mail jalegre@lamolina.edu.pe

**ABSTRACT**

The Peruvian Amazon covers 60% of Peru's territory and consists of tropical forests with very high biodiversity. The predominant soils are Ultisols, which are acidic, infertile, and low in organic matter and phosphorus (P) with a high percentage of aluminum saturation. Currently, 10 million hectares of this region have been deforested by migratory slash-and-burn agriculture and. Soil organic carbon (SOC) and available P are the best indicators of soil productivity and fertility and monitoring them over time will allow for the diagnosis of the recovery or degradation of Amazonian soils. The objective was to evaluate the dynamics of SOC and P over five years in 15 technological soil use systems (SUS) along the Tarapoto-Yurimaguas highway in the Peruvian . The study was conducted in two locations in Yurimaguas (Loreto) and Tarapoto (San Martin), on Ultisols soils. The SUS evaluated in the lower Amazon were primary and secondary forest, multi-layer SAF (*Cedrelinga cateniformis* and *Centrosema macrocarpum*) with 10% and 4% clay, Brazil nut (*Bertholletia excelsa*) with coffee (*Coffea arabica*), oil palm (*Elaeis guineensis*) with kudzu (*Pueraria phaseoloides*), palmito (*Bactris gasipaes*), pijuayo (*Bactris gasipaes*) with kudzu, improved grass (*Brachiaria brizantha*) with centrosema and degraded (native grass with a predominance of torourco (*Axonopus compressus*)). In the high forest, cocoa (*Theobroma cacao* L.) was evaluated with secondary forest shade, cocoa with planted shade trees, cocoa without shade with centrosema cover, improved coffee (*Coffea arabica* L. var. Caturra) and traditional coffee, both under shade. SOC, bulk density and available P were measured at two depths (0-15 and 15-30 cm). The evaluations were carried out during the lowest and highest rainfall periods, with an annual average of 2200 mm. SOC shows fluctuating dynamics, with accumulation favored by dry seasons and decomposition favored by rainy periods. In general, the surface layers of the SUS contain higher SOC, fluctuating from 0.35 to 1.94% in the SUS located in the Amazonian plain, which tend to have lower COS content than the SUS located in the high jungle, which fluctuated between 0.74 and 3.92%. Of the SAFs, cocoa grown under secondary forest shade has the highest SOC content (1.68-3.92%), while perennial crops such as oil palm, pijuayo, and others exhibit the lowest contents (0.57-1.69%). Available P was very low in the lowland forest SUS, except for the fertilized pijuayo, and the upland forest SAFs had higher levels due to better soils and fertilization. SOC showed a cyclical accumulation trend favored by the dry season and greater mineralization during wet seasons. The surface horizon had higher SOC and P contents, which were higher in the SUS of the Upper Forest. Among the forest-cocoa SAFs, SOC and P were higher than in systems with perennial crops. SOC was proven to be a robust indicator that depends on climate and soil management.

# Effects of straw returning method and irrigation lower limit on soil water and salt regulation and crop physiological characteristics in saline-alkali land of the Yellow River Delta

**Hanyu Zheng[1], Jie Zhang[1*], Tingting Chang[1], Baihui Li[1], Ronglu Wu[1], Yidan Zhang[1], Le Cui[1], and Dong Zhang[1]**

**ABSTRACT**

Optimizing saline-alkali soil management in the Yellow River Delta requires understanding the interaction between irrigation regimes and straw return methods under water scarcity. A maize-wheat rotation system was employed with two irrigation lower limits (W1: -30 kPa, W2: -60 kPa) and four straw return methods (RS: in-situ return; RM: manure return; RB: biochar returning; RG: pellet returning) on soil parameters (pH, EC, organic matter, available nutrients) and crop physiological indicators (antioxidant enzymes, photosynthesis, growth traits, and yield). The RB treatment with W2 irrigation is projected to significantly improve soil conditions by reducing EC and increasing organic matter. RB and RM treatments are anticipated to enhance antioxidant enzyme activities while reducing MDA content and boosting photosynthetic rate. The moderate water deficit with RB/RM treatments is expected to achieve higher water use efficiency while maintaining or improving yield by 5-10%. The findings will demonstrate that moderate water deficit combined with biochar or manure returning constitutes an effective model for sustainable agricultural production in saline-alkali soils.

**ABSTRACT**

The intensification of agriculture has often led to the degradation of soil, which is a critical non-renewable resource. This study suggests that regenerative organic practices can reverse this trend, enhancing soil ecosystem functions and improving water and nutrients biogeochemical cycles. Our research, conducted at the European Regenerative Organic Center (EROC), will specifically investigate: (1) the temporal dynamics of soil quality indicators – including organic matter pools, nutrient content, microbial community structure and activity, hydrological and physical properties – under a prescribed regime of cover crops, organic amendments, and minimal disturbance; and (2) the subsequent translocation of soil-derived benefits into the plant system, measured as shifts in nutrient content and secondary metabolite profiles.

Preliminary baseline data and the experimental framework for tracking changes in key soil health indicators: soil organic matter (SOM) dynamics, microbial biomass and activity, and water-stable aggregates. Crucially, this study moves beyond soil metrics to explicitly trace the soil-plant continuum. We are analyzing how shifts in soil microbial community structure and nutrient cycling – particularly the mobilization of nitrogen, phosphorus, and micronutrients – influence the biosynthesis of plant secondary metabolites and the nutrient density in harvested crops.

Achieved and expected results include a quantifiable increase in soil organic carbon and a shift in microbial biodiversity towards fungal-dominated communities, providing a mechanistic understanding of the soil-plant nexus. We anticipate demonstrating that these ecological intensification strategies not only support yields but fundamentally enhance the nutritional value of crops. The broader impact of this work is to provide robust, scientific evidence to catalyze a circular bioeconomy, where agricultural value is derived from enhancing natural capital rather than depleting it, directly supporting European objectives for sustainable food systems.

**ABSTRACT**

The dynamics of the land cover of the territory within the modern boundaries of the Smolensk Lakeland National Park (Russia). A comprehensive study in the Smolensk Lakeland National Park analyzed natural recovery of ecosystems on abandoned farmlands: 3 chronoseries (Pine, Spruce, and Mixed coniferous-broadleaf reforestation) across 7 stages. The methodology included 173 vegetation plots, 80 soil pits, >2,500 soil, 447 macrofauna and 196 metagenome samples.

Successions of the 3 series develop according to a common scheme, but have specific features. Due to similar environmental conditions and nearly identical recovery responses, the Pine and Spruce series were grouped into one technobiogeome by M.A. Glazovskaya (units with a similar recovery response after plowing ceases. In a 1:150,000 scale, the map of technobiogeomes is based on indicator properties that define each recovery stage:

Stage 0: plowing area.

Stage 1 (fallow meadows; up to 30 years of reforestation): A continuous Oi and Oe layer forms. Macrofauna diversity is low ("arable" type). The soil microbiome begins to shift. Soil macrofauna diversity increases ("meadow" type).

Stage 2 (forests; up to 30 years): A fragmented Oe layer appears. In P and S series, total carbon (SOC) and nitrogen (Ntot) levels recovered in the Oi layer, soil pH recovered.

Stage 3 (60-70 years): A Oa layer forms. In the Oi layer of the M series, SOC and Ntot are restored. Forest herbs begin to replace meadow species. In soil, "sorest" macrofauna appeared.

Stage 4 (up to 80 years): The Oa layer gains mass. The former plow layer (Ap) degrades significantly. Epigeic macrofauna diversity is fully restored.

Stage 5 (up to 110 years): The A(p) horizon transforms into a native-like A layer. The soil saprophagous complex recovers. Tree species ratio normalizes; herbaceous weedy plants disappeared.

Stage 6 (>110 years): In herb and shrub layers, composition of plant life-forms is restored. The soil microbiome is fully recovered. Windfall soil complexes and large decomposing logs appear. Signs of the old plow layer remain visible in the soil profile.

According to the cluster analysis, P, S and M forest ecosystems recover in 30, 70 and 80 years, respectively. According to ordination regression based approach, ecosystem recovery rates decrease with time. The P and S series ecosystems recover in 75 – 105 years, faster than the M series (117 – 127).

# Impact of Intensive Vegetable Production on the Properties of Andisol

**Grizel D. Candelario[1], Victor B. Asio[1*], Deejay M. Lumanao[1], and Luz G. Asio[2]**

[1]*Department of Soil Science, Visayas State University, Baybay City, Leyte, Philippines*

*Email: vbasio@vsu.edu.ph

**ABSTRACT**

The conversion of forests to agricultural land use is widespread across many parts of the tropics and is considered a major cause of soil degradation (Asio et al., 2024). On Leyte Island in central Philippines, large areas of volcanic mountain slopes with young volcanic soils (Andisols) have been cleared and converted into intensive vegetable farms. The cool and wet climate (Af in Koeppen climate classification) due to its high elevation (700-900m asl) and the excellent physical properties of the Andisols favor the intensive cultivation of high-value vegetables such as cabbage (*Brassica oleracea*), beans (*Phaseolus sp.*), squash (*Cucurbita maxima*), bell pepper (*Capsicum annuum*), Chinese pechay (*Brassica rapa*), eggplant (*Solanum melongina*), and tomatoes (*Solanum lycopersicum*). Farmers practice heavy application of chicken manure, combined with chemical fertilizers, with or without lime. The objective of the study was to evaluate the impact of intensive vegetable cultivation on the morpho-physical, chemical, and biological properties of the Andisol soil formed from andesitic pyroclastics (Jahn and Asio, 2006). Using the adjacent area approach (space-for-time substitution approach), farms that had been cultivated intensively for varying durations ranging from over 10 to over 60 years were evaluated and compared with the adjacent natural forest. The five (5) farms selected were intensively cultivated for >10, >20, >30, >40, and >60 years, respectively. Soil profiles representing the forest and the vegetable farms were described and sampled, and composite surface samples from the 0-20 and 20-40 cm soil depths were collected for laboratory analysis of physical, chemical, and biological properties.

Results revealed that the soils in the forest and intensively cultivated farms have comparable horizons in their profiles, suggesting similar genesis. The soils are all young volcanic soils characterized by a cambic B horizon (Bw). Prolonged cultivation increased bulk density due to soil compaction from tillage and field operations, thereby decreasing porosity. Conversely, the forest showed lower bulk density and higher porosity values. The forest exhibited the highest water-holding capacity due to better soil aggregation and higher organic matter content. However, long-term intensive cultivation, particularly in sites with over 60 years of cultivation, reduced the water-holding capacity due to soil compaction and structural alterations. Agricultural practices slightly modified the natural soil textures, which were primarily driven by erosion, sedimentation, translocation, and weathering. Soil pH changed slightly due to prolonged cultivation. However, pH fluctuations occur across different cultivation periods, with deeper soils exhibiting slightly higher pH values. Soil organic matter decreased with prolonged cultivation, particularly in surface layers, while total nitrogen levels remained relatively stable. Available phosphorus levels increased with long-term cultivation, attributed to fertilizer use and organic material application. Exchangeable potassium levels remained higher in cultivated farms than in the forest, emphasizing the impact of agricultural practices on nutrient management. Exchangeable calcium and magnesium concentrations varied among farms, influenced by management practices and fertilizer application. Long-term cultivation led to a decrease in soil exchangeable calcium levels, highlighting the impact of intensive farming on soil nutrient dynamics and fertility. Comparable $CO_2$ evolution rates were observed between vegetable farms and the forest site. Still, farms with longer cultivation durations exhibited higher rates due to greater organic matter input from crop residues and compost.

## ABSTRACT

Herbivore grazing is a key driver of soil organic carbon (SOC) sequestration in grassland ecosystems. Plant diversity responses and their linkages to soil limiting resources play a critical role in mediating the impacts of grazing on SOC dynamics. Soil nitrogen (N) is widely recognized as the primary limiting resource in grassland ecosystems, however, the mechanisms by which grazing regulate SOC stocks by shaping the relationships between soil N availability (in terms of quantity and spatial heterogeneity) and plant diversity across varying spatial scales remain poorly understood. Here, we conducted a 9-year controlled sheep grazing experiment in the Horqin sandy grassland of northeastern China to explore how grazing impacts SOC stocks at the large (25 m×25 m) and small (5 m×5 m) spatial scales. We found that grazing significantly increased SOC stocks at both large and small scales. At the large scale, grazing not only directly increased SOC stocks but also promoted SOC sequestration via enhancing the positive correlations between the heterogeneity of soil N availability and plant α-diversity. At the small scale, in addition to directly increasing SOC stocks, grazing facilitated SOC sequestration through boosting the relationships between the quantity of soil N availability and plant α-diversity. Furthermore, grazing had no effect on SOC stocks by altering plant β-diversity, irrespective of spatial scale. Therefore, our findings indicate that the scale-dependent mechanism underlying grazing-induced promotion of SOC stocks operates through regulating the associations of the quantity and heterogeneity of soil limiting resources and plant α-diversity in grasslands. These findings further highlight the significance of grazing-mediated synergistic linkages among "soil resource heterogeneity-plant diversity-ecosystem function" for maintaining grassland ecological processes. We therefore recommended long-term moderate sheep grazing as an effective grassland management practice for enhancing grassland soil C sequestration.

## ABSTRACT

Understanding the key factors that determine soil quality is essential for the recent and rapid expansion of rubber plantations in the tropics. Tropical China is an ideal experimental area because its rubber plantations are geographically dispersed and belong to different climatic zones. Soil quality in this study was comprehensively evaluated using a soil quality index (SQI) based on 28 soil physical, chemical and biological properties. And the factors driving variation in the SQI of rubber plantations were analyzed utilizing the redundancy analysis and a structural equation model. The results indicated that no age effect of the plantation on soil quality was observed in the same rotation period, whereas the SQI of rubber plantations was found to be relatively low after long-term cultivation. There was an apparent discrepancy in the spatial distribution of the SQI of rubber plantations. And the SQI demonstrated a declining trend with increasing soil depth, with the SQI of the surface soil layer (0-10 cm) exhibiting a significantly higher value than that of deeper soils. Soil condition was found to be predominant in the SQI variation of rubber plantations, particularly the seven soil properties including saturated water capacity, easily oxidizable organic carbon, ammonium nitrogen, available phosphorus, total potassium, manganese, and zinc. The direct effects of geographical location, vegetation cover, and climatic variables on rubber plantation SQI variation were relatively weak, while they indirectly affected the SQI variations by influencing the soil condition. The SQI results are expected to provide a quantitative foundation for enhancing soil quality in rubber plantations in the tropics.

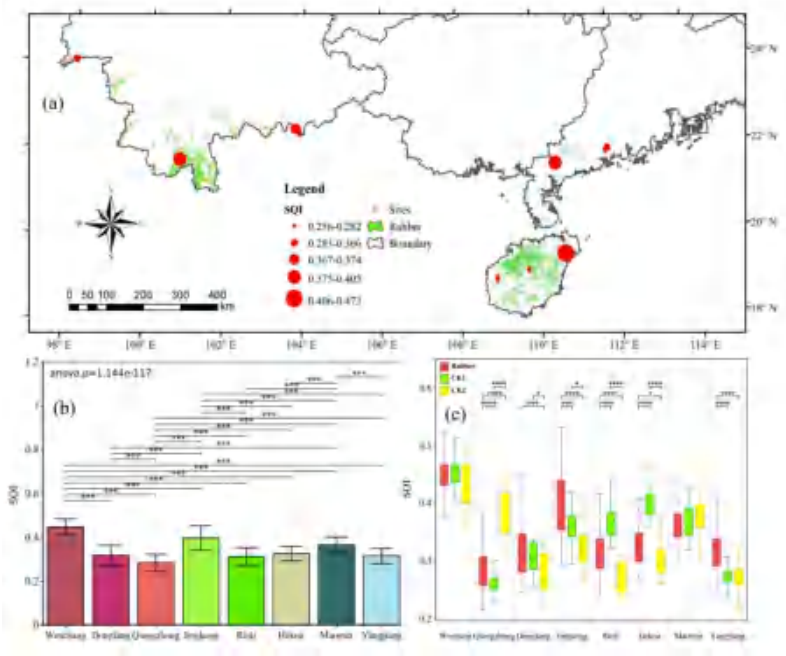

Fig.1. Soil quality index (SQI) values under rubber plantations on tropical China: (a) spatial distribution, (b) variation among eight planting regions, (c) difference between rubber plantations and References plots (CK1 and CK2 are two tropical vegetation).

## ABSTRACT

Phosphorus is an important indicator for understanding the characteristics of urban soils, as its concentrations reflect both the intensity and the duration of anthropogenic influence in cities. In urban environments, phosphorus levels are shaped by multiple factors, including the degree of urbanization, historical and current land use, atmospheric deposition, inputs from traffic and pets, management of green areas, fertilizer use, and organic waste accumulation. Soil available (labile) phosphorus (SAP) is particularly important because it directly reflects the portion of phosphorus that is exchangeable, mobile, and accessible to plants and humans. Monitoring SAP makes it possible to reconstruct past land-use practices, detect disturbed or anthropogenic horizons, and assess the magnitude of human impact on the urban pedosystem. Excessive SAP concentrations may also migrate through the unsaturated zone and affect groundwater quality, while imbalances in the root zone can limit nutrient uptake and influence vegetation health. Therefore, SAP represents a valuable chemical marker for interpreting the properties and functioning of urban soils. This study examines the variability of SAP in Belgrade's soils in relation to the degree of urbanization, represented by four spatial zones (central, suburban, external, and rural). SAP was measured in 126 composite samples from topsoil (0–10 cm) and subsoil (10–40 cm) using the Egner–Riehm Al method (Knežević and Košanin, 2011). Mean SAP concentrations (mg/100g) in topsoil followed a clear urban-rural gradient: central (65.44) > suburban (38.58) > external (13.25) > rural (7.25). Subsoil showed the same pattern, ranging from 65.28 in the central zone to 3.88 in the rural zone. SAP values displayed a wide range in urban zones (e.g., 0.52–558.74 mg/100g in central topsoil), while rural soils showed considerably narrower variability. Overall, extremely high SAP concentrations were recorded in some locations, which considerably exceeds the upper threshold of the very high SAP class (>20 mg/100 g) by more than an order of magnitude. The results indicate a pronounced increase of available phosphorus toward the city centre, forming a distinct urban "hotspot". These exceptionally high SAP concentrations, particularly in the central and suburban zones, likely reflect long-term cumulative anthropogenic inputs typical of large metropolitan areas, such as the continuous population growth, development of the transport network and increase in vehicles, higher presence of pets, among others. This pattern emphasizes the need to account for urbanization processes in soil planning and management and their influence on regional phosphorus cycling and phosphorus availability for urban vegetation.

# Rate of decomposition of litter fall and nutrients recycling in three soil use systems in the Peruvian Amazon

**Alegre, J. [1]*, Pérez, K., and Vega-Ravello, R.**

[1] *Soil Science Department, Universidad Nacional Agraria La Molina - UNALM, Lima, Peru*

*E-mail jalegre@lamolina.edu.pe

**ABSTRACT**

Within the overall functioning of forests and other soil use systems (SUS) in the humid tropics, litter plays a very important role in energy flows and nutrient recycling and is often considered the largest flow of nutrients between vegetation and the soil surface. Decomposition and nutrient input are a fundamental process for the growth of trees, shrubs, and other species in the great biodiversity of plants found in the forest in the humid tropics. The study was conducted in three contrasting and representative SUS in the humid tropics of the Peruvian Amazon in Yurimaguas (Department of Loreto), including primary forest (PF), pijuayo (*Bactris gasipaes*) with kudzu (*Pueraria phaseoloides*) (PK), and improved grass (*Brachiaria brizantha*) with centrosema (*Centrosema macrocarpum*) (IG). The decomposition rate of leaf litter and the contribution of carbon (C), nitrogen (N), phosphorus (P), and potassium (K) was evaluated over a year using nylon mesh decomposition bags with a 5 mm opening, which were placed in very good contact with the soil surface. Six bags were collected monthly from each SUS to evaluate the remaining biomass and released nutrients. Analysis of variance (ANOVA) was used, where the SUS and months were considered as the main effects. During the evaluation year, rainfall was 2,200 mm per year, with periods of higher rainfall between September and March. When characterizing the chemical composition of leaf litter, the PF system had the highest % of C, lignin, and lignin/N ratio, the PK had the highest % of N and K and the lowest %P and lignin/N ratio, while the IG had the lowest % N and lignin and the highest % P. The PF soil is extremely acidic with 60% aluminum saturation, while the PK and IG soils have a moderate pH and lower acidity. The PK and IG systems showed similar decomposition rates, higher than that of the PF, and the remaining biomass at the end of the year was 8.32% and 6.58%, respectively. Likewise, N release rates were higher in the PK and IG systems, increasing during the rainy season, as these systems maintain leguminous cover crops that recycle N and decompose more quickly. The contribution of leguminous leaf litter in the recycling process improves the quality of humus with the formation of humic and fulvic acids that also determines the quality of the clay-humic complex and maintains better soil physical and chemical properties.

At the end of the evaluation, the following order of nutrient release from leaf litter was observed in the three systems evaluated: potassium > phosphorus > nitrogen = carbon. The dynamics of decomposition are linked, first and foremost, to the composition of plant material in terms of lignin concentration and the lignin/nitrogen ratio, followed by climatic conditions and the coverage (architecture) of the system, and finally the intense activity of the microorganisms and macrofauna associated with soil quality and health.

## ABSTRACT

Soil microbial communities play a critical role in nutrient cycling and agroecosystem resilience, yet their responses to long-term tillage practices in semiarid environments remain poorly understood. This study evaluated the effects of 20 years of conventional tillage (CT), minimum tillage (MT), and no-tillage (NT) on soil bacterial communities, integrating physicochemical analyses with high-resolution 16S rRNA amplicon sequencing to characterize shifts in microbial diversity and taxonomic composition. Soil samples were collected from a long-term tillage experiment established in Policoro, Southern Italy, where durum wheat (*Triticum durum*) and faba bean (*Vicia faba*) have been grown under a biennial rotation for over 20 years. Composite soil samples (0–30 cm depth) were taken from replicated plots.

Although major chemical properties, such as pH, organic matter, total nitrogen, and carbonates showed no significant differences among treatments, MT and NT soils improved the availability of key micronutrients relative to CT. Copy numbers of the functional microbial genes involved in denitrification (*nirK*, *nirS*), iron reduction (*gltA*), and sulfate reduction (*dsrAB*) were significantly higher under NT and MT than CT, indicating stimulated anaerobic microbial processes in reduced-tillage systems.

Sequencing revealed a pronounced compositional restructuring of bacterial communities across treatments. NT and MT soils were enriched in copiotrophic phyla such as Actinobacteria and Firmicutes, consistent with improved nutrient retention and reduced physical disturbance. Conversely, CT soils were dominated by oligotrophic phyla adapted to nutrient-poor and disturbed environments. Venn analysis highlighted distinct microbial signatures for each management system, with MT harboring the greatest number of unique genera, followed by NT and CT, demonstrating that long-term tillage intensity strongly filters community membership. Beta-diversity analyses (PCoA, PCA, PERMANOVA) demonstrated clear community separation among tillage regimes, confirming robust shifts in bacterial assemblages, although alpha diversity (Faith's PD) showed no significant differences among treatments.

Overall, long-term NT and MT practices reshape soil bacterial communities toward functionally enriched, nutrient-responsive taxa and promote key microbial processes, underscoring the ecological advantages of conservation tillage for sustainable soil management in semiarid agroecosystems.

## ABSTRACT

Soil knowledge across Europe varies considerably depending on biogeographical region and land use. In this context, there is a notable lack of information regarding soil ecosystem service interactions, particularly in Boreal, Alpine, and Atlantic regions under wetland and semi-natural land uses. On the other hand, urban, forest, and mining soils show high uncertainty due to their pronounced heterogeneity and contamination levels. This study evaluates key physico-chemical parameters related to different ecosystem services across 25 experimental sites distributed over five biogeographical regions (Alpine, Atlantic, Boreal, Continental, and Mediterranean) and seven land use types (urban, industrial, agricultural, forest, mining, semi-natural, and wetland). The effects of region and land use on a range of soil quality and health indicators including physical and chemical properties at 0–20 cm depth were assessed. Results show that organic soils in the Boreal region have significantly higher total organic carbon (TOC), particulate organic carbon (POC), $NH4^+$, and exchangeable Na compared to mineral soils in other regions. Among mineral soils, higher inorganic carbon, exchangeable Ca, cation exchange capacity (CEC), and pH were found in the Mediterranean region. At the regional level, industrial soils from Alpine region showed higher levels of bioavailable Al and Fe than agricultural and wetland land uses. In the Atlantic region, semi-natural soils exhibited higher soil water at field capacity (SWC), soil water at wilting point (SWW), TOC, POC, $NH4^+$, and bioavailable Al compared to agricultural soils. In the Boreal region, mining soils showed higher TOC and POC than agricultural soils. In the Continental region, forest soils contained more TOC and POC than soils under urban, agricultural, mining, and semi-natural uses. Finally, in the Mediterranean region, semi-natural soils displayed higher SWC, SWC, TOC, POC, exchangeable Ca, and CEC compared to industrial soils. These findings highlight the elevated organic matter content of organic soils, and the surprisingly high fertility indicators in Mediterranean soils, which are typically considered low fertility. In general, Semi-natural and forest uses tend to enhance soil organic matter and structure.

**ABSTRACT**

Publishing soil data is pivotal for advancing soil research and informing policy decisions, as it provides harmonized information and facilitates access to relevant data (Panagos et al., 2022). Adhering to FAIR principles enhances the reusability and interoperability of data, contributing to a better understanding of soil and agricultural systems (Lachmuth et al., 2025). Long-term agricultural field experiments (LTEs) are essential for comprehending sustainable farming systems, offering invaluable insights into management practices and their impact on soil processes, productivity and environmental interactions, which unfold slowly, necessitating decades to observe measurable changes (Johnston & Poulton, 2018). The Austrian Agency for Health and Food Safety (AGES) has therefore established several LTEs in major agricultural production areas in Austria to provide data and deepen understanding of the impact of various agricultural management practices on soils such as different tillage systems. This study describes data obtained from a tillage LTE established in 1988, and still running today, containing data on soil chemical, physical and biological parameters, primary production (yields), plant nutrients and management data. The tillage LTE, which is conventionally managed, is located in Fuchsenbigl, Lower Austria, in the main production area of the Marchfeld (north-eastern lowlands and hills). Three different treatments are applied: minimum tillage (5-8 cm), reduced tillage (15 cm) and conventional tillage (25-30 cm). The soil parameters are available at various soil depths to a maximum of 100 cm. This study offers invaluable insights and advances our understanding of the agroecological implications of contrasting tillage systems.

**ABSTRACT**

Selecting agricultural practices that strengthen the resilience of production systems is essential for improving agricultural sustainability. This is especially true in the U.S. Northern Great Plains (NGP), where extreme weather events are common, and the adoption of soil health practices can provide substantial agronomic and environmental benefits. The objectives of this research were (i) to identify and rank the most frequently studied soil health practices and indicators in the NGP, and (ii) to quantify the effects of the five leading practices on soil organic carbon (SOC). A comprehensive search was conducted in Web of Science, Scopus, and ProQuest to identify all published articles, theses, and dissertations using the following search terms: [("soil health" or "soil quality") and ("Northern Great Plains" or "North Dakota" or "South Dakota" or "Montana" or "Wyoming" or "Minnesota" or "Nebraska" or "Alberta" or "Saskatchewan" or "Manitoba")]. The search returned 897 publications, which were then screened to remove duplicates. From the complete database, a total of 160 studies were selected using the following criteria: (i) conducted in cropland or rangeland systems, (ii) located within the NGP, and (iii) evaluated at least one soil health practice falling within one of the following broader categories: cover crops, crop rotation, crop sequence, crop-livestock integration, grazing, non-agricultural ecosystems (e.g., grassland, prairie), reduced tillage, organic amendments, residue management, and water management. Across all studies, the five most measured soil health indicators were, in order: soil organic carbon (SOC), bulk density, soil inorganic nitrogen, total nitrogen, and pH. The five most frequently studied practices were crop sequence, cover crops, no-till, crop rotation, and grazing. For the meta-analysis, we focused on SOC and these five leading soil health practices. To ensure equivalent comparisons across studies, the dataset was stratified by soil depth (topsoil [0–15 cm] and subsoil [15–30 cm]) and study duration (short-term [≤ 7 years] and long-term [> 7 years]). The SOC effect size was expressed as the ratio of SOC under the soil health practice relative to its corresponding control. In the topsoil, all practices increased SOC across both study durations, with the strongest effects observed under long-term crop rotation, cover crops, and grazing. In contrast, short-term studies showed greater SOC gains from crop sequence, no-till, and grazing. In the subsoil, cover crops did not significantly affect SOC at either study duration, whereas no-till consistently increased SOC in the long term. Overall, none of the practices increased subsoil SOC in the short term. These findings indicate that increasing SOC and improving the resilience of production systems in the NGP is achievable when soil health practices are implemented, and that these benefits can be strengthened when multiple practices are integrated.

# The nonlinear response effect of arable land quality on arable land fragmentation in mountain areas

**Ranran Pang[1,2], Fengkui Qian[1,2]**

*[1] School of Humanities and Law, Northeastern University, Shenyang 110169, China*
*[2] Key Laboratory of Land Protection and Utilization, Liaoning Provincial Department of Natural Resources, Shenyang, Liaoning*

## ABSTRACT

Clarifying the nonlinear impact of arable land fragmentation (ALF) on arable land quality (ALQ) has important significance for the protection and sustainable utilization of arable land resources. Taking the mountain areas in eastern Liaoning Province, China as the research object, this study used the LESA (Land Evaluation and Site Assessment) model and the landscape pattern indices to construct an evaluation system for ALQ and ALF. The piecewise linear regression model and the conditional inference trees were used to analyze the nonlinear impact of the ALF indices on ALQ and the thresholds. The results show that ALF shows a two-stage impact on ALQ, i.e., strong inhibition and weak promotion. The critical thresholds of the impact of the ALF indices, including the arable land fragmentation index (ALF), shape fragmentation index (SFI), distribution fragmentation index (DFI), and area fragmentation index (AFI) on ALQ are 0.155, 0.341, 0.07, and 0.089, respectively. In terms of the fractal dimensions of ALF, the impact of mean patch size (MPS) and aggregation index (AI) on ALQ is characterized by strong suppression and weak promotion, with thresholds of 5.842 ha2 and 96.618%, respectively. Edge density (ED) and area-weighted mean shape index (AWMSI) exhibit strong inhibition and weak promotion impacts on the ALQ, with critical thresholds of 2.28 and 0.155 m/ha, respectively. The comprehensive evaluation of the multiple indices of ALF shows that when AWMSI ≤ 1.977, MPS > 6.593 hm2, and ED ≤ 172.719, the optimal ALQ in the mountain area appears. The research results provide support for the protection and management of arable land.

# Initial soil carbon status governs soil C stock changes, while pore characteristics improve after conversion of arable land to semi-natural grassland

**Johannes L. Jensen[1], Esben Ø. Mortensen[1], Jørgen Eriksen[1], Bent T. Christensen[1], Lars J. Munkholm[1*]**

[1] *Department of Agroecology, Aarhus University, Denmark*

## ABSTRACT

The conversion of arable land to grassland is widely recognized as an effective measure to mitigate climate change and reduce soil degradation. However, the extent to which this conversion influences soil properties remains poorly understood, particularly in relation to initial soil organic carbon (SOC) content and the subsequent rate of change in soil characteristics.

Soil samples were collected from the Askov long-term straw incorporation and cover cropping experiment, initiated in 1981, terminated in spring 2020, and subsequently converted to semi-natural grassland. The site is located in southern Jutland, Denmark (55°28′N, 09°06′E) on sandy loam in a cool temperate climate. The experiment followed a two-factorial split-plot design with three replicates: main plots varied in straw incorporation rate (SR), and subplots included cover crop (CC) treatments with or without ryegrass. Spring barley (*Hordeum vulgare* L.) was grown from 1981 to 2019, with straw incorporated at 0, 4, 8, or 12 Mg ha$^{-1}$ yr$^{-1}$. In 2020, a grass mixture was undersown in barley; after harvest, no fertilizer was applied, and grass biomass was cut annually in August and left on the plots.

Loose soil was sampled from 0–20 cm in December 2019 (pre-conversion) and October 2023 (3.5 years post-conversion). Intact 100 cm$^3$ cores were taken from 6–10 cm in spring 2020 and autumn 2023. SOC was determined by dry combustion. Intact cores were analyzed for water retention at matric potentials of −1, −3, −10, −30, and −100 kPa, air permeability at −3, −10, and −30 kPa, and gas diffusivity at −10 kPa. Soil porosity was estimated from bulk density and predicted particle density (Schjønning et al., 2017).

SOC content was significantly influenced by SR and CC both before and after conversion. Bulk density decreased from 1.53 to 1.43 g cm$^{-3}$ and was only affected by SR prior to conversion. SOC stock change from 2020 to 2023 showed a near-significant SR effect (P = 0.07), with the greatest increase under straw removal and the largest decrease under 12 Mg straw ha$^{-1}$ yr$^{-1}$. SOC stock change correlated strongly with initial SOC. Before conversion, total porosity and plant-available water capacity were significantly affected by SR and CC, mainly through differences in 3–10 µm and 10–30 µm pores. After conversion, treatment effects disappeared, but total porosity increased from 0.415 to 0.455 m$^3$ m$^{-3}$, primarily due to expansion of >30 µm pores, especially >300 µm. Relative gas diffusivity, air permeability, and pore organization improved significantly, while tortuosity decreased. These findings indicate that conversion to grassland affected SOC dynamics depending on initial SOC status but markedly improved soil structural properties, overriding prior management effects.

## ABSTRACT

Healthy soils are fundamental to the sustainability of tropical grain production systems, particularly in regions characterized by high temperatures, increasing dry spells, and rapid turnover of soil organic matter. Under these conditions, management practices that strengthen biological functioning are essential for maintaining soil resilience and stable crop yields. Embrapa's Soil Bioanalysis Technology (SoilBio) provides an integrated approach to soil health assessment, combining routine chemical analyses with the quantification of key enzymatic activities—arylsulfatase (ARYL) and β-glucosidase (BETA)—which reflect essential nutrient-cycling processes. These indicators can provide insights into how cover crops influence soil functioning over time. SoilBio was applied to a field experiment established in 2021 in Balsas, Maranhão State, a major soybean-producing area within the MATOPIBA region of Brazil. The objective was to assess how forage grasses and other cover crops affect soil health and cumulative soybean yield across four growing seasons. Cover crops used in succession to soybean or in consortium with off-season maize included four forage species [*Urochloa brizantha* cv. Marandu, *U. ruziziensis*, *Megathyrsus maximus* var. Zuri, *M. maximus* var. Tamani] and a legume (*Crotalaria spectabilis*). Controls were soybean/fallow, soybean/maize, and soybean/millet. Treatments were arranged in strips with three repetitions. Soil samples from the 0–10 cm layer were collected in March 2024 and April 2025 for SoilBio analyses, and cumulative yield was calculated from four growing seasons. Yield was related to cycling, storage, and nutrient supply function scores. Forage grass–based treatments significantly improved soil biological functioning, with ARYL and BETA activities increasing by 67% and 85%, respectively, compared with fallow. These changes were accompanied by a 14% increase in soil organic matter and a 13% rise in cumulative soybean yield. Soybean productivity was strongly correlated with the SoilBio cycling function score ($r^2 = 0.56$), while no significant relationship was observed with storage or supply scores, indicating that nutrient cycling processes are the primary drivers of yield responses under the evaluated tropical conditions. The results highlight the importance of forage grasses as effective cover crops to promote soil health in soybean production areas of Maranhão. Additionally, the study demonstrates the robustness of SoilBio as a practical and sensitive tool to support the identification of sustainable soil management practices, reinforcing its value for guiding management decisions in tropical agricultural landscapes.

## ABSTRACT

Improving and maintaining soil quality in order to increase and sustain agricultural output is vital to India's food and nutritional security. To increase nitrogen use efficiency and reduce losses in Vertisols, a better understanding of nitrogen dynamics is necessary. The continuous use of organic manures in conjunction with fertilizers may increase mineralization and immobilization of plant nutrients, altering their levels in various organic and inorganic forms in soil (Umesh et al. 2014). When fertilizer N is applied preplant, it is concentrated at the beginning of the season, with soil N becoming the dominant N pool once the fertilizer N supply is depleted or immobilized (Bufogle et al. 1997). In the long-term fertilizer experiment being studied across the country, farmyard manure (FYM) incorporation has resulted in increased N mineralization potential in different cropping systems.

The existing system of fertilizer application is based on the nutrient requirement of the individual crop ignoring the carry over effect of the manures or fertilizer application to the succeeding crop to a great extent. Further, application of inorganic fertilizers even in balanced amount doesn't sustain the soil productivity. The indiscriminate use of chemical fertilizers is likely to cause environmental hazards, necessitating the need to develop a sustainable production system. In this context, integrated use of fertilizer with organics like farmyard manure, vermicompost and green manure assumes a greater importance as these organics improve the soil productivity and sustainability and brings down the mounting pressure on inorganic fertilizer substantially. Long-term fertilizer experiments (LTFE) have generated enormous and valuable information which could be used for sustainability of high input intensive agriculture. Therefore, the present investigation was carried out to study the long-term effect of nutrient management on various N fractions and their relative contribution to yield of sorghum and wheat.

The experiment was laid out in randomized block design with the following treatments for sorghum and wheat: (CK); absolute control (plots did not receive NPK fertilizers and FYM), (CF1); 50% NPK, (CF2 + OM); 75% NPK (recommended dose of fertilizer) + FYM, (CF3); 100% NPK, (CF3+S); 100% NPK + sulphur @ 37.5 kg $ha^{-1}$, (OM); FYM @ 10 t $ha^{-1}$ (each for sorghum and wheat) annually 20 t $ha^{-1}$ and (CF3+RM); 100% NPK + residue management. Each treatment was replicated four times. The required amount of well-decomposed FYM was applied on an oven-dry basis 5-7 days before sowing the sorghum and wheat crops. The recommended dose of fertilizer for sorghum it was 100: 50: 40 kg N, $P_2O_5$ and $K_2O$ $ha^{-1}$ and for wheat it was 120: 60: 60 kg N, $P_2O_5$ and $K_2O$ (annually for both the crops it is 220: 110: 100 kg N, $P_2O_5$ and $K_2O$ $ha^{-1}$) applied through urea, single super phosphate and muriate of potash in all treatments with two splits of nitrogen at the time of sowing and the remaining at 30 days after sowing for sorghum and 21 days after sowing for wheat. The full dose of P and K was applied at the time of sowing.

The representative moist soil samples were collected through a soil auger from surface layers (0–15 cm) from each plot during wheat and arranged as a composite sample as per standard protocol for laboratory analysis of soil. Organic carbon was determined following the procedure as described by Walkley and Black (1934). Available N was determined by alkaline-$KMnO_4$ method (Subbiah and Asija 1956). Available P was determined by extracting soil with 0.5 *M* $NaHCO_3$ as described by Olsen *et al.* (1954). Available K was determined by neutral normal ammonium acetate method (Hanway and Heidel 1952). Total N in soil samples was determined by digestion of soil samples with sulphuric acid at a temperature between 360 and 410 $^0$C in presence of $K_2SO_4$: $CuSO_4$ mixture followed by distillation. The ammonia liberated in the distillate was absorbed in boric acid and titrated against 0.005 *N* $H_2SO_4$ (Bremner 1965a). Inorganic (ammonium + nitrate)–N was determined by 2 *M* KCl extract as per the method given by Bremner (1965b).

**Mineral N dynamics in Sorghum-Wheat cropping sequence**

The results of the present experiment indicated that, the mineral N among various treatments ranged between 25.6 to 55.3 mg $kg^{-1}$ (Figure 1). The mineral N was increased significantly with the increasing levels of NPK alone or in combination with FYM. The application of FYM @10 tones $ha^{-1}$ each for sorghum and wheat (20 tones annually) and 75% NPK along with FYM were equally effective in improving the status of mineral N in soil. However, the magnitude of increase in mineral N was noted in the order of 50% NPK, 100% NPK and 150% NPK which could be attributed to the increasing order of fertilizer application. The increase in the mineral N content of soil with the

combined application of manures and fertilizers might be due to higher accumulation of organic matter and its subsequent decomposition and mineralization which contributed to accumulating higher amount of N over suboptimal treatments (Basumatary and Talukdar 1998). The contribution of inorganic N to total N was increased with the fertilizer N application to both the crops increased from 75 to 100% NPK. The higher mineral N contribution, however measured in plots receiving balanced fertilization alone or along with FYM. The higher mineral N content in soil was noticed during sorghum compared to wheat. The greater mineral N levels in soil during sorghum can be linked to favourable soil conditions, as contrasted to extremely low temperatures during wheat season, which may impact mineralization.

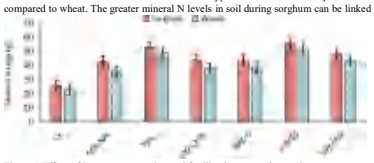

Figure 1 Effect of long term manuring and fertilization to sorghum-wheat sequence on mineral N during sorghum and wheat cropping in Vertisol

**SOC and Soil Properties**

The SOC content increased with various fertilizer and manure treatments over the initial status (4.6 g $kg^{-1}$) after continuous cropping for 37 years in all the treatments except 50% NPK. The increase in SOC content under integrated use of fertilizers and organic manure treatments might have been due to direct incorporation of organic matter, better root growth and more plant residues addition. Continuous use of balanced fertilizer over a period of time increased the available N, P, K and S status gradually under all the treatments than the control, and the maximum increase was observed with 75% NPK + FYM. The favourable soil conditions provided by FYM addition might have helped in mineralization of additional soil N leading to build-up of higher available N (Santhy *et al.* 1998). Almost all treatments enhanced available P status in soil, with the exception of the control, 50% NPK, and FYM alone treatment (FYM 10), which showed very little improvement. The higher available K observed under the NPK + FYM treatment is attributed to the direct addition of K through FYM, improved cation exchange capacity, reduced K fixation, reduced NPK level (50% NPK) and control treatments receive limited K inputs and show greater K depletion. The various fertilizer treatments greatly increased the soil's S status. This increase in available S was due to the application of single superphosphate (SSP) as a source of P, which contains a significant amount of S. The application of 75% NPK caused significant improvement in soil physical (bulk density, hydraulic conductivity and MWD) and biological properties (dehydrogenase, MBC, urease and phosphatase) indicating overall improvement in soil condition as evidenced by soil quality index (SQI). Based on the SQI, organic carbon, dehydrogenase activity, and hydraulic conductivity were identified as sensitive indicators that can change rapidly in response to management interventions. The sensitivity of organic carbon, dehydrogenase activity, and hydraulic conductivity suggests that these variables can serve as early and reliable indicators of soil quality changes resulting from management interventions. Manna et al. (1996) observed that an increase in dehydrogenase following the application of FYM might be attributed to an increase in microbial growth with the addition of carbon substrate. The only organic treatments found to be effective were those that increased dehydrogenase activity significantly. This can be ascribed to the fact that, as the primary source of carbon, organic materials and nutrients give energy for soil microbes and increase the number of pores, which are considered crucial in the soil-water-plant relationship, as well as maintaining excellent soil structure in conjunction with dehydrogenase.

**N uptake and N use efficiency**

The N uptake increases with N fertilization levels with balanced use of P and K fertilizer and showed further increase in presence of FYM. In general, the N uptake response was improved when 75% NPK was supplemented with FYM. The magnitude of N use efficiency was slightly increased with increase in levels of N, however, it was improved with balanced fertilization, further improvement was noticed with organic manure. Wanjari et al. 2022 reported that nutrient use efficiencies (NUE) in general of applied N, P and K in majority of crops gradually improved with addition of each nutrient. The efficiency further improved with INM, i.e. NPK+FYM across LTFE

sites. However, NUE had drastically reduced due to imbalanced use of fertilizers (Jadhao et al. 2019).

**Yield and sustainable Yield Index**

The various fertilizer treatments recorded significant increase in the grain yield of sorghum and wheat (Figure 1) over control (after 37th cropping cycle). The productivity, which further improved with the combined application of organic and inorganic fertilizers (75% NPK+ FYM). The increase in yield of sorghum and wheat was recorded to the tune of 39.5 per cent and 49.2 per cent over sole chemical fertilizer (100% NPK) highlighting importance of organic manure in availability of nutrients and thereby maintaining soil fertility. Furthermore, the integrated supply of nutrients was found beneficial for higher grain yield of sorghum and wheat which can be attributed to the addition of organics through FYM and supply of balanced nutrition in addition to micronutrients. Application of 75% RDF + FYM was significantly superior over 100% NPK indicating possibility of compensating 25% chemical fertilizer through FYM. Yaduvanshi *et al.* (2013) reported that yield of rice could be sustained with 50% recommended dose of NPK with green manure (GM) or FYM indicating the usefulness of organic manure in replacing chemical fertilizer.

The SYI of system productivity (sorghum and wheat) was greater in 75% NPK + FYM. The application of FYM alone resulted in a lower SYI of system productivity when compared to the application of inorganic fertilizers alone or in combination with FYM, which could be related to sole application of FYM's could not sustain sorghum and wheat yields. The system's sustainability can be realized by an integrated approach to nutrient management. As a result, applying 75% NPK + FYM @ 5 t $ha^{-1}$ could be an alternative for achieving long-term greater yields in the sorghum-wheat cropping system. Singh (2010) reported that the increase in SYI following the application of 150% NPK indicates that the levels of nutrients applied at 100% NPK are insufficient to realize the potential crop yields. Of course, an increase in SYI as a result of FYM treatment over and above NPK suggests that, in addition to nutrient supply, soil physical and biological factors are also crucial components in maintaining crop yield.

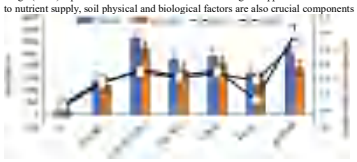

Figure 1 Effect of long-term manuring and fertilization to sorghum-wheat sequence on yield and sustainable yield index of sorghum and wheat

**Correlation among mineral N fraction and yield**

The inorganic N fraction was found to be significantly and positively correlated with all the forms of N indicating dynamic equilibrium between different fractions. This implies that, the dominant N fractions are the potential contributor towards plant available N (Kaur and Singh 2014). As a results, the contribution of the dominant N fractions are generally more in achieving sustainable yield. The yield of sorghum and wheat was significantly and positively correlated with the different N fractions. The higher correlation coefficient was recorded among yield and $NO_3$-N followed by $NH_4$-N indicating dominance of nitrate-N fraction for obtaining higher yield of sorghum and wheat.

Based on 37 years of long-term fertilizer experiment on the sorghum-wheat sequence, integrated nutrient management is critical for maintaining soil fertility, improving nitrogen dynamics, and yield sustainability in Vertisols. The combination of organic manure (FYM) with chemical fertilizers, particularly the 75% NPK + FYM treatment, significantly increased mineral N availability, soil organic carbon, and soil nutritional status when compared to fertilizer use alone. These enhancements resulted in improved N absorption and nitrogen-use efficiency, showing that long-term FYM integration improves N dynamics and mineralization. Importantly, the efficacy of 75% NPK + FYM was comparable to 100% NPK alone, demonstrating the potential to save 25% chemical fertilizer without sacrificing soil health or crop sustainability. Furthermore, long-term crop performance trends show that integrated nutrient supply consistently produces the highest grain yields of sorghum and wheat. The substantial positive association between mineral N fractions and yield highlights the relevance of increased nitrogen availability in promoting long-term productivity. Overall, the study demonstrates that combining organics and inorganic fertilizers not only sustains soil health over decades, but also enhance environmental sustainability by reducing fertilizer dependence. Thus, the 75% NPK + FYM strategy emerges as a feasible, resource-efficient choice for maintaining yield and soil quality in intensive sorghum-wheat production systems.

## ABSTRACT

With increasing rice production demands and water scarcity, developing water-saving irrigation techniques for paddy fields is a global priority. The impact of these techniques on soil structure remains unclear, especially under varying water-carbon conditions. From 2022-2023, field experiments examined four biochar rates and two irrigation methods (controlled irrigation (CI) and flooding irrigation (FI)), resulting in five treatments: CK (0t/ha+CI), CA (60t/ha+CI), CB (30t/ha+CI), CC (10t/ha+CI), and FK (0t/ha+FI). Compared to FK, CK decreased mean weight diameter (19.73-25.54%), soil organic matter (4.64-9.79%), total nitrogen (2.68-10.59%), dissolved organic carbon (1.90-9.48%), water content at saturation (0.23-15.83%) and permanent wilting point (3.69-7.87%), while it increased unstable aggregates index (6.29-15.11%) and fractal dimension (1.59-1.88%). Biochar treatments (CA, CB, CC) mitigated CK's adverse effects on soil aggregate stability, total nitrogen, and water retention capacity and significantly improved these indicators. CA increased porosity across various effective pore diameters, while CB and CC primarily increased the proportion of porosity for diameters >250μm. Simulation results indicated that compared to CK (3.879μm²), the intrinsic permeability (K) of soil under CA, CB, and CC treatments increased by 106.69%, 77.77%, and 3.31%, respectively, while FK showed a contrasting decrease of 3.58%. K correlated well with >250μm porosity and connected porosity representing microstructure, with correlation coefficients of 0.96 and 0.94. Overall, biochar improved chemical properties and micropore structure (porosity for diameters >250μm, connected porosity) of soil aggregates under CI, enhancing macroaggregate functions such as soil stability and hydraulic properties.

## ABSTRACT

While the role of biochar in improving problem soils has gained recognition, its specific impact on loessial soil remains insufficiently studied, particularly due to a lack of long-term field monitoring data. This study aims to develop a Soil Quality Index (SQI) for biochar-amended loessial soil based on 25 soil property indicators. A field experiment was conducted from 2017 to 2024, comprising six treatments with biochar (derived from apple tree branches) applied at rates of 0%, 1%, 2.5%, 4%, 5.5%, and 7%. Following the establishment of a Minimum Data Set (MDS), a comprehensive SQI will be calculated by integrating the selected indicators using multivariate statistics-specifically Principal Component Analysis-combined with non-linear scoring functions. The objectives of this research are to (1) assess the effects of biochar application on soil quality through multiple evaluation methods, and (2) develop predictive models for soil quality based on key soil factors under biochar amendment. Data analysis is currently underway.

## ABSTRACT

The soil is a kind of porous medium made from different size and shape of solid particles and gap with a certain form. There was the irregularity and the randomness characteristics in the physical property indexes of the soil. Because of the complexity of the soil composition, restricted by research methods and technical means, it was difficult to describe the nature and forms of the soil quantitatively. After the 1990, with the cross and integration of the subjects, fractal geometry entered the fields of soil science, and was used to describe soil properties such as soil particle surface area, soil particle weight and particle size distribution. Not only the soil particle morphology could be reflected by fractal dimension, but the soil structure could be describe by the change of the soil particles fractal dimension. Fractal theory has become an important method for quantitative description of soil character. The obvious results could be obtained by use of fractal theory to explain the phenomenon which was irregular, instable and complex. The application of fractal theory in soil science provides a new methodology and approach for studying the fine structure of the soil. HunShanDaKe sand is located in the Inner Mongolia autonomous region, is the nearest sand to Beijing. Since 1960s, HunShanDaKe sand area expands significantly, desertification land area of the early 1960s and the mid 1970s was 192000 $hm^2$ and 265900 $hm^2$. After the 1990s, the average annual desertification expansion rate increased. Under the action of strong cold air in the spring and autumn, sand could fly over the yanshan mountains to Beijing , formed the dust storm, threat the ecological environment of the region.

Two series of plots was built. One was in the sand of 16 years governance, 10 years governance and natural restoration of grassland; another was in the sands of 16 years governance, but with different succeed stage of flowing sand, semi-fixed and fixed sand. Three 80 cm soil profile was dig in each plot, and soil sample of 0 ~ 5 cm 5 ~ 10 cm, 10 ~ 20 cm, 20 ~ 30 cm, 30 ~ 40 cm, 40 ~ 60 cm was took to experiment room. According to the classification standard of soil particles, division level of soil particles was Gravel particles: Fine gravel (2 ~ 1 mm); sand: coarse sand (1-0.25 mm), fine grains of sand(0.25 ~ 0.05 mm); Powder: coarse powder (0.05 ~ 0.01 mm), fine powder (0.01 ~ 0.005 mm); Clay: thick clay(0.005 ~ 0.002 mm), clay( < 0.002 mm). The grain composition of the soil sample was measured by use of soil screening method and the hydrometer method.

Through the field investigation and room analysis, by using of fractal model created by Peiling Yang, the granulometric distribution and the fractal dimensions of the sand soil under different protection time and different stationary state in Hunshandake Sandy Land was studied. It was showed that: (1) The soil belongs to sand soil texture classification according to Chinese standard. The sand fraction of soil particles was mainly distributed in 1 ~ 0.05 mm diameter section, content was 85.97% ~ 96.59%. Coarse sand (1 ~ 0.25 mm) content was 14.8% ~ 52.9%, fine sand (0.25 ~ 0.05 mm) content was 14.10% ~ 69.96%. Powder and clay content was less than 5%, 0.01 ~ 0.005 mm of fine powder and 0.005 ~ 0.002 mm thick clay content was the minimum; (2) Coarse sand and clay grain contents were the main factors to decide fractal dimension. The more coarse sand grain content in the soil, the smaller the fractal dimension. The more clay content in the soil, the bigger the fractal dimension. No matter what kinds of recovery time and fixed stage, fractal dimension of soil particle was relevant to mechanical composition of soil particles. Giving the same recovery time and different fixed state, the fractal dimension were significantly negative relevant to the content of coarse sand (1 ~ 0.25 mm) in the soil particles, negative relevant to the contents of fine gravel (2 ~ 1 mm) and fine sand (0.25 ~ 0.05), significantly positive relevant to the content of clay (< 0.002) and thick clay (0.002 ~ 0.005) , positive relevant to the content of coarse powder (0.05 ~ 0.01) and fine powder (0.01 ~ 0.005). Giving the different recovery time, the fractal dimension were significantly negative relevant to the content of coarse sand(1 ~ 0.25 mm) , negative relevant to the content of fine gravel (2 ~ 1 mm) and fine sand (0.25 ~ 0.05 mm), significantly positive relevant to the content of coarse powder (0.05 ~ 0.01 mm), fine powder (0.01 ~ 0.005 mm) and clay (< 0.002 mm) , positive relevant to the content of thick clay (0.002 ~ 0.005 mm); (3) Sand soil fractal dimension changed with the soil layer, the deeper the soil layer, the smaller the fractal dimension; (4) With the protection time increased, sandy silt and clay content increased and sand content decreased, the fractal dimension would increased. The fractal dimension of the soil was bigger under higher vegetation coverage than that under lower vegetation coverage, the fractal dimension of the soil was greater under fixed sandy land than that under unfixed sandy land. The results would provide the theory basis for the sandy land protection.

# Long-Term No-Tillage Effects on Plant Residue Decomposition and Soil Organic Carbon Formation and Accumulation Patterns in a Japanese Andosol

**Daniel AsiamahAboagye [a], Han Lyu [b], Hideaki Yasuno [a], Masakazu Komatsuzaki [c], Haruo Tanaka [b] and Soh Sugihara [b]**

*daaboagye003@gmail.com

## ABSTRACT

Long-term no-tillage (NT) can enhance soil carbon stocks in Japanese Andosols and therefore has the potential to contribute to climate change mitigation in temperate humid environment. However, uncertainties still remain on the long-term NT effects on residue decomposition and C accumulation patterns and variability in distribution into distinct SOC fractions and their implication for soil carbon stabilization. We conducted a one-year field incubation experiment using $^{13}C$ labelled plant residue applied to undisturbed soils from long-term NT and disturbed soils from conventional tillage (CT) plot, taken from the Centre for International Field Research, Ibaraki University, Japan. The objective of the study was to quantify the effects of long-term NT versus CT and mode of residue C input (surface vs mixing) on residue decomposition and vertical migration of residue-derived C into distinct SOC fractions in Japanese Andosol. $^{13}C$-labelled ryegrass residue (C:N = 25.8, 7 atom% $^{13}C$) was applied at 2 Mg C $ha^{-1}$ (1.8 g C $kg^{-1}$) under three treatments: surface application on NT (NTSA), mixing with CT (CTMIX) and surface application on CT (CTSA, positive control), with soil-only controls (NT and CT) and incubated under field conditions (n = 4). Residue-derived C (RDC) in SOC was assessed over time by $^{13}C$ analysis at four depths (0–2.5, 2.5–5, 5–10, 10–15cm). Residue-derived $CO_2$ emissions, microbial biomass C (MBC), and dissolved organic C (DOC) were also measured. Soil organic matter (SOM) was separated into particulate organic matter (POM, >53 µm) and mineral associated organic matter (MAOM, <53 µm) by particle-size based fractionation method. We found that long-term NT effect and mode of residue C input (surface vs mixing) exerted distinct influences on residue mineralization and accumulation dynamics, possibly driven by different underlying mechanisms. 23.6 - 48.8 % of applied $^{13}C$ labelled plant residue C was mineralized to $CO_2$ with NTSA and CTSA treatment (surface applied residue) showing approximately two-fold higher mineralization than CTMIX (residue mixing). Consequently, the proportion of added residue C retained in SOC was greater under CTMIX. NTSA and CTMIX exhibited similarly reduced priming effects (P.E.), whereas P.E was strongly induced under CTSA, likely due to contrasting microbial responses. Residue derived C accumulation was limited to the soil surface (0-2.5cm) under NTSA and CTSA with larger C remaining (15-30%) in the POM fraction vs MAOM, indicating that surface residue application and NT systems preferentially promote residue-derived C accumulation in POM. Within the surface treatments, MAOM formation was also enhanced in CTSA compared to NTSA especially in 0-2.5cm which could be related to the differences in C saturation degree and microbial C assimilation ability. The findings from this study have important implications for C sequestration under long-term tillage management.

# Land Use and Management Effects on Soil Health of Three Soil Types in the Republic of Serbia

**Mirna Štrbac[2] and Maja Manojlović[1*]**

[1] *University of Novi Sad, Faculty of Agriculture, Novi Sad, Republic of Serbia*

[2] *University of Novi Sad, Faculty of Agriculture, Novi Sad, Republic of Serbia*

**ABSTRACT**

Land use and management practices affect soil health, and in the most cases intensive conventional management practices led to deterioration of soil properties and therefore, soil become less resilient to climate change. As organic agriculture is recognized as an approach that cares more about soil health and environmental protection (by use of only natural fertilizers and biopesticides), the aim of this research was to examine and compare the soil health of three soil types under different production systems: organic (from 5-10 years, and >10 years) and conventional, as well as to compare it with the soil health under natural soil (pasture).

Soil samples were taken from 20 farms, within three soil types (Chernozem, Humugley, and Stagnosol) with contrasting soil properties, particularly different in pH-values. In total, 160 samples were taken from 0-25 and 25-50 cm soil layers and prepared for the analysis of soil physical, fertility, and biological properties.

The results of the soil physical properties showed that land use systems (pasture and arable) affected aggregate stability and mean weight diameter (MWD), where MWD was significantly higher on pasture. However, bulk density and total porosity were the parameters the most sensitive to change of the system of the production (organic and conventional). In all three soil types, soil organic carbon (SOC) reserves were highest under pasture, following organic agriculture, and lowest under conventional agriculture. Moreover, the effect of organic agriculture on SOC was the most pronounced on Stagnosol. Regarding dehidrogenase and urease enzymatic activity, the highest values were measured on pasture on all three soil types. Moreover, on Humugley and Stagnosol, higher enzymatic activity was within organic agricultural practices compared to conventional.

In conclusion, although conversion from natural (pasture) to arable land led to loss of SOC and deterioration of soil health, the organic farming management has advantage compared to conventional in respect to soil biological parameters as enzymatic activity, especially on the less fertile soils.

# Multispecies pastures and the soil science dilemma

**Gary Clark*, Peter Sale, and Caixian Tang**

*La Trobe Institutefor Sustainable Agriculture and Food, Department of Ecological, Plant and Animal Sciences, La Trobe University, Bundoora, VIC 3086, Australia*

*g.clark@latrobe.edu.au

**ABSTRACT**

Increased plant diversity in pasture systems for animal production has positive effects on soil and animal health, and productivity. Diverse root systems can ameliorate poor soil structure, particularly at depth, and hence increase water availability in the soil profile, thereby improving plant production during the increasingly prevalent dry periods experienced in modern agricultural production. Our particular interest is multispecies pasture (MSP) swards for dairy production. The practice to implement a multispecies pasture varies; however, our study focussed on three dairy farmers in the high-rainfall zone of southern Victoria, Australia. These farmers, twice annually, inter-sow a multispecies seed mix of annual grasses, forbs and herbs, into existing perennial ryegrass pasture. Our study was primarily a partial budget analysis (Sale *et al,* in preparation). Transitioning to MSP was profitable, mostly attributed to the elimination of fertilizer, and importantly, with sustained milk production. Most agricultural systems acidify the soil, and particularly dairy systems due to heavy use of synthetic fertilizers and hence, require regular additions of lime to maintain soil pH. Farmers using MSP have been able to eliminate additions of lime, whilst maintaining satisfactory soil pH. Soil tests on one farm using MSP show alkalisation of an acidic soil profile, even at depth.

The dilemma for soil science is to explain how nutrient levels are maintained and sustained in these soils despite lack of fertilizer inputs, while diversifying plant species leads to alkalisation of the soil.

Most of the literature reports on the outcomes of plant diversification for crop and forage production and for animal health in grazing systems. However, little attention has focussed on the mechanisms for sustained nutrient availability from a dairy pasture soil with limited inputs of synthetic fertilisers. Management techniques that are likely to increase nutrient recycling include long rest periods between grazing, ensuring that adequate plant residue are retained on the surface, and concentrated confined grazing to ensure even spread of animal waste. However, the question is, will these well-fertilised dairy systems slowly run-down the soil fertility?

This poster summarises the findings of a critical literature review with the aim to compare the plant and soil biological pathways and nutrient cycling of a conventional N-fertilised pasture to an inter-sown multispecies pasture.

# Four Decades of Soil Organic Carbon Dynamics in Seasonally Flooded Haor Wetlands of Northeastern Bangladesh amid Landscape Transformation

**M. J. Uddin[1*], A. Faiz[1], A. Fairuz[1], M. R. Hasan[1], and F. Z. Arabi[1]**

*Presenting Author: juswe@du.ac.bd

## ABSTRACT

Long-term hydrological variability and land-use change have raised serious environmental concerns regarding the stability of soil organic carbon (SOC) and the transformation of ecologically significant wetland ecosystems. This study investigated historical landscape changes in the haor basin wetlands of northeastern Bangladesh and evaluated associated SOC dynamics driven by climate change and anthropogenic pressures. This study evaluated four decades (1985-2025) of landscape dynamics and SOC variability in the haor wetlands of northeastern Bangladesh by integrating multi-temporal remote sensing with field-based soil measurements. Land use and land cover (LULC) changes were analyzed at both regional and site-specific scales using Landsat, Sentinel-2, and European Space Agency's Climate Change Initiative (ESA-CCI) datasets processed in a geographic information system (GIS) environment. Changes in vegetation, surface water, flood-prone areas, and urban expansion were quantified and validated using the Normalized Difference Vegetation Index (NDVI), Normalized Difference Water Index (NDWI), and Built-Up Index (BUI) for the 1985-2025 period. Field data from nine representative sites were used to assess SOC concentration and stock in the 0–15 cm soil layer. Between 2017 and 2025, the region experienced a 16.3% reduction in flood-prone areas and a 12.5% expansion of urban land, alongside increasing vegetation cover linked to agricultural intensification. NDWI declined by approximately 15% over the four decades of the study period, reflecting reduced inundation and altered hydrological regimes. Despite these changes, SOC stocks remained largely stable over the past 40 years, currently ranging from 30 to 122 Mg $ha^{-1}$ across sites. Higher SOC retention was consistently associated with clay-rich soils and recurring flooding, which maintained anaerobic conditions and limited organic matter decomposition. The findings highlight the critical roles of land-use decisions, hydrological regulation, and clay- mediated mineral protection in maintaining carbon security within lowland agro-wetland systems. Persistent anaerobic conditions have buffered soil organic carbon against land-use and hydrological changes in the haor wetlands. However, continued flood reduction and wetland conversion may undermine this stability. Overall, this study provides a mechanistic framework for integrating wetland carbon conservation into climate policy and land-use planning across floodplain and wetland ecosystems of South Asia. To safeguard these substantial carbon reserves, hydrologically informed wetland management, carbon-conserving agricultural practices, and strategic regulation of urban expansion are essential.

# Vegetation-Driven Soil Organic Carbon Regulate Mercury Accumulation in Karst Soil Profiles

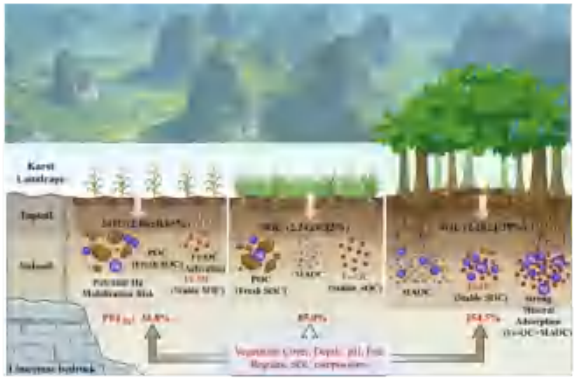
**Jicheng Xia[1, 2*], and Liping Yang[1]**

*[1] Key Laboratory of Karst Georesources and Environment, Ministry of Education, College of Resources and Environmental Engineering, Guizhou University, Guiyang 550025, China*
*[2] Urban karst critical zone & climate-environmental change observation and research station of Guizhou Province, Guiyang 550081, China*
* jcxia@gzu.edu.cn

**ABSTRACT**

Vegetation regulates soil mercury (Hg) sequestration primarily through the formation and transformation of soil organic carbon (SOC) pools, yet the mechanisms underlying this control remain poorly quantified, especially in reactive karst landscapes. Here, we examine Hg distribution and speciation across cropland, grassland, and forestland soil profiles in a typical karst catchment, combining measurements of total Hg (THg), dissolved Hg (DHg), mineral-associated organic carbon (MAOC), particulate organic carbon (POC), iron-associated organic carbon (Fe-OC), stable carbon and nitrogen isotopes with partial least squares structural equation modeling (PLS-SEM) and multivariate nonlinear regression analysis (MNRA). We show that forestland soils accumulate the most Hg, with topsoil concentrations exceeding 110 μg $kg^{-1}$ and profile enrichment surpassing 154.5%, due largely to the accumulation of MAOC. The role of Fe-OC in Hg retention strengthens markedly during succession from cropland to forestland, underscoring mineral adsorption as a key sequestration pathway in karst systems. Vegetation cover, soil depth, pH, and iron oxides collectively modulate Hg stability by governing SOC composition: stable SOC promotes sustained sequestration, whereas labile SOC may facilitate Hg release via microbial activity. Globally, this SOC control dominates in unpolluted areas, whereas polluted areas are influenced mainly by direct inputs. Our findings reveal that vegetation restoration enhances sustained soil Hg storage, while agricultural use may elevate mobilization risks from reactive carbon pools. These results highlight the need to incorporate vegetation cover feedbacks into Hg risk assessments and global cycling models.

**Keywords:** Mercury accumulation, Vegetation covers, Whole- soil- profile, SOC, Karst



Highlight:

(1) Topsoil under different vegetation covers shows significant Hg enrichment, with Hg content decreasing with depth and forestland showing the highest enrichment intensity.

(2) Contributions to soil Hg accumulation follow the order MAOC > Fe-OC > POC, with mineral adsorption-protection as the key mechanism.

(3) The regulatory factors for Hg accumulation shifted from SOC in non-polluted areas to geological background and exogenous inputs in polluted areas.

(4) Vegetation restoration drives global greening and enables sustained stable Hg sequestration via promoting MAOC formation and providing a nature-based solution to historical Hg remobilization.

# THE LEGISLATIVE BASIS FOR SOIL PROTECTION – THE RED SOIL BOOK

**O. Bezuglova**

*Southern Federal University, Rostov-on-Don, Russian Federation*

e-mail: lola314@mail.ru

**ABSTRACT**

The legislative basis for the creation of the Red Soil Books in Russia is the Federal Law "On Environmental Protection" (January 10, 2002), which states that the Red Soil Book of the Russian Federation and the Red Soil Books of the constituent entities of the Russian Federation are established to record and protect rare and endangered soils. Article 62 of this Law states that the procedure for classifying soils as rare and endangered, as well as the procedure for establishing land use regimes for land plots whose soils are classified as rare and endangered, are determined by law. However, regulatory documents and methodological recommendations governing the compilation and maintenance of Red Data Books of Soils in Russia have not yet been developed. Only general methodological approaches are found, substantiated in scientific articles and monographs. The reasons for this situation are quite objective, as the soils of different regions of the country differ in their genesis, properties, fertility, and the degree of agricultural development and transformation.

Regional Red Data Books of Soils should serve as the legislative basis for scientifically based protection of the soil cover of each region. Uniform principles for compiling Red Data Books of Soils have been developed for the entire country; however, in regions with specific soil cover characteristics, the development of this document may require specific considerations.

For example, for regions with a high percentage of cultivated land, identifying areas for the conservation and study of Red Data Book soils is particularly problematic. Here, the most fertile soils are also the most actively used in agriculture, which significantly alters their morphology and properties. For example, in the Rostov Region, such soils are chernozems. In fact, such soils in their native form remain only within the boundaries of Specially Protected Natural Areas, and the areas they occupy are so small that they can even be classified as endangered soils.

For regions with a high proportion of cultivated land, such as the Rostov Region, the virtual absence of virgin soil varieties poses several additional challenges. Therefore, in the process of developing the Red Data Book of Soils for the Rostov Region, special attention is being paid to the first section of the Red Data Book of Soils—the identification of soil standards. Given the high intensity of chernozems used in the Rostov Region and their significant importance in ensuring food security for the country, it is essential to ensure high-quality monitoring to prevent their degradation.

**ABSTRACT**

Forest expansion following agro-pastoral abandonment is widespread in European mountains and has been further accelerated by recent climate warming (Piccinelli et al., 2020). Previous studies show that woody encroachment does not necessarily increase soil carbon, as accumulation often occurs mainly in woody biomass while soil responses remain variable and context-dependent (Guidi et al., 2014). Recent evidence also indicates that forest expansion alters soil aggregation, reducing microaggregate (Ortiz et al., 2022). Climate, local environmental conditions, and land management strongly modulate these responses, highlighting the lack of a universal pattern and the need for site-specific studies in mountain ecosystems. In this study, we investigated how soil physical (bulk density, aggregate stability) and chemical (total C and N, inorganic N forms, available P) properties change along a gradient of a pasture recolonization by larch, from an actively managed pasture to a mature forest, through a case study in the Northwestern Italian Alps (LTER research site Tellinod, Aosta Valley Region, NW Italian Alps; ~2100 m a.s.l.). Topsoil (0–15 cm) was sampled in five plots representing successive recolonization stages (started around 2008), for a total of 50 samples. Our results show that soil physical and chemical properties varied clearly along the gradient. Bulk density was highest in the grazed pasture, while aggregate stability was lower and soil erodibility (K) higher in the mature forest. pH showed no significant differences, whereas total C and N were slightly lower in the pasture and significantly reduced in the mature forest. Ammonium, nitrate, and dissolved organic carbon (DOC) were lowest in the pasture and mature forest, indicating that successional stages differ in their activity within the carbon and nitrogen cycles, with nutrient availability highest in intermediate stages. Reduced total C in the mature forest likely contributes to lower aggregate stability and higher erodibility. These findings highlight the tight coupling between soil structure and fertility during woody encroachment and underscore the importance of local studies for sustainable land management and biodiversity conservation in alpine environments.

## ABSTRACT

Periodic burning to promote grass regrowth is a common management practice in extensive cattle ranching in Colombian savannas, leading to soil degradation and unsustainable landscapes. The introduction of improved grass forages with higher palatability, combined with rotational grazing, allows burning cessation and enhances productivity. However, the effects of this management shift on soil carbon (C) and nitrogen (N) cycling remain poorly studied. In tropical savannas, native trees represent important inputs of organic matter to soils and can strongly influence C and N dynamics. Here, we assessed the impact of replacing burning with improved forages on soil C and N dynamics in the Vichada Department, Colombia and evaluated the role of native trees (*Curatella americana*) in shaping these dynamics.

We compared two contrasting managements using a fence-line approach: a conventional system with annual burning, continuous grazing, and a low stocking rate (0.006 livestock units (LU) $ha^{-1}$; *conventional*), and an improved system where an improved grass forage (*Urochloa humidicola*) was introduced 10 years ago, burning was ceased, and rotational grazing with high stocking rate (1 LU $ha^{-1}$) was implemented (*improved*). In each system, eight trees located at least 100 m apart were selected. Soil samples were collected at three depths (0-10, 10-20, and 20-30 cm) and at two distances from the tree trunk 0.5 and 2.5 times the canopy radius, (representing beneath and outside the tree canopy, respectively). Tree leaves and pasture biomass were also sampled. Soil and plant samples were analyzed for total C and N, as well as $\delta^{13}C$ and $\delta^{15}N$.

Soil C concentration (0-30 cm) was significantly higher under improved than under conventional management (16.2 vs. 13.2 g C $kg^{-1}$), likely due to burning cessation. This increase was mainly driven by higher soil C beneath trees in the improved system compared to the conventional (16.8 vs. 13.0 g C $kg^{-1}$). Burning cessation increased native tree growth and litter inputs to soil, as confirmed by higher soil $\delta^{13}C$ values (+0.73‰) beneath trees in the improved system, indicating a greater contribution of C derived from $C_3$ trees (−29.67‰) relative to $C_4$ grasses (−13.71‰). Soil $\delta^{15}N$ values were significantly lower under improved management (5.84‰) than under conventional (6.46‰), suggesting reduced N losses following fire burning cessation, as gaseous N losses during burning are $^{15}N$-depleted. This reduction in N losses was reflected in higher soil N concentrations and lower C:N under improved management.

Overall, replacing burning with improved forages and rotational grazing increased soil C and N concentrations, enhanced tree contributions to soil C accrual, and reduced N losses, mitigating the environmental impacts of cattle ranching while increasing system sustainability and productivity and supporting savanna conservation by sparing land.

# The effect of winter-sown oat catch crops on nitrogen leaching after livestock grazing

**B. Malcolm[1*], W. Hu[1], M. Beare[1], S. Maley[1], S. Dellow[1] and A. Taylor[2]**

[1] *New Zealand Institute for Bioeconomy Science Limited (Plant & Food Research Group, Lincoln, New Zealand)*

[2] *New Zealand Institute for Bioeconomy Science Limited (AgResearch Group, Lincoln, New Zealand)*

*Brendon.Malcolm@plantandfood.co.nz

**ABSTRACT**

Grazing of livestock on high-yielding annual forage crops (e.g. fodder beet, kale) can have detrimental effects on water quality outcomes, particularly through mineral-nitrogen (N) leaching with reported losses of up to 180 kg N/ha. This is largely because of: 1) high N returns in urine patches under high livestock densities, and 2) bare soil with no plant N uptake for long periods under wet winter-early spring conditions.

The objective was to test the effect of oat catch crops establishment and associated sowing timings and tillage practice on mineral-N leaching losses following simulated winter grazing, compared with typical fallow conditions.

Repeat field leaching experiments over two years (2021 and 2022) using 40 intact soil monolith lysimeters (50 cm diameter x 70 cm deep) were conducted in Southland, New Zealand. Simulated livestock treading was applied to the Waikiwi soils (Typic Firm Brown Soil) inside the lysimeters, followed by a winter application of fresh cow urine (equivalent to 200 kg N/ha). Imposed treatments included early (Jul/Aug; winter) and late (Sep/Oct; spring) cultivation at 10 or 25 cm depth compared with a non-cultivated winter fallow control. Oats were then hand-sown in 50% of all cultivated lysimeters in winter or spring, and drainage water was collected and analysed for mineral-N (ammonium and nitrate) until winter oats reached green-chop silage maturity (Nov/Dec).

Winter-sown oats were shown to reduce mineral-N leaching by 35–61% compared with the fallow control. Delayed sowing until spring achieved similar reductions (28–54%), indicating a potentially longer window of opportunity to establish catch crops for reducing mineral-N leaching in colder climates. Cultivation increased leaching in some cultivated, non-seeded plots when compared with the fallow control (by up to 76%), likely from enhanced N mineralisation; however, oats were shown to mitigate this added risk. Reductions in mineral-N leaching were attributed to the 62–137 kg/ha of N captured in aboveground biomass of oats, where yields were between 2.7 and 12.8 t DM/ha. Oat yields and N uptakes were on average 6.1 t DM/ha and 35 kg N/ha greater with early sowing than late sowing.

We conclude that sowing oat catch crops in cold regions of New Zealand can significantly reduce mineral-N leaching losses from winter forage crop grazing, despite the added risk of N mineralisation from the practice of catch crop cultivation in winter.

# Effects of Different Land Use Types on Soil–Microbial Ecochemical Stoichiometry in Agro-Pastoral Ecotones

**ABSTRACT**

Ecological stoichiometry is an important representation for understanding nutrient cycling and balance in ecosystems. The agro-pastoral ecotone, as a key interface connecting the two major food production systems of farming and animal husbandry, has become an ecologically fragile zone due to land use changes caused by the frequent replacement of cropping systems. However, the response patterns of soil-microbial ecological stoichiometric characteristics to different land use types in the agro-pastoral ecotone remain unclear. This study focused on the agro-pastoral ecotone in Inner Mongolia and selected six typical land use types: no grazing (NG), rotational grazing (RG), continuous grazing (CG), grass-field rotation (CT), continuous maize farmland (NT), and abandoned land (LH). By measuring indicators such as soil organic carbon, total nitrogen, total phosphorus, and microbial biomass carbon, nitrogen, and phosphorus, the study systematically analyzed the effects of land use types on soil and microbial stoichiometric ratios and their driving mechanisms. The results showed significant differences in soil nutrient content and stoichiometric ratios among different land use types, with the highest SOC and C:Psoil and N:Psoil under NG, the highest TN and TP under RG, and the highest C:Nsoil under LH. CT treatment significantly increased MBC, C:Nmic, and C:Pmic, while CG treatment significantly increased MBP but had the lowest C:Nmic. The qMBC was highest under CT, qMBP was highest under CG, and the chemical stoichiometric imbalance was highest under LH. Redundancy analysis revealed that the C:Pimb, N:Pimb, and C:Pmic were the main drivers of microbial entropy changes, indicating that phosphorus supply-demand imbalance is a key limiting factor restricting soil microbial growth and metabolic efficiency in this region. This study elucidates the response patterns of soil-microbial stoichiometric characteristics to land use types in the agro-pastoral ecotone and finds that CT treatment is most advantageous in maintaining soil carbon storage and enhancing microbial resource utilization efficiency, while LH treatment leads to severe stoichiometric imbalance. In the future strategies for cropping system replacement in the agro-pastoral ecotone, phosphorus limitation should be a key consideration to stabilize nutrient cycling in the soil-microbial system.

# Iceland's degradation history is taking a hopeful turn through revegetation and ecosystem monitoring

**Elva B. Benediktsdottir[1*], Hrafnhildur V. Fridriksdottir[1], Solveig Sanchez[1], Sigurlaug B. Gudmundsdottir [1] and Johann Thorsson [1]**

[1] *Land and Forest, Iceland (Gunnarsholt, Iceland)*

*elva.bjork.benediktsdottir@landogskogur.is

**ABSTRACT**

Iceland, a 100,000 km² volcanic island in the North Atlantic, has experienced diverse ecosystem states over the last millennium. Before the human settlement, almost half of the country consisted of mountain birch woodlands and heathlands. However, following the settlement the vegetation cover got significantly reduced due to both anthropogenic and environmental factors, and interactions thereof. Today, roughly 40% of the country is considered degraded or highly degraded with large areas where the entire soil profile has been completely lost. This is due to both inherited Andosol properties and land management. Andosols can have little particle cohesion and low bulk density, resulting in high erosion risk when exposed. At the same time, they have high water and carbon retention potentials, both contributing to their relatively high fertility. This suggests that the currently vast degraded areas have considerable potential for carbon sequestration through revegetation. Revegetation projects have been ongoing since 1907 with the establishment of the Soil Conservation Service of Iceland, now Land and Forest Iceland. These areas have been systematically monitored with respect to inputs and soil carbon yields since 2007, when Iceland selected revegetation as a countermeasure under the Kyoto protocol. To achieve this a sampling grid of 1x1 km² was superimposed on a map of Iceland followed by selecting all points intersecting with revegetation areas larger than 0.5 ha and active since 1990. These potential sampling points were visited and those qualifying for sampling then selected, in total 640 points. Permanent 10 x 10 m sampling plots were established at each location and sampled during 2007-2011. The sampling campaign was repeated in 2018-2022 with both revisiting existing points and establishing new or expanded areas. In each plot, five 50x50 cm randomly distributed subplots were laid out for assessing species richness and vegetation cover using a modified Braun-Blanquet scale, followed by soil sampling at 0-5, 5-10, 10-20, and 20-30 cm depths. Both total carbon and total nitrogen were analyzed using the Dumas method. The results from this ongoing project provide invaluable data on the feasibility of different reclamation approaches under various conditions and soil carbon sequestration. Current results show a general increase in carbon stocks, but they vary with site conditions and inputs. Further data analysis will focus on identifying the efficient ways to revegetate degraded areas and how to facilitate consequent vegetation succession.

## ABSTRACT

Evaluating the long-term soil erosion dynamics and their responses to anthropogenic forcing at the regional level is crucial for assessing the impacts of soil conservation efforts and informing future policy development. The soil erosion issue is particularly severe in southwestern China due to its large hilly areas and extensive human activities. However, due to the lack of long-term records, there has been insufficient evaluation of the historical variations in cropland erosion across the spatial scales of decades and centuries, which hinders a comprehensive understanding of the main drivers and their effects. By using the Revised Universal Soil Loss Equation model in combination with remote sensing-based multisource data, the spatial and temporal evolution of cropland soil erosion in the Tuojiang River Basin (TRB) in China from 1911 to 2017 is assessed in this study. We also employl geographically and temporally weighted regression (GTWR) to assess the spatial and temporal heterogeneity ofl the anthropogenic factors impacting cropland soil erosion in the TRB from 1911 to 2017. The study resultsl indicate that (1) in the past century, an average of 77.70% of the TRB has exhibited a slight soil erosion level,l with the upper stream experiencing a higher rate. (2) The amount of soil erosion increased slightly from 1911 tol 1960, dramatically increased by 70.07% from 1960 to 1980, and then decreased by 34.759 from 1980 to 2017. Cropland soil erosion mainly occurred in the upper stream, but it has been expanding to the downstream regionl since 2000. The high rate of cropland cultivation in the densely populated upper reaches is the main cause of accelerated erosion. (3) The increase in cropland soil erosion has primarily been driven by population growth and cropland expansion with contrary effects, reflecting a complex interplay of diverse natural and anthropogenic mechanisms. Spatiotemporal differentiations in the influences of both factors became evident with thel economic reform and implementation of ecological conservation policies that have been occurring since 1980.l These results can provide valuable insights for decision-makers for better understanding the long-term evolutionl of cropland soil erosion and the implementation of targeted soil conservation measures.

**ABSTRACT**

Ecological degradation from oil palm monocultures stems from extensive land clearing and the promotion of single-species stands. Oil palm agroforestry is an alternative to restore soil health that is commonly diminished through monoculture management practices. This study evaluates the soil chemical and biological characteristics of an oil palm agroforestry system established in 2022 in Sabah, Malaysia. In the agroforestry system, the incorporation of native tree species increases the planting density and diversity of the system. We hypothesized that increased aboveground vegetation density and diversity would induce changes in soil biological and chemical properties. The experimental design compared three management systems: oil palm monoculture, oil palm agroforestry, and an adjacent riparian zone. Soil replicates (n=5) were analyzed for soil chemical properties (total nitrogen (N), total and available phosphorus (P), total potassium (K), total carbon (C)), soil bacterial abundance and diversity using 16S rRNA amplicon sequencing.

Results showed that while overall soil microbial alpha diversity did not differ significantly across management systems, LefSe Biomarker Analyses revealed that the proportion of unique taxa increased with vegetation diversity (riparian > agroforestry > monoculture). Soil acidity, total N, available and total P, and total K were significantly higher in the cultivated zones (monoculture and agroforestry) than in the riparian zone (Table 1). From this result, soil chemical properties were likely influenced by fertilizer management and not by aboveground vegetation differences. Total soil carbon content (Table 1) remained consistent across all sites. However, functional profiling of the microbiome indicated that the riparian and agroforestry systems possessed a higher abundance of carbon degradation pathways. This suggests that more diverse aboveground litter inputs are already shaping the microbial functional potential to decompose a broader range of organic substrates.

These findings are crucial for the ongoing evaluation of the ecological trajectory of an oil palm cycle, which typically lasts for 25 years. As the palms in this study are currently juvenile, more changes in soil properties are expected as palms grow and approach maturity. Ultimately, this study provides evidence that alterations in aboveground diversity and density can influence the soil properties of oil palm-based landscapes.

# Aggregate-Size-Specific Carbon and Nitrogen Responses to Reduced and Deep Tillage in Japanese Andosols

**Ulendo Taizya[1], Hiromi Fujiki[2], Tawiah Joseph Kotey,[1] Asano Maki[3]**

*[1]Graduate School of Science and Technology, Doctoral Program in Agricultural Sciences, University of Tsukuba, Tsukuba, Japan*

*[2]Be a Good Friend Inc. Tsukuba, Japan*

*[3]Institute of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan*

*s2430252@u.tsukuba.ac.jp

**ABSTRACT**

Tillage strongly influence soil aggregate structure and nutrient dynamics. However, these processes remain poorly characterized in Japanese natural farming systems. In particular, direct comparisons of reduced tillage (RT) and deep tillage (DT) at aggregate size-specific Total Organic Carbon (TOC) and Total Nitrogen (TN). Although mechanistic studies in Andosols have clarified soil organic matter (SOM) stabilization pathways, the effect of tillage on nutrient partitioning within aggregates under real farm conditions remain unclear. This study investigates aggregate-size specific carbon and nitrogen responses to tillage effects in Japanese natural vegetable farms.

Soil profile surveys and pre/post-cultivation sampling were conducted in RT and DT farms in Ibaraki Prefecture. Soil aggregates were fractionated by wet sieving across aggregate fractions (63 µm – 2mm), and aggregate-associated TOC and TN concentrations, along with basic physicochemical properties, were analyzed.

The results from RT soil showed well-developed soil structure, higher TOC, TN and markedly higher available Phosphorous among the study sites. RT significantly increased microaggregates and demonstrated strong size-dependent shifts in TOC and TN, including increases in 63 µm and 500 µm fractions and reductions in 2 mm fraction. In contrast, DT exhibited disturbed soil structure with weakened aggregate stability, declining TOC and TN with depth, and lower Cation Exchange Capacity (CEC). DT reduced microaggregates and increased larger, unstable aggregates. Overall, TOC and TN distributions were more strongly differentiated by aggregate size than by tillage practice alone. Reduced tillage preserved clear-size specific patterns of TOC and TN, whereas deep tillage diminished these differences in Japanese Andosols.

## ABSTRACT

Crop diversification offers a pathway toward sustainable agriculture. Traditional intercropping systems, such as the "Three Sisters" intercropping and maize-bean systems, may offer several ecological benefits but are often incompatible with mechanization in large-scale systems. This study investigates the impact of traditional intercropping on soil carbon and nitrogen dynamics, and associated soil microbiology. Specifically, it evaluates whether row-based designs of traditional maize-based intercropping systems can sustain yields under low-input Mediterranean farming. Field experiments in Central Portugal employed a randomized block design with replicates to compare five treatments: maize (M), beans (B) and squash (S) monocrops, and maize-beans (MB) and maize-bean-squash (MBS) intercropped. Planting densities were: 80,000 plants $ha^{-1}$ for M; 53,333 maize and 26,666 bean plants $ha^{-1}$ for MB (2:1 ratio); and 53,333 maize, 26,666 bean, and 5,333 squash plants $ha^{-1}$ for MBS (10:5:1 ratio). The crops were sown in rows, facilitating mechanization. No nitrogen fertilization was applied during the cropping season. Crop health was monitored through chlorophyll analysis. At the maize VT phenological stage, soil carbon emissions were measured using LI-7810 Trace Gas Analyzer. The abundance of N-fixing bacteria was determined using standard microbiological method, and the results were expressed as colony-forming units per gram of soil ($10^5$ CFU $g^{-1}$). N-fixing bacterial populations in MB (43.0 CFU) and MBS (43.7 CFU) were significantly higher than in M (32.7 CFU). Similarly, soil carbon emissions in MB and MBS (3.3 and 3.4 µmol $m^{-2}$ $s^{-1}$, respectively) were significantly higher than in M, reaching parity with the B. This suggests that intercrops maintained high metabolic rates despite lower plant densities. Chlorophyll analysis revealed a "stay-green" effect in intercropped beans, which delayed senescence by 26 days compared to B. This sustained soil metabolic activity facilitated a compensatory growth response, enabling intercropped maize to significantly outperform monocropped plants on an individual basis. Consequently, intercropped maize achieved a total yield comparable to the monocrop despite a 33% lower plant density, representing to a 2.7-fold increase in individual plant productivity relative to M. Ultimately, this synergy allowed the MB system to achieve the highest land equivalent ratio (LER) and water use efficiency (1.96 and 10.6 kg/ha/mm, respectively), while the MBS system was limited by the competitive exclusion of squash (zero yield), resulting in a lower LER (1.33). These findings show that traditional intercropping acts as a biological primer for N-deficient soils, where optimized microbial synergies and temporal niche differentiation stabilize productivity and resource-use efficiency without the need for synthetic fertilizers.

## ABSTRACT

Affected by global climate change and long-term unreasonable planting and fertilization, agricultural production is increasingly threatened by soil degradation, nutrient depletion, and water stress. This study aims to reveal the combined effects of biochar-based microbial fertilizers and irrigation levels on soil quality and wheat growth, providing essential insights for sustainable agricultural management. This study conducted a pot experiment, including four application levels of biochar-based microbial fertilizer and four irrigation levels. The effects of biochar-based microbial fertilizer on soil nutrients, wheat physiological and biochemical indicators, and yield are explored. Biochar-based microbial fertilizers under different irrigation levels significantly enhanced nutrient utilization efficiency, stabilized organic matter, and improved soil bacterial community composition. Under varying irrigation levels, biochar-based microbial fertilizer enhanced wheat photosynthesis, increased soluble protein accumulation, and effectively boosted wheat yield. This study reveals the mechanisms by which biochar-based microbial fertilizers improve soil quality and clarifies their potential to promote wheat physiological growth and increase yield under different irrigation levels, offering a promising sustainable solution for building efficient soil-crop systems.

## ABSTRACT

Water crisis is restricting the production of maize, and deficit irrigation, though essential in saving water, is likely to enhance nutrient limitations and physiological drought stress, which accelerates the decay in growth and yield as irrigation is reduced. The researchers measured the capacity of a biochar-based microbial fertilizer (BMF) in mitigating the impact of drought through the enhancement of soil physical structure, nutrient buffering, as well as rhizosphere functionality and, in turn, enhancing the water productivity of maize under conditions of controlled deficit irrigation. Factorial pot experiment entailed a mixture of various rates of irrigation of well-watered and severe deficit along with the graded rates of BMF application. The parameters of maize growth and yield have been measured together with soil physical parameters, significant chemical parameters (pH, organic carbon, available nutrient forms, mineral forms of nitrogen), and biological functioning (enzyme activity and proxies of microbial activity). The decreasing monotonic shifts in plant height, leaf expansion, biomass development, and reproductive efficiency in the unamended treatment were brought about by the reduction of irrigation. Comparatively, BMF structured these trends of droughts by enhancing water holding capacity and hydraulic conductivity of the soil, organic carbon and cation exchange capacity, and enhancing nutrient availability and retention. BMF chemically and biologically secured the mineral N supply and maximized the conservative nitrogen cycling that preferably operated canopies in the long term and reduced the damage with limited water due to stress. Their findings give a mechanistic foundation for integrating biochar-based microbial fertilizer in deficit irrigating in order to co-optimize the condition of the ground and the nutrient retention and maize strength, and offer a sustainable approach to enhancing disciplinary cultivation in a water-restricted setting on a large scale.

**ABSTRACT**

Land use change can alter soil properties and soil health. Increased population pressure and related food needs are the most important drivers of conversion of natural vegetation to cultivated land. Converting native vegetation land to high tunnel production is a very economical and high-return land use management. Research on soil properties under land-use change could help managers to clarify the status of soil health and make timely appropriate management decision, which is of great significance for the sustainable utilization of land resources. The effect of organic farming system and cover crops on soil health indicators in high tunnels after land-use change, however, is not well understood. Field experiments were conducted to determine the effects of oraganic farming systems and winter-planted cover crops on soil health of vegetable production systems in humid environments. We tested soil bulk density, organic carbon, total nitrogen, extractable phosphorus, extractable potassium, available water content, saturated hydraulic conductivity and conducted soil health assessment. The results can provide a References for farmers to manage soil health in the Southeast United States.

**ABSTRACT**

Oil palm (*Elaeis guineensis*) is predominantly cultivated as a monoculture, involving repeated fertiliser applications, resulting in lower soil health. A viable alternative to monoculture oil palm is oil palm agroforestry, which can potentially increase soil health by better supporting the soil microbial ecosystem, leading to improved crop growth. However, oil palm agroforestry has never been tested in Malaysia, prompting this study to assess whether agroforestry implementation would influence oil palm growth compared to monoculture. In this study, two agroforestry treatments were established: one interplanted native tree (*Nauclea subdita*) between two palms (low-density), and two interplanted native trees between two palms (high-density). Growth parameters (height, frond number, and chlorophyll content) were measured twice per year. Significant treatment effects were observed only at the first measurement for oil palm height and frond number ($p<0.05$). Oil palm height in the high-density treatment did not significantly differ from that in monoculture or low-density agroforestry, indicating an intermediate height response. Meanwhile, frond number was considerably higher in high-density agroforestry than in monoculture or low-density agroforestry, indicating altered growth under agroforestry conditions; however, there was no difference in relative chlorophyll content. Comparisons of relative growth between treatments at the two measurement times showed differences; low-density agroforestry had higher relative frond growth than the higher-density treatment (similar to the monoculture), but lower chlorophyll values than the monoculture. These findings provide early insights into the effects of oil palm growth responses in monoculture and agroforestry, where low-density agroforestry showed a comparable growth response to monoculture; however, additional trees altered growth patterns. This suggests that the early influence of agroforestry on oil palm performance can only be observed when more than one tree is interplanted between palms.

**ABSTRACT**

Soil health provides a fundamental basis for sustaining ecosystem functioning, enabling sustainable agricultural development, and safeguarding food security. Its conceptual scope has expanded from a narrow focus on "soil fertility" to a more integrative capacity encompassing productivity maintenance, environmental regulation, and ecosystem service provision (Doran et al., 1996; Lehmann et al., 2020; Bünemann et al., 2018). However, conventional soil health assessments typically depend on sparse sampling and laboratory measurements, which limits their ability to characterize continuous regional-scale spatial patterns and to disentangle heterogeneous driving mechanisms. To address this bottleneck, this study selected Hailun City, a representative agricultural county in the black soil region of Northeast China, as the test area. A soil health index (SHI) was developed using physicochemical and biological indicators from the 0–20 cm layer, and digital soil mapping (DSM) coupled with machine-learning algorithms was employed to shift from "field-scale diagnosis" to "regional-scale inference," providing actionable and quantitative technical support for black soil conservation and cropland quality improvement (Nabiollahi et al., 2018; Zeraatpisheh et al., 2020).

We established an end-to-end workflow comprising "indicator reduction–index construction–machine-learning mapping–accuracy assessment–driver analysis." First, principal component analysis and correlation-based screening were used to derive a minimum data set (MDS), thereby reducing multicollinearity and redundancy and improving index robustness (Li et al., 2019; Iheshiulo et al., 2024). Next, linear and nonlinear scoring functions were applied to transform indicators with different units into standardized scores ranging from 0 to 1, which were then aggregated (e.g., via weighted integration) to construct the SHI and enhance sensitivity and interpretability with respect to soil condition changes (Andrews et al., 2002, 2004). For spatial prediction, we integrated terrain-, remote sensing–, soil-, and management-related environmental covariates, and implemented random forest (RF), gradient boosting machine (GBM), and support vector machine (SVM) models to simulate and compare the spatial distribution of SHI, thereby producing a reproducible regional-scale soil health mapping workflow (Vasu et al., 2016; Zeraatpisheh et al., 2020).

The results revealed marked differences in model performance for representing SHI spatial patterns: RF achieved the highest accuracy ($R^2$ = 0.61), outperforming GBM ($R^2$ = 0.49) and SVM ($R^2$ = 0.43). The RF-derived SHI map exhibited strong consistency with the distribution of black soils in Hailun, current land-use patterns, and topographic gradients, and more reliably captured spatial heterogeneity and potential key control zones of soil health within the black soil region. Overall, the proposed integrated framework—linking SHI construction, machine-learning-based mapping, and mechanistic interpretation—offers both scientific rigor and operational feasibility. It enables conversion of limited point observations into decision-support products for local implementation, and provides a transferable pathway for zoned management of black soil conservation, cropland quality enhancement, and sustainable agricultural management (Nabiollahi et al., 2018; Iheshiulo et al., 2024).

# Transformation patterns of precipitation-soil water-crop water in karst regions and their impact on maize yield

**Xu Yang[1,2*], Ke Zhang[2,3], Zimei Miao[1], Tingting Chang[4], Mir Moazzam Ali Talpur[4], Jie Zhang[4], Yujie Zhang[5], Hengji Qin[4], Saffi Ur Rehman[4], Hiba Shaghaleh[4], Yousef Alhaj Hamoud[2]**

## ABSTRACT

In recent years, the southwestern karst region of China has experienced frequent sudden, seasonal, and regional droughts, which have exerted serious direct and indirect impacts on agricultural production, the ecological environment, and socio-economic development. Research on the formation mechanisms of agricultural drought in karst regions remains limited, particularly with respect to the transformation processes among precipitation, soil water, and crop water, and the systematic effects of these transformation processes on maize yield are poorly understood. This study elucidates the dynamic transformation patterns among precipitation, soil water, and crop water during the maize growing season and clarifies the impact of dynamic changes in precipitation, soil water, and crop water on maize yield. During the summer maize growing season, the intra-annual temporal variation patterns of precipitation, crop water, and soil water are similar, with values in July–August exceeding those in June and September. This pattern is primarily attributable to the fact that peak precipitation in the study area predominantly occurs in July and August. Across different regions, a decrease in precipitation during July–August leads to corresponding decreases in crop water demand, while soil water exhibits varying degrees of increase, indicating that a portion of precipitation is transformed into infiltrated soil water. Moreover, Correlation coefficients between soil water, crop water demand, and summer maize grain yield all exceed 0.62, and these correlations are stronger than those between precipitation and summer maize grain yield. In most regions, summer maize yield is most strongly correlated with crop water demand, followed by soil water. The findings of this study have great implications for agricultural drought resistance and efficient water resource utilization in karst regions.

*mengru.wang@wur.nl

**ABSTRACT**

Soil nutrient imbalances have negative impacts on the environment and crop yield. It is therefore of major importance that farmers make sustainable soil nutrient and carbon management decisions by implementing measures that stimulate soil quality, water quality, crop productivity, and biodiversity, and minimize GHG emissions. Given the fact that the effectiveness of measures strongly varies over space and time, it is important to increase our insight into the current and potential soil nutrient and carbon budgets, i.e. difference between inputs and outputs, and the impact of measures affecting these budgets and associated impacts. This study presents the NutriFarm model as a decision support tool that can evaluate the effect of various soil, crop and nutrient measures affecting the five abovementioned goals. The tool not only evaluates macro-nutrients (N, P, K), but also S, Ca, Mg, Zn, and Cu, and soil organic carbon (based on the RothC model) and its interactions with soil organic nitrogen. The tool covers EU-27, the United Kingdom and Switzerland, and is aimed to be used by farmers or farm advisors. This tool is freely available on the NutriPlatform, i.e., a platform that was built as part of the NutriBudget project (Grant agreement ID: 101060455). This platform can be used by multiple stakeholders, because it also includes the results of ten different roadmaps for policymakers. This stimulates the dialogue between farmers and policymakers on the transition towards a sustainable agricultural sector.

# Optimized fertilization strengthens the soil health–yield relationship by enhancing biological activities

**ABSTRACT**

Chemical fertilizers support crop production, yet their long-term consequences for soil health, particularly the biological functions, remain poorly understood. Here, we used four long-term (≥ 10 years) field experiments with contrasting fertilization regimes evaluate the effects of chemical fertilization on soil health, microbial functions, and their linkages to wheat productivity. We found that improved fertilization practices, characterized by moderately reduced fertilizer inputs, significantly enhanced soil health and also led to a modest increase in wheat grain yield compared with typical farmer fertilization practices, primarily through enhanced biological functions. Bacterial and archaeal phylogenetic diversity, but not fungal diversity, was positively associated with the soil health index. Notably, rare bacterial taxa were the key drivers of biogeochemical functions, including carbon, nitrogen, phosphorus, and sulfur cycling. Appropriate fertilization rates (255 kg $ha^{-1}$ ~ 375 kg $ha^{-1}$) promoted positive linkages among soil health, biological functions, and wheat yield via increased grain number. In contrast, no significant effects were observed in the excessive fertilization treatment (420 kg $ha^{-1}$ ~ 870 kg $ha^{-1}$). Collectively, our findings emphasize the role of soil microbiome in mediating soil health and crop productivity, underscoring the necessity of integrating biological indicators into nutrient management strategies for sustainable agricultural intensification.

## ABSTRACT

Grassland–crop rotations (GCR) are increasingly promoted as a sustainable strategy to enhance soil organic matter and nutrient retention. However, the influence of differently managed grasslands on nutrient leaching in subsequent croplands, i.e. their legacy effects (LE), remain poorly understood. In this 15-year field experiment in a temperate agroecosystem (Lusignan, France), we evaluated how grassland LE influences leaching losses of six nutrients ($NO_3$-N, PO4-P, K+, Ca2+, Mg2+, and $SO_4$-S). Three grassland management practices in GCR varying in grassland duration and nitrogen fertilization were investigated and compared to continuous grassland and continuous cropland. Zero-tension lysimeters at 105 cm depth were used to monitor drainage and leachate chemistry.

Compared with continuous cropland, grassland LE reduced nutrient leaching losses in all GCR treatments by 1-37%, depending on the nutrient. These effects were jointly regulated by LE on nutrient concentrations in leachate and on drainage quantity: LE on $NO_3$-N, $K^+$, and $SO_4$-S leaching losses was mainly controlled by concentration variations, whereas $Ca^{2+}$ and $Mg^{2+}$ losses were more closely linked to drainage intensity. Compared to a 3-year grassland phase, a 6-year grassland phase exhibited stronger legacy benefits. Nitrogen fertilization had minimal influence, and responses to successive GCR cycles varied by nutrient.

Our findings demonstrate that grassland LE play a key role in shaping nutrient leaching in GCR systems, with implications for designing effective nutrient management strategies. Extending grassland phases and using cover crops during fallow periods may reduce nutrient leaching while sustaining productivity.

*nttimbas@up.edu.ph

## ABSTRACT

The selected soil properties of lowland rice soils in Siniloan, Laguna, were evaluated to identify potential constraints affecting rice production. Farmers were interviewed to determine fertilizer management. Soil and plant samples were collected from 22 farms across the study site during the 2024 dry season and analyzed to determine soil texture, pH, soil organic matter (SOM), available phosphorus (P), exchangeable potassium (K), and total P and K in rice flag leaf tissue. A P adsorption test was conducted at the site with the lowest available P to describe its fixation potential. Most farmers apply P (9.86 kg P/ha) and K (18.69 kg K/ha) at suboptimal rates. In some farms, N is applied at 300 kg N/ha, exceeding the recommended rate for rice. The sites had low soil pH and acidic conditions, limiting nutrient availability. SOM was generally at a medium level, while available P ranged from 1.33 to 82.33 ppm, with some sites below deficiency thresholds and others above optimal levels, likely due to proximity to residential and lake-connected areas. The P adsorption data were fitted to the Freundlich model. The site with the lowest available P showed high fixation capacity. Most sites had exchangeable K values below the recommended levels. Plant tissue analysis revealed low total P and K concentrations in rice plants. Correlation analysis showed a significant relationship between total P, available P, and OM. These results emphasize the need for site-specific nutrient management to address potential production constraints and improve rice yields in the study area.

# Synergistic Effects of Irrigation Regimes and Duckweed Species on Microplastic Dynamics in Paddy soil

**Zhenchang Wang**[1*] ,**Kexin Chen**[1]

[1] *College of Agricultural Science and Engineering, Hohai University, Nanjing, China*

*wangzhenchang@hhu.edu.cn

**ABSTRACT**

Rice (Oryza sativa L.) is one of the most important staple crops worldwide, and the stability of paddy ecosystems is critical for food security and environmental sustainability. In recent years, microplastics (MPs) contamination in agricultural soils and waters has become an emerging environmental concern. Microplastics can adversely affect crop growth, alter microbial community structure, and pose potential ecological and human health risks through food chains. Duckweed, a common floating aquatic plant in paddy fields, has shown strong potential for pollutant adsorption; however, its regulatory role in microplastic-contaminated paddy systems under different irrigation regimes remains poorly understood.

In this study, a controlled paddy system experiment was conducted to investigate the interactive effects of irrigation regime, duckweed species, and microplastic exposure on rice growth, microbial communities, and microplastic behavior. A three-factor experimental design was employed, including two irrigation regimes—continuous flooding (CF) and alternate wetting and drying (AWD), two duckweed species—Lemna minor and Landoltia punctata, and the presence or absence of microplastics. Rice growth performance, physiological responses, microbial community structure and functional potential, and microplastic adsorption by duckweed were systematically analyzed.

The results showed that, compared with CF, AWD irrigation exhibited distinct drying phases during the rice growth period and achieved significant water-saving effects. Under MPs stress, rice growth was markedly inhibited during the middle and late growth stages, as evidenced by significant reductions in plant height and total biomass, accompanied by decreases in chlorophyll fluorescence parameters, indicating impaired light-use efficiency and tolerance to high light intensity. Meanwhile, MPs exposure induced oxidative stress responses in rice, significantly activating the antioxidant enzyme system at the early stage of exposure.

Duckweed exhibited a strong capacity to adhere microplastics, with pronounced species-, tissue-, and hydrological-dependent differences. Landoltia punctata showed significantly higher microplastic adsorption on leaf surfaces and roots than L. minor, particularly under AWD conditions. Structural analyses indicated that the higher surface roughness and increased fold–pore structures of Landoltia punctata, especially under drying–rewetting cycles, enhanced the physical interception of microplastics. In addition, shifts in microbial communities and dissolved organic matter composition under AWD further strengthened hydrogen bonding and electrostatic interactions, contributing to the stabilization of adhered microplastics.

Overall, this study highlights the importance of integrating irrigation management and biological regulation to mitigate microplastic risks in paddy ecosystems. The combination of alternate wetting and drying irrigation with Landoltia punctata provides a promising eco-friendly strategy for enhancing paddy field sustainability under microplastic contamination scenarios.

# Organic slow-release nitrogen fertilizer affects soil organic carbon sequestration, greenhouse gas emission, and rice yields under water-saving irrigation

**Shurong Hao[1*], Congyi Liu[1], Zhenchang Wang[1],Yi He[1],Wentan Liu[1]**

*[1]College of Agricultural Science and Engineering, Hohai University, Nanjing 210098, China;*

srhao@hhu.edu.cn (S.H.);liucongyi2022@163.com (C.L.); wangzhenchang@hhu.edu.cn (Z.W.);251310010025@hhu.edu.cn (Y.H.);221610010019@hhu.edu.cn (W.L.)

*Correspondence: srhao@hhu.edu.cn (S.H.)

**ABSTRACT**

Water-saving irrigation and organic slow-release nitrogen fertilizer are extensively employed in paddy fields, however, their effects on soil organic carbon sequestration (SOCS), greenhouse gas (GHG) emissions, and rice yields require further exploration, especially under aquaculture wastewater irrigation. Here, we conducted a field experiment to investigate the impacts of different irrigation regime (FSI: frequent and shallow irrigation; II: intermittent irrigation) and nitrogen fertilizer management (CK: no N fertilize; NPK: N fertilizer provided by inorganic fertilizer; SRF: N fertilizer provided by organic slow-release fertilizer) on SOCS, GHG emissions, and rice yields. Results showed that II effectively mitigated $CH_4$ emissions while concurrently increasing $CO_2$ and $N_2O$ emissions relative to FSI. Conversely, compared with NPK, SRF significantly reduced $CH_4$, $CO_2$, and $N_2O$ emissions.II significantly reduced 10.6%~13.4% $CH_4$ emission but increased 5.9%~11.3% $CO_2$ and 22.8%~27.0% $N_2O$ emission compared with FSI, and SRF significantly reduced 20.2%~21.3% $CH_4$, 10.6%~14.7% $CO_2$ and 21.3%~25.2% $N_2O$ emission compared with NPK. Compared with FSI_NPK, II_SRF significantly increased soil nutrients (TN, $NO_3$-N), rice yields by 48.7%, SOCS by 95.3%,and significantly reduced GWP by 17.2%, NGHGE by 69.5%, GHGI by 51.2%,contributing to the most mitigation of the greenhouse effect.Moreover, Soil SOC was a main predictor of $CH_4$ emission and was notably negatively related to $CH_4$ emission,while soil MBC and TN were primary predictors of rice yields and were notably positively related to rice yields.In conclusion, intermittent irrigation combined with organic slow-release nitrogen fertilizer is the optimal water and nitrogen management strategy, which can conserve water, improve rice yields, sequester carbon, and reduce greenhouse gas emissions. These findings provide valuable theoretical guidance for formulating water and fertilizer management strategies aimed at water conservation, yield increase, carbon sequestration, and emission reduction in paddy fields in China.

# Soil Science Education in Kazakhstan Universities: Strengthening Soil and Geological Literacy for Sustainable Land Management

**Aigul Zhapparova***

Department of Soil Science, Agrochemistry and Ecology, Kazakh National Agrarian Research University, Almaty, Kazakhstan

E-mail: aigul7171@inbox.ru

**ABSTRACT**

Soil is a strategic resource underpinning food production, ecosystem services, and climate regulation. In arid and semi-arid countries such as Kazakhstan, sustainable land management depends directly on the competence of soil and land-use specialists. Kazakhstan faces extensive land degradation, including erosion, salinization, desertification, and decline of soil organic matter. Similar challenges characterize Central Asia, where climate variability and irrigation-driven land transformation increase soil vulnerability.

This contribution shares Kazakhstan's experience in soil science education at the university level and reflects on recent structural changes in curricula. Reduced contact hours in soil science and geology-related disciplines have limited field practice, laboratory training, and students' engagement with soil profile description, parent material interpretation, and landscape–soil relationships. Simultaneously, decreasing emphasis on fundamental soil disciplines has narrowed academic depth in soil genesis, mineralogy, soil physics, and soil chemistry. In regions highly sensitive to salinization, wind erosion, and climate stress, soil education must develop practical diagnostic skills, critical thinking, and systems-based understanding of land processes. Strengthening soil literacy is therefore not only a disciplinary task but a strategic component of sustainable development and food security policies across Central Asia.

The presentation discusses approaches to maintaining soil science and geology as core competencies within land-related programs, including agronomy, horticulture, soil science and agrochemistry, land management, ecology, forestry, water management, and agricultural engineering. Based on current teaching practice, future-oriented directions are proposed: defining minimum learning outcomes for soil and geological literacy; preserving mandatory field and laboratory modules; integrating digital soil mapping and GIS tools into curricula; aligning with international soil classification frameworks; and reinforcing interdisciplinary links between soil science, geology, climate science, and land policy.

By sharing this experience, the contribution aims to support international dialogue on strengthening resilient and practice-oriented soil education systems.

*[4] National Research Council - Institute of BioEconomy (Department of Biology, Agriculture and Food Sciences, Sesto Fiorentino, Italy)*

*[5] Wrocław University of Environmental and Life Sciences (Institute of Soil Science, Plant Nutrition and Environmental Protection, Wrocław, Poland)*

*jjlelis@ufv.br

**ABSTRACT**

In 2005, the national 'Soil of the Year' programme was initiated by the German Soil Science Society, then followed by other national societies. The successful implementation of the national World Soil Day initiatives encouraged new educational projects aimed at increasing the public awareness of soils as natural resources. In 2023, the WSY Task Force was established at the initiative of the President of IUSS, Edoardo Constantini, launching the WSY as a new project at the 100th Anniversary ofthe IUSS.

Through the World Soil of the Year (WSY), the IUSS seeks to celebrate a specific soil annually, in recognition of our collective responsibility to sustain soils and their functions, and to promote public awareness of this crucial and increasingly threatened resource. It is expected that the WSY initiative will aid in compiling a registry of soil heritage, to recognize the inherent natural and cultural values of soils, thereby helping to open doors for soil science to integrate with environmental protection activities and projects.

The World Soil of the Year (WSY) Working Group is an initiative of Division 1 of IUSSS. The WSY celebrates a special soil profile that has relevance to the environment and society. Proposals are made by national soil science societies that are members of the IUSS. The proposals must highlight the importance of soil profiles for natural or other managed ecosystem services; their uniqueness as natural features and the potential risk of their degradation and/or extinction due to natural or anthropogenic causes; their cultural relevance; and their geographic distribution. A requirement for proposals to be selected is a clear plan for outreach and communication at both the national and international levels.

The Chernozem of the Balti steppe, Moldova, was the inaugural "IUSS World Soil of the Year," presented during the closing ceremony of the 2024 Centennial Congress in Florence.

The "Gleysol - Hydromorphic soil supporting forest growth in the steppe region from the Carpathian Basin", proposed by the Hungarian Soil Science Society, was selected as WSY 2025. The representative soil profile is located at the Püspökladány Experimental Station within the Hortobágy National Park, a UNESCO Biosphere Reserve and recognized UNESCO World Heritage Site. The soil is part of a unique cultural landscape dominated by grasslands and salt-affected pastures in the Hungarian Plain.

The WSY initiative helps connect people with soils, both in the WSY country and internationally. Therefore, the chosen soil must be recognizable in similar landscapes worldwide. The focus is on communicating with people who are distant from soils in a way that is understandable to all. Emphasis is put on the use, functions, ecosystem services, and cultural and historical heritages.

# Current Status and Future Trends of Soil Education in Mongolia

**Khadbaatar Sandag***

[1] *Mongolian National University of Education, Geography Department, Ulaanbaatar, Mongolia*
*khadbaatar@msue.edu.mn

**ABSTRACT**

Soil cover plays a vital role throughout human history by ensuring food security, regulating water resources, filtering pollutants, mitigating climate change, and protecting biodiversity. Modern research defines soil as a key component of ecosystem services, and its degradation directly impacts food security, water quality, and climate stability (FAO, 2015).

In Mongolia, geography has been taught since the establishment of the first modern schools in the early 20th century, which marked the beginning of soil education within the school curriculum. Geography is taught as an integrated subject in primary education and as an independent subject in middle and high schools, with soil concepts occupying a specific place, similar to most international education systems. Currently, primary schools in Mongolia introduce basic soil concepts through the "Human and Nature"course. In grades 7 to 12, geography is taught for 1–2 hours per week (70–75 hours per academic year), of which soil-related content accounts for approximately 10–15 hours. Compared to other natural and social science subjects in secondary schools, this is twice as low. Although the proportion of soil education within geography might seem comparable to other countries at first glance, its actual content is highly deficient. This study evaluated the geography curriculum and textbooks for grades 7 to 12 of General Education Schools (GES). The analysis revealed a heavy dominance of basic knowledge, such as soil structure, properties, and distribution, whereas critical issues like soil degradation, pollution, restoration, and sustainable management are severelyunderrepresented.

Research on soil education in Mongolia remains scarce and has mostly been analyzed strictly within the scope of natural sciences. Soil topics in geography lessons are often repetitive, lack content on soil utilization and protection, and rely on overly generalized concepts of soil erosion and degradation (Davaadorj, 2024). Therefore, there is an urgent need to evaluate the current level of soil education and enrich it with content aligned with land degradation, desertification, and climate change adaptation, emphasizing the value of soil through industries, agriculture, and pasture management.

At the higher education level, the training of soil specialists is primarily centralized at the Mongolian State University of Life Sciences (MSULS). Although MSULS recruits students for agronomy-soil science programs annually, enrollment remains extremely low. This is attributed to a shortage of job opportunities and the limited hours dedicated to soil content in GES geography classes. Furthermore, while soil science is a compulsory course in the geography departments of the National University of Mongolia (NUM) and the Mongolian State University of Education (MSUE), they lack specialized soil science undergraduate programs. Although these universities offer advanced master's and doctoral programs in soil science, enrollment continues to be low. Consequently, graduate opportunities in the domestic soil sector are limited, and students increasingly pursue master's and doctoral degrees in soil science abroad.

Soil education is an integral part of environmental education and is closely aligned with the Sustainable Development Goals (SDGs). However, this study demonstrates that its scope, depth, and cognitive level within the current educational systemare insufficient.Thus, it is crucial to systematically reform curriculum and textbook contents, align them with modern educational trends, and support teacher professional development to enhance the quality of soil education in Mongolia.

# Making Darcy visible: A simple apparatus for teaching Saturated Flow in Soil

**R. McLenaghen[1*], C. Deepagoda[1], and B. Main[1]**

[1] *Affiliation of the Authors (Department of Soil & Physical Sciences, Lincoln University, Christchurch, New Zealand)*

*E-mail Address of Presenting Author

(roger.mclenaghen@lincoln.ac.nz)

**ABSTRACT**

Darcy's Law relates the volumetric flow rate (Q) through a porous medium to the hydraulic conductivity (K), the cross-sectional area (A), and the hydraulic head gradient denoted by $(h_2-h_1)/L$. Owing to its wide range of practical applications, it is one of the fundamental principles taught in soil physics courses and demonstrated experimentally in undergraduate laboratories. At the first-year (100-level), students typically measure drainage rates in differently textured/structured soils using drainage tubes and a constant water head via a marotte container. While at the second-year (200-level), more advanced field methods such as the augered-hole and Guelph permeameter are introduced to determine hydraulic conductivity. Despite this, the concept of *total hydraulic head*, central to Darcy's theory, remains difficult to explain in the classroom clearly and demonstrate effectively in the laboratory.

In this study, a new teaching and experimental apparatus was developed to demonstrate Darcy's Law by varying the water head while maintaining a constant column length. Based on the Mariotte principle, the apparatus provided a simple and cost-effective means of maintaining a constant hydraulic head throughout the experiment. Using an aeolian sand with a narrow pore size distribution (50–100 μm), students determine the volumetric water flow at different head values. After graphing the results, an excellent agreement ($r^2>0.99$) was observed between hydraulic head (kept constant at 10, 20, 30, and 40 cm) and the corresponding Darcy flow rates. The estimated hydraulic conductivity was then used to predict the flow rate at a 50 cm head, which closely matched the measured value, thereby validating the approach.
Overall, this apparatus offers a cost-effective, practical and visually intuitive tool for enhancing undergraduate understanding of saturated flow dynamics and the role of hydraulic head in governing water movement through soils.

# Deciphering Soils through the Power of Games

**Alma Barajas-Alcalá**[1*]

[1] *National School of Higher Studies (ENES), National Autonomous University of Mexico (UNAM), Morelia, Mexico*

*abarajas@enesmorelia.unam.mx

**ABSTRACT**

In university level soil science education, many concepts lack equivalents in students' everyday knowledge. Terms such as calicata, or Luvisol (LV) may seem unfamiliar or even intimidating to those approaching soil studies for the first time. At the bachelor's degree in Geohistory at the National Autonomous University of Mexico (UNAM), campus Morelia, we have incorporated the telepictionary technique as a playful and collaborative tool to facilitate the understanding of soil science concepts.

Over three generations of students, this game has allowed young learners to transform unknown terms into their own drawings, creating visual and narrative associations that strengthen their analytical thinking and conceptual memory. Through images, participants reinterpret the technical language of soil science from their own perspectives and context, successfully integrating its basic principles.

The results show that learning mediated through play not only sparks creativity, curiosity and enjoyment, but also fosters a deeper appropriation of knowledge. When classifying soils, students recall the images created collectively, turning a complex task into a meaningful experience. This approach demonstrates that play can serve as a bridge between imagination and science, between the soils and those who study it.

**ABSTRACT**

Soil Education in Brazil manifests itself across multiple educational spaces, both formal and non-formal, with purposes ranging from teaching and outreach to the popularization of science (Silva, Vezzani & Lima, 2022). Various fields of knowledge and learning environments can be mobilized in this process, such as virtual museums. Science museums have become consolidated as spaces of non-formal education, fostering dialogue between science and society and contributing to Soil Education. In this regard**,** Pedron et al. (2022) point out that soil education in museums is a continuous process of knowledge production that begins with the conception of collections, continues through their study, is expressed in the form of exhibitions, develops pedagogical practices, and involves the analysis of educational and scientific activities through interaction with the public. Within this context, this study aims to present the Virtual Soil Museum of Northern Paraná (MUVISOLOS)**,** highlighting it as a virtual environment dedicated to scientific dissemination and the appreciation of pedological heritage. According to Henriques (2018)**,** virtual museums are characterized as collections of digital records — images, texts, audio files, and other data of scientific, historical, or cultural interest — accessed through electronic media. They are defined as institutions without a physical location but with an interactive presence in virtual space. The MUVISOLOS (https://muvisolo.wixsite.com/museu-de-solos-norte) is linked to the Geography degree program at the State University of Northern Paraná, and was created in 2024 with the purpose of providing, in a virtual environment, information about the soils of the 125 municipalities of Northern Paraná. The museum seeks to promote understanding of the region's pedological heritage and to foster awareness regarding the sustainable use and conservation of soils.

# From Soil Pits to Global Goals: Reimagining Soil Education for a Sustainable Future

**Said Al-Ismaily[1]*, Aminat Umarova[2] and Johan Bouma[3]**

[1]Department of Soils, Water and Agricultural Engineering, College of Agricultural and Marine Sciences, Sultan Qaboos University, Muscat, Oman, [2]Soil Science Faculty, Moscow State University, Moscow, Russia, [3]Wageningen University, Wageningen, Netherlands

*E-mail: esmaily@squ.edu.om

## ABSTRACT

Soil science stands at a crossroads. Despite its key role in food security, water, climate, biodiversity, and the SDGs, its teaching remains narrow. This work calls for a transformative curriculum uniting science, sustainability, and social engagement. Using examples from Sultan Qaboos University (SQU) (Oman) and Moscow State University (Russia), and insights from Europe (Veenstra et al., 2024), this study shows how inquiry-based learning, SDG-focused teaching, and community projects build skills in systems thinking, ethics, and problem-solving. At Sultan Qaboos University (Oman), the BSc in Soil Sciences was restructured as a whole-program reform anchored in graduate attributes and aligned with the SDGs. Outcomes linked soil functions to ecosystem services in arid settings. The SQU model, unlike piecemeal course updates, ensures coherence and progressive learning, echoing Spronken-Smith et al. (2011) that holistic design builds enduring competencies - a sustainability imperative. To unlock soil education's transformative potential, key strategic actions are recommended: (1) Link soil functions to ecosystem services and sustainability outcomes to integrate the SDGs; (2) Institutionalize interdisciplinary collaboration across engineering, economics, and policy; (3) Expand student-led research, living laboratories, and stakeholder partnerships to enhance experiential learning; (4) Integrate emerging technologies such as modeling, machine learning, and data analytics to advance soil understanding, prediction, and decision-making, and (5) Invest in faculty development, global mobility, and impact evaluation to sustain educational innovation. Soil education is thus re-designed, moving beyond technical training to become a catalyst for sustainability - inspiring curiosity, responsibility, and action. Embedding soil in SDG policies and education is vital stimulate future generations to see soil as the living foundation of life.

# SUSTAINABLE LAND MANAGEMENT STUDY IN TERTIARY INSTITUTIONS FOR LAND RECLAMATION: KEY TO SUSTAINABLE AGRICULTURE

**Adejumo Sifau A[1*] and Oke Samson[1]**

[1] *Department of Crop Protection and Environmental Biology, University of Ibadan, Ibadan, Nigeria*

*E-mail Address: sifauadejumo@gmail.com

**ABSTRACT**

Land contamination/pollution reduces the carrying capacity of the land and its ability to meet the food demand of the ever-growing population thereby posing threats to food safety and security. Education on sustainable methods for managing soil resources and restoration of polluted soils through research is pertinent for increasing agricultural production and promoting food security. SLM approach refers to the use of one or several SLM Technologies. Study was carried out on the integrated use of environmentally friendly and cost-effective methods like bioremediation and phytoremediation for managing contaminated soils. The phytoremediation potential of *Leuceana leucocephala* on the heavy metal and crude oil polluted soils amended with compost and biochar. The heavy metal contaminated soil was collected from the lead acid battery waste dumpsite that was first mixed with uncontaminated soil to give a 50% level of contamination before the addition of compost and biochar. Uncontaminated soil was also spiked with crude oil at 5% of the soil weight measured at 500 grams/cup. Biochar and compost were applied at the rates of 0, 2.5, 5,10 tons/ha (0-Control, 2.5t/ha-C1, 5t/ha-C2, 10t/ha-C3, 2.5t/ha-B1, 5t/ha-B2, 10t/ha-B3) while control treatment served as check. Seeds of *Leuceana leucocephala* were first subjected to $H_2SO4$ treatment to break the dormancy before planting at 7 days after soil amendments with compost and biochar. Data were collected on growth, proline, phenolics, heavy metal uptake, biomass and post-cropping metal analysis. Results showed that heavy metal contamination and oil pollution affected the growth of *L. leucocephala*. However, application of compost and biochar, especially their combination, gave the highest number of leaves, plant height and biomass accumulation in *Leuceana leucocephala*. The proline and total phenolic contents of the plants grown in the heavy metal-polluted soil (unamended) were the highest compared to those treated with organic amendment. This indicated the ability of the amendments in reducing stress on the phytoremediator while enhancing metal uptake. Plants grown in the soil without amendments had the highest concentrations of these metabolites which enhanced the tolerance of these plants in contaminated soils. Results of post-cropping soil analysis however, showed increase in soil lead content with C2. This shows that application of organic amendments enhanced plant growth but also immobilized metal for uptake by phytoremediator. In conclusion, *Leuceana leucocephala* was able to grow on heavy metal and crude oil polluted soils amended with compost and biochar and produced higher amounts of proline and phenolics, for tolerance in the polluted soils. The use of organic amendments in combination with phytoremediation technology could be promoted for sustainable soil management and can be included in the soil management curriculum.

## ABSTRACT

As soil science educators we need to rebuild communities of knowledge and train work ready graduates. There is not only a lack of graduates with field-based soil skills, but there is also a disconnect between soils and landscapes. Graduates often have limited field descriptive and interpretation skills. Students like learning in the field; it helps them to comprehend soils as not only part of the biophysical and cultural landscape but also as part of a functioning ecosystem. In the field, there is more time to think and to interact with teaching staff so that learning occurs at a deeper level. But we are increasingly offering less opportunities to do this in tertiary institutions, even though we know intuitively that learning in the field is highly effective, as it is a pedagogically aligned approach.

Soil judging competitions (SJC) provide an experiential approach to teaching and learning essential skills in soil science. SJC are designed to upskill participants in the ability to accurately describe soil profiles and make land use interpretation decisions, compared to an expert description/ interpretation. These competitions have been run in Australia since 2012 and in New Zealand since 2016.

In 2024, the Moana Oceania Soil Judging Competition (MOSJC) was hosted in New Zealand, as part of the joint conference of the New Zealand Society of Soil Science and Soil Science Australia. This SJC involved over 200 participants and 35 teams from 9 countries in the South Pacific region: including 80 students and 70 working professionals. This study aimed to determine the impact of the MOSJC on participants' learning of soil-related knowledge and skills and on their attitudes towards soil science. Participants were asked to complete voluntary pre- and post-competition surveys covering demographic information and self-reported understanding and ability.

Ninety-eight participants completed the pre-contest survey and 56 completed the post-contest survey. Results showed an increase in participants' self-reported skill and knowledge of understanding soil judging characteristics (e.g. soil morphology and site interpretation). Most participants had positive attitudes towards soil science and soil judging, with no significant change due to the competition. Self-reported responses about desired gains from the competition included networking (30%), technical skills (25%), knowledge building (20%), regional knowledge (15%), and professional development (10%).

The wider contribution of soil judging to society is built around increasing how we connect to the soil. If we can support people to have relevant soil knowledge and a deep understanding of the soil within the planet ecosystem, we can strive for soil security and a sustainable future. To achieve this, education is key to building enduring connections to soil.

*[5]Department of Education, Government of Catalonia, Spain*
*rosa.poch@udl.cat

**ABSTRACT**

The **European Soil Strategy 2030** warns of a widespread lack of knowledge about soil in European educational curricula. The main shortcomings identified are: the very limited inclusion of soil health in compulsory content, especially at the early educational stages; a fragmented and disconnected treatment of soil in relation to key areas such as biodiversity, climate change, and food security; and a shortage of teaching resources and practical activities that enable soil to be addressed as an essential resource for sustainability.

This context reinforces the need to promote **innovative educational initiatives** that integrate soil health into the curriculum and encourage active student participation. The guide **Exploring the Soil**, promoted by the Government of Catalonia with the support of European funds and designed by CREAF-UAB and UdL, aims to **raise students' awareness and foster their commitment** to improving soil quality in nearby environments, such as school grounds and municipal spaces.

The methodology combines two educational strategies: **Service-Learning (ApS)**, which integrates curricular learning with real community service, connecting knowledge with action; and **Citizen Science**, which involves the active participation of non-experts—in this case, students—in scientific processes to generate data and knowledge useful to society.

The structure of the guide provides a sequence of sessions adaptable to the organization and possibilities of each educational center, including: introductory sessions that provide context and knowledge about soil and its current challenges; practical field and laboratory sessions to analyze indicators based on physical, chemical, and biological soil properties; and the preparation of a synthesis document (scientific article, poster, or report) summarizing the results, which is presented at a final institutional recognition event attended by local administrations or interested research centers. The initiative promotes **applied scientific knowledge, environmental awareness, and transformative action**, contributing to sustainable land management and the fight against the climate emergency.

During late 2025 and throughout 2026, a **pilot test** will be carried out in which several secondary schools will implement this project under the guidance of the authors. The purpose of this presentation is to introduce the project and its conceptual and methodological characteristics, as well as to present the first results of soil quality assessments conducted by Catalan secondary school students.

*leroshenko@unl.edu

**ABSTRACT**

Collegiate soil judging is an academic competition where students analyze soil profiles and interpret land usage. However, despite its educational benefits, the costs associated with travel, lodging, and competition fees can be prohibitive, especially for teams from smaller or less-funded institutions. This lack of financial support not only limits students' opportunities to engage in these enriching experiences but also creates disparities in access to professional development and networking opportunities within the field of soil science. The objective of this study was to identify the key financial challenges faced by these teams and provide baseline demographic information for soil judging teams in the United States. We surveyed 50 current head coaches of soil judging programs in the United States to understand team funding, student participation, and obstacles to sustaining a successful program. We found that coaches consistently identified limited time and funding as the most limiting factors to maintaining a soil judging program. Despite dedicating an average of 3-6 hours per week to recruitment, training, and travel, most coaches receive no formal compensation. Financial constraints not only place the burden of fundraising predominantly on coaches but also limit student participation. Our survey showed that one in four soil judging teams reported limiting the number of students who traveled to a contest due to financial limitations, and over half required students to cover part of their own expenses. Moreover, most teams cannot attend two contests per year unless the contest is nearby geographically, or if they spend significant time and effort fundraising, which further exacerbates the issues with coaches' time and compensation. The skills learned from soil judging are critical for the next generation of successful soil scientists, and when programs are under-resourced, students miss out on these transformative opportunities. Addressing these challenges is essential to adequately support coaches for their invaluable contributions and ensure that students can develop critical skills and engage in opportunities necessary for success in soil science.

# Building Soil Science Literacy: Assessing Impact in K-12 Teacher Training

**First S. Chapman[1*], Second M. Holzer[2]**

*[1]Soil Science Society of America, Madison, WI, USA*

*[2] Department of Geology, Rutgers University, New Brunswick, NJ, USA*

*schapman@sciencesocieties.org

**ABSTRACT**

The Soil Science Society of America (SSSA) K-12 Teacher Outreach Committee created a one-day in-service program to provide ready-to-use, hands-on training in soil science for middle (grades 6-8) and high school (grades 9-12) educators. This initiative addresses the gap in soil science education: while the Next Generation Science Standards (NGSS) form the basis for new science standards across the United States, soil is not specifically included in the disciplinary core ideas, leading to less classroom focus. The program we developed aims to build teacher competency, confidence, and comfort using SSSA-developed, modular teaching materials. The committee has successfully conducted six in-service events, created web resources, and translated materials into Spanish. This presentation will outline the program, share assessment data from workshop participants, and propose a model for other scientific societies to implement similar outreach.

[2] Faculty of Psychology, Chulalongkorn University, Bangkok

*agrpyst@ku.ac.th

## ABSTRACT

Laboratory instruction in mineral identification involves multiple diagnostic steps, which can be challenging for undergraduate learners. Integrating computer-based technology into teaching may enhance instructional effectiveness for students in the digital era. This study aimed to evaluate the effectiveness of using the Mineral Identification Program (MIP) in a soil science laboratory course for undergraduate students in agriculture. The participants were 39 second-year students in a Bachelor of Science (Agriculture) program. Descriptive statistics were used to assess students' perceptions of the new instructional method. Most students had GPA between 2.00–2.49 and 2.50–2.99, and nearly all had no prior experience in mineral identification. The findings indicated that students held highly positive attitudes toward the new teaching approach. More than 80% of respondents selected levels 4 and 5 ("agree" or "strongly agree") on all items related to correctly, ease of learning, and satisfaction. In terms of learning outcomes, post-test scores were significantly higher than pre-test scores at P value< 0.000. These results suggest that the MIP-based instructional approach was well received and effectively enhanced students' learning performance. Continued development of innovative, active-learning approaches is recommended to support the achievement of learning outcomes in future courses.

**Keywords:** Laboratory Learning, Soil Science, Mineral Identification Program, Learning Outcomes

**Acknowledgments**

# Fostering Soil Science: Insights from the 1st European Soil Judging Contest

**Minerva García-Carmona[1], Luis D. Olivares-Martinez[1*], Victoria Arcenegui[1], Javier Nadal Fuentes[1], Víctor Bori, Lucía Casado[1], Marcos Domenech[1], Aitana González[1], Fuensanta García-Orenes[1], Jorge Mataix-Solera[1]**

*[1] Soil Science and Environmental Technologies Group (GETECMA), Department of Agrochemistry and Environment, Miguel Hernández University (UMH), Elche, Spain.*

*lolivares@umh.es

**ABSTRACT**

Soil Judging Contests serve as a practical and formative approach to soil science, offering students an engaging opportunity to describe, interpret, and classify soils in the field. The 1st European Soil Judging Contest, organized by the Soil Science Department of the University Miguel Hernández (Spain) with the assistance of Environmental Sciences students, was held in Alcoi, Alicante, Spain, from 1-5 September 2025. The event brought together teams from eight participating countries: France, Germany, Hungary, Italy, Latvia, Poland, Portugal, and Spain.

This kind of contest aims to foster a European network for field-based learning and promote collaboration among universities and young scientists. Each national team comprises four members—either undergraduate, master's, or doctoral students—alongside one or two coaches. The competition features an intensive four-day program that includes classroom instruction, field simulations, and two days dedicated to the competition. Participants utilize a comprehensive field manual that outlines soil descriptions according to the two main global classification systems in the last versions: Soil Taxonomy and the World References Base for Soil Resources.

The competition format includes two profiles for team contest and two for individual part. Teams are tasked with describing a designated soil profile within one hour, focusing on the characteristics of various soil horizons and subsequently classifying the soils based on the collected data. Evaluation is conducted by filling out specific forms for each soil profile, with points awarded for each data entry, culminating in a total score that determines the competition winner.

Pre-competition and post-competition online sessions facilitated logistical explanations and collected participant feedback. Competitors expressed positive experiences regarding the educational aspects and motivation to further engage in soil sciences and scientific outreach initiatives.

The educational value of these contests is significant; they promote active learning, critical observation, and practical skills in soil description and classification. Moreover, they encourage teamwork and problem-solving abilities while contributing to the scientific dissemination of soil science. Therefore, this event not only highlights the importance of practical soil science education but also strengthens the connections among future soil scientists across Europe.

More detailed information and the materials used can be found on the website: https://esjc.es/

**Acknowledgments**

We thank the scientific committee of the contest, participants, to all our Sponsors, BIP Erasmus+ funding program, IUSS, SECS, and Generalitat Valenciana for their invaluable contribution to the success of the 1st European Soil Judging Contest.

# Co-developing soil science teaching and learning across North-South – a unique educational collaboration between The University of Melbourne and National University of Laos

**Alexis Pang[1*], Anthony Weatherley[1], Vannaphone Putthana[2], Phimmasone Sisouvanh[2], Phoutthasone Sibounnavong[2], Avakat Phasouysaingam[2], Vangkham Solattanavong[2]**

*[1] School of Agriculture, Food and Ecosystem Sciences, Faculty of Science, The University of Melbourne, Australia*
*[2] Faculty of Agriculture, National University of Laos, Lao PDR*
*alexisp@unimelb.edu.au

**ABSTRACT**

This presentation describes a novel, exemplar cross-country university collaboration in soil science education involving co-design of curriculum and pedagogy. As one of the four key work packages (WP4) of the Australian Centre of International Agricultural Research (ACIAR) project *Quantifying the impacts of nitrogen use and developing sustainable agricultural nitrogen management strategies in Laos rice-based farming systems* (2022/102) (ACIAR 2025), University of Melbourne (UoM) has been collaborating closely with the National University of Laos (NUoL) on the curriculum design and development, official approval, and incipient delivery of the new Bachelor of Science in Sustainable Agricultural Land Management (BSc SALAM), where soil science is a core component of the degree. The BSc SALAM is designed to educate the next generation of leading soil scientists, agronomists, land resource managers, agribusiness professionals and agri-entreprenuers. It is also one of the key pillars for the present ACIAR project, in strategic capacity-building of indigenous soil and crop analytical and advisory capabilities in Laos PDR.

The pedagogical design of soil science learning by UoM-NUoL will be based on the 11 Soil Science teaching principles (Field et al., 2011), inspired by the joy and fascination of soil science and discipline-adjacent practitioners and educators (Hartemink et al. 2014), and determined to make long-term impacts on farming practices, natural resource management and environmental sustainability of Lao PDR in meeting national strategic objectives and the UN Sustainable Development Goals (UN SDGs) 4,5,15-17.

This collaboration while still underway, has seen mutual exchanges of knowledge about soil science and teaching that stems from deeper understanding of the distinct agro-ecological, climatic and pedological contexts between Australia and Laos. As part of the project, existing links and resource sharing between NUoL, the Department of Land Management (DLAM), National Agriculture and Forestry Research Institute (NAFRI), and regional/provincial agricultural offices are being strengthened and leveraged upon.

To illustrate this dynamic collaboration, this presentation will describe how the content of soil science subjects in BSc SALAM will be delivered through authentic learning techniques aligned with Field et al. (2011). This includes clearly linking soil science principles and practices to the spectrum of agricultural production systems in Laos and Australia, environmental sustainability concerns such as greenhouse gas emissions, fertilizer use, and practical skills in the laboratory and field.

# Building Soil Literacy Through LADA: Teaching Soil Assessment, SOC Understanding, and Reliable Sampling

**Maira Kussainova[1,2,3]*, Sklyarov Vladimir[1], Nursultan Nurgali[4], Stuart Bowlin[5]**

*[1] Kazakh National Agrarian Research University, Almaty, Kazakhstan*

## ABSTRACT

Strengthening soil literacy is critical in regions experiencing rapid land degradation and limited soil data, such as Kazakhstan. The LADA (Land Degradation Assessment in Drylands) methodology provides an effective educational framework that links visual soil diagnostics, organic carbon understanding, and standardized sampling practices. Teaching LADA-based indicators—structure, salinity, compaction, vegetation cover, and erosion—enables students, farmers, and civil society to rapidly interpret soil condition, even in data-sparse landscapes.

Organic carbon literacy is especially important. Kazakhstan currently relies on sparse public datasets (only 52 ISRIC samples nationally) and various AI-based soil predictions that remain unreliable without dense field sampling. By integrating LADA field observations with SOC concepts, learners better understand carbon formation, loss pathways, and the risks associated with incorrect baselines. Practical exercises illustrate how sampling depth, land-use history, moisture, and salinity influence SOC variability and the accuracy of carbon-credit calculations.

A key component of soil-literacy education is training in reliable sample collections. Learners follow standardized procedures for composite sampling, depth separation (0–30/30–60 cm), contamination control, labeling, and GPS documentation. These skills help overcome the baseline inconsistencies commonly found in national soil assessments and reduce uncertainties in future soil databases.

Experience from university teaching, research field schools, and digital soil-monitoring activities demonstrates that combining LADA diagnostics, SOC education, and proper sampling significantly improves practical competence. This integrated approach prepares students, young researchers, and community participants to critically evaluate AI-generated predictions, contribute to local carbon-monitoring initiatives, and support the development of a unified national soil-information system. Such capacity is essential for sustainable agriculture, climate-resilient land management, and long-term environmental stewardship.

**ABSTRACT**

The Mediterranean region is one of the most susceptible regions for soil degradation and desertification and is considered a climate change "hotspot". A new generation of soil experts equipped with interdisciplinary training, skills and integrated approaches is needed to develop and implement innovative, sustainable, and long-term solutions for soils and related ecosystem services.

In 2024, the Medsoils-Challenge project was funded by the European Union Erasmus+ program "Cooperation Partnerships in Higher Education", to develop a pilot Joint Master's degree in "Applied Soil Science for Mediterranean Areas" (https://medsoil-challenge.eu/).

The project involves four universities and two technical partners from four Mediterranean countries (Italy, Spain, Slovenia, and Türkiye) in the design and piloting of an annual Master's course. The project includes:

- in-depth analysis of training needs and skills mapping, involving experts and stakeholders;
- scientific and administrative design and signing of the Master's program, including its content and tools;
- development of a pilot annual Master's degree, involving students selected by the four universities.

The Master's course is planned in a blended mode, featuring online lectures and exercises, as well as four intensive weeks, one in each participating country, with face-to-face activities, field excursions and practical exercises. This will be followed by a two-month internship in a company or research center and a final thesis, completing the educational path. Sixteen scholarships, covering all student expenses including mobility during face-to-face activities, are covered by the project funds. This dynamic Master's program will feature instructors from various disciplines relevant to soil science, alongside academics in the field, empowering students with the knowledge needed to address future challenges.

The course will be divided into four modules:

1) Soil survey and classification: including field survey and mapping methodologies, identification of pedofeatures, WRB and Soil Taxonomy classification
2) Soil quality monitoring: introducing the main methodologies for monitoring indicators of soil quality and health
3) Technology supporting soil survey and monitoring: including proximal soil sensing, introduction to remote sensing, digital soil mapping and decision support systems
4) Applications of soil science: including urban and rural development planning, land evaluation, soil conservation and recovery, participatory processes, and carbon farming.

The course will begin in September 2026 and conclude in September 2027 with the thesis defense.

# Sculpting the Campus, Cultivating Soil: An Eco-Art Pedagogy of Care and Action

**Lipeng Jin**

[1]*Experimental Art School, Sichuan Fine Art Institute, Chongqing, China*

jin.lipeng@hotmail.com

**ABSTRACT**

This proposal presents the "Healing Garden" as a replicable eco-art pedagogical model for innovative soil education,inspired by the integrative "soil-soul-society" paradigm. It uniquely integrates eco-art, eco-pedagogy, and constructive activism under the ethical and design framework of permaculture. We reposition the university campus as a "social sculpture"—a living material reshaped through direct, care-driven actions to foster new human-soil relationships. Our model's distinctiveness lies in three interwoven strands: (1) Permaculture as Foundational Design Language, transforming marginalized spaces into learning commons and valuing local knowledge-holders; (2) Eco-Art as Embodied Learning Methodology, where soil literacy is cultivated through sensorial co-creation (e.g., Mandala Gardens, soil paintings with compost pigment, ecological dry toilets as public sculpture); and (3) "Inviting-In" as Constructive Campus Activism, curating the campus as a site for engaged, co-learning communities. The student-managed composting system—diverting 28.42 tons of kitchen waste—demonstrates scalable ecological repair and enhanced student agency. This model offers a framework for "soil education as social-ecological practice," transforming institutions into nodes of resilience, bioregional care, and participatory learning.

# Cultivating Soil Literacy in China: Assessing the Soil Collage as a Transformative Educational Tool

**Yan Zhu[1*], and Lingqiong Wu[2]**

[1] *Abovefarm (Department ofEducationfor Sustainable Agriculture, Shanghai, China)*

[2] *Nantong University (Department ofManagement, Nantong, China)*

*yzhu@abovefarm.org

**ABSTRACT**

Background: Soil literacy is regarded as the comprehensive understanding of soil as a living, dynamic ecosystem that sustains life on earth, the appreciation of its vital role in supporting our planet and human society, and the practices that contribute to soil health. The pervasive "soil blindness" in modern society underscores a critical gap in soil science education, from schools to civil society. To bridge this gap, we introduced "La Fresque du Sol" (the Soil Collage), an innovative educational tool co-designed by 38 soil scientists in France by ADEME (French National Agency for Ecological Transition) andAFES (French Soil Science Society). As a 3-hour participatory design workshop where participants use scientific cards and collective intelligence to reconstruct the puzzle of soil ecosystem, this tool moves beyond traditional pedagogy and adopts engaging, interactive methods that make the complex, hidden world of soil tangible and relevant.

Research Question: To what extent does the soil collage contribute to enhancing soil literacy of the general public?

Method: We have conducted pre-workshop survey and post-workshop semi-structured interviews among 16 urban residents aged 22-55 in Eastern China, including community gardeners, college students, company employees, and nature lovers.

Results and Discussion: Preliminary assessment of survey data and qualitative analysis of interview data reveal significant shifts in participants' soil literacy across three dimensions:

• Cognitive: A marked increase in understanding of soil as a living, complex ecosystem and its nexus with climate and water systems.

• Affective: A strong emergence of emotional connection and appreciation of soil, awareness of soil artificialization, concern for soil degradation, and a sense of responsibility.

• Behavioral: A demonstrated increase in intention to adopt soil-friendly practices (e.g., composting, informed consumption) and engage in community advocacy (e.g., planning a forest garden/food forest).

Conclusion: La Fresque du Sol transcends the conventional definition of an educational game by offering an innovative blend of engagement, thought-provoking and participatory design. It fosters collaborative knowledge construction and facilitates deep emotional resonance among participants. More than just a learning tool, it serves as a powerful and scalable pedagogical intervention that effectively translates ABSTRACT soil science concepts into a compelling narrative of human-soil interconnectedness. Our findings advocate for integrating such experiential and participatory approaches into the future of soil science education worldwide—from formal curricula to lifelong learning platforms—to cultivate a soil-literate global citizenry essential for a sustainable planet.

**Acknowledgments**

We would like to extend our sincere gratitude to the developers of La Fresque du Sol, namely Antoine Pierart and his colleagues atADEME whose groundbreaking approach to soil education served as the foundation for this presentation. Our appreciation also goes to Paris2050 Workshop for fostering an environment of collaborative learning and interdisciplinary dialogue. Their commitment to translating complex soil science into an engaging and accessible format is a testament to the power of collective intelligence.

# Soil: Eternal Heritage and Khayyam's Perspective

**Seyed Kazem Alavipanah[1*], Jafar Jafarzadeh[2]**

*[1] Department of Remote sensing and GIS, University of Tehran, Tehran, Iran*

*[2] Department of Remote sensing and GIS, University of Tehran, Tehran, Iran*

**ABSTRACT**

Soil, a silent yet life-sustaining foundation, is one of the most fundamental elements for the continuity of human life and ecosystems. Today, soil erosion and pollution have become among the most critical environmental challenges, highlighting the urgent need to reconsider the human-nature relationship. Protecting soil is not merely an environmental issue but also a cultural and ethical responsibility, which can be reinforced by drawing on the literary and intellectual heritage of great thinkers.

Omar Khayyam, the renowned Persian poet and philosopher, frequently addressed soil in his quatrains, placing it at the center of his philosophical and poetic reflections. In one notable quatrain, he writes:

*"Every blade of grass that grows beside a stream*
*Seems to have sprung from the lips of an angel.*
*Do not trample the grass to shame it,*
*For it has risen from the soil that nurtures the tulip."*

This verse elegantly captures Khayyam's view that life and beauty emerge from the soil, and that all living beings, even a simple blade of grass, merit respect. The grass, as a metaphor, reflects both the fragility and sanctity of life, while the soil symbolizes the ultimate source and return of existence. By drawing attention to the origin of life in the soil, Khayyam conveys an ethical as well as mystical message: the impermanence of worldly forms and the unity of human fate. In Khayyam's thought, soil is both the origin and the ultimate destination of human beings, embodying the cycle of birth, decay, and return. Although not expressed in conventional Sufi terminology, his view resonates with mystical concepts such as annihilation, permanence, and return to the origin. Combining philosophical reasoning with poetic intuition, he presents soil as a mirror for comprehending the truth of existence, where death is not an absolute end but a stage within the cyclical process of being. From a scientific standpoint, soil is also the product of a slow and gradual process; forming just one centimeter of soil may take hundreds to thousands of years. This fact renders soil an intergenerational legacy, whose destruction can lead to irreparable consequences. Linking this scientific reality with Khayyam's symbolic view offers a fresh interpretation of his quatrains, presenting soil not only as a philosophical and poetic subject but also as a vital resource for humanity's future. Poetry has the power to translate scientific concepts and environmental warnings into the language of human emotion and thought. When Khayyam speaks of soil, he invites the audience to reflect on its value and humanity's responsibility toward it. In this context, Khayyam's thought, beyond its literary and philosophical significance, has the potential to play an enlightening and ethical role in contemporary environmental discourse. Protecting soil, in this reading, is tantamount to safeguarding life and the future of humanity.

# Asking once more; What is the essential knowledge of soil in early education, particularly in Monsoon Asian countries?

**ABSTRACT**

Soil is an essential resource for our life and soil education is an important task worldwide. However, soil may be taken for granted in Monsoon Asian countries. This area comprises only 18% of the world cultivated area while it produces 33% of world GDP and supports 48% of world population. This is at least partly due to high rice yield with paddy filed production system. People in these countries may not fully recognize such benefit. On the other hand, soil degradation and decrease in productivity may also slowly occur in these countries. At the same time, many world conflicts and environmental issues are becoming closer between physically distanced countries due to enlarging scale of problems and extensive transportation network worldwide. Soil is one of the important key to solve the“crisis”, and teaching soil is an urgent issue all over the world. So, we ask once more, what should be taught about soil in early education? Is there any topic particularly of Monsoon Asian countries to draw more attention to soil?

Understanding soil through its function is valid. Soil as a base for natural and planted vegetation, and providing food for us may come in the center of the soil function. Other important functions are providing space for diverse soil organisms, decomposition of organic matter, serving as pool for organic matter, playing fundamental role in the quality and availability of terrestrial water. In early education, firstly, feeling and becoming familiar with soil and recognize soil as a part of the natural environment is very important. Then basic knowledge of soil which leads to understanding above soil function is necessary.

To learn about soil in Monsoon Asian countries including Japan, rice production systems could be a good tool, and we suggest learning about comprehensive rice production systems. By learning such, pupils can learn where soil materials come from which link to river water function and landform, soil characteristic, climate, civil engineering systems of irrigation canal, and benefit we obtain from such production system, in addition to some of the above soil function. Such study not only covers science but also social studies. We will present an example of a field workshop for primary school students and their parents about rice production and soil (Hirai and Mori, 2020). They did soil surveys on differently treated rice fields and surrounding environment, calculated number of stalk clump and wet soil for one portion of rice. Through such workshop, participants can understand the relationship between forest, soil, water, paddy field, rice and their life.

*kosakit88@gmail.com, kosakit8@vega.aichi-u.ac.jp

**ABSTRACT**

There is no doubt that soil education is an urgent issue to achieve SDGs by 2030. In spite of its importance soil may be neither taught effectively in educational sector nor understood comprehensively in civil society in many countries, allowing soil and land degradation to lead us to face a variety of global environmental challenges. The objective of this research is to develop a comprehensive soil education package, particularly for achieving SDGs, to be applicable to those from pre-school children to the general public in as well as out of doors.

The contents of the package include the topics for stimulating the sense of wonder, for providing basic knowledge of soil forming processes and its distribution pattern to understand the principles of soil and land use management, nutrient cycling in an ecosystem and various aspect of ecosystem services, and for facilitating practical observation and experiments in a field and/or laboratories. In each topic the contents are arranged in problem-finding-solving style, i.e., observing the current status of nature, objects or problems first, then raising the question why it is so, and discussing among the learners and finally finding the answer or solution.

Here will be presented three topics developed and modified for the elementary school children and high school and university students: 1) soil nutrient regulating plant growth, 2) soil-related research competition, and 3) training course for pedology. The first topic is developed and recommended for the 6th grade children in the elementary school. They are to learn the role of nutrient held, exchanged and served by soils for plant growth by comparing water-extract of soils with tap water. The second has been conducted and managed by the Japanese Society of Soil Science and Plant Nutrition since 2009, being participated by about 30 high school teams from all over the country in 2025. Most of their research are highly motivated and self-driven, partially guided by supervisors such as school teachers and/or the members of the society. The third was started in 1989 by the Japanese Society of Pedology so as to train the undergraduate and graduate students in describing, classifying and evaluating soils in the field. Forty to fifty, sometimes more, students are participated every year and the contents well complement the course work of Soil Science and related subjects provided in the class rooms and labs in the university. This training course is now in the upgrading process to meet the level required for joining a variety of international soil judging contest/competitions frequently conducted nowadays in different locations/ecosystems in the world. The questionnaire survey and/or participation observation proved they work efficiently in stimulating sense of wonder, enhancing intellectual curiosity and improving the skill of analyzing as well as integrating the information of soils and soil sciences for achieving SDGs.

* alessandrorosa@utfpr.edu.br

**ABSTRACT**

As Artificial Intelligence (AI) and Large Language Models (LLMs) increasingly function as informal tutors for university students and professionals in civil society, they reshape how Soil Science is learned. While these tools promise to democratize access to technical knowledge, we hypothesize that they inherently suffer from "Algorithmic Pedagogical Fossilization," a phenomenon where AI reinforces historical paradigms at the expense of modern, robust methodologies.

This study aims to investigate this bias using Geostatistics and Digital Soil Mapping as a pedagogical case study. We posit that current LLMs are influenced by three distinct biases: (1) Representation Bias, caused by the predominance of historical literature (e.g., classical Method of Moments) in training data compared to newer, less voluminous literature (e.g., Model-Based Geostatistics/REML); (2) Frequency Bias, where statistical word associations favor traditional terminology; and (3) Simplification Bias, where the model's alignment for user satisfaction prioritizes intuitive, visual explanations (such as experimental variograms) over complex, ABSTRACT concepts (such as likelihood functions).

We will present a systematic evaluation of major Generative AI models when prompted to explain and generate code for spatial interpolation tasks. We anticipate demonstrating that, without expert mediation, these "digital tutors" fail to provide the necessary pedagogical scaffolding to lead learners from simple concepts to rigorous uncertainty quantification. Consequently, uncritical adoption of AI in soil education risks creating an "illusion of competence," where students can execute tasks using obsolete workflows without understanding their statistical limitations. We conclude by discussing the urgent need to integrate "AI Literacy" into the soil science curriculum to ensure future professionals can critically interrogate, rather than passively consume, algorithmic guidance.

# A Study on the Educational Value and Innovative Mechanism of the "Freshmen's Cup of Hometown Soil" Practical Teaching Model

**Jiandong Sheng*, Ning Li, Ze Wang, Junhui Cheng,Hao Luo**

College of Resources and Environment, Xinjiang Agricultural University, Urumqi 830052, China

*E-mail:sjd@xjau.edu.cn

**ABSTRACT**

Against the backdrop of the reform of agricultural education and the Rural Revitalization Strategy in the New Era, how to organically integrate professional cognitive education, practical teaching, and serving the "Three Rural Issues" has become an important question that higher agricultural colleges and universities need to urgently address. Since 2021, the College of Resources and Environment, Xinjiang Agricultural University, has continuously carried out the "Freshmen's Cup of Hometown Soil" social practice activity, which guides freshmen to collect soil samples from their hometowns before enrollment, complete systematic analysis, application and feedback after enrollment, and has constructed a continuous practical teaching model of "Touching Soil-Understanding Soil-Improving Soil-Utilizing Soil". Based on the implementation process and phased results of this activity, this paper systematically sorts out and summarizes the "Freshmen's Cup of Hometown Soil" practical model from the aspects of innovation in practical teaching, students' professional identity, synergy between scientific research and talent cultivation, and paths of achievement transformation. The study holds that this model has effectively expanded the temporal and spatial boundaries of practical teaching for agricultural majors, strengthened students' understanding and emotional identification with soil science and modern agriculture, and at the same time provided practical support for the construction of regional soil big data and green agricultural development, which has important References significance for the innovation of practical teaching models in higher agricultural education in the context of New Agricultural Sciences.

# It's the pits! Cementing theory through practice in soil science teaching

**Paul D. Hallett[1*] and Graeme I. Paton[2]**

[1] *School of Biological Sciences, University of Aberdeen, Aberdeen, UK*

*paul.hallett@abdn.ac.uk

**ABSTRACT**

Week 1 of soil science teaching at the University of Aberdeen takes students armed only with spades, a measuring tape, a Munsell colour chart and a sampling sheet to dig a soil pit and describe the profile using FitzPatrick's Soil Description book. They work in groups of 4-5, gelling as a cohort in mutual despair of the complex task ahead. Over the next few hours, soil scientists are born. Starting with little knowledge, each group describes their profile and the surrounding environment, and they consider how the soils are formed and used. Students leave with some knowledge of 3 RSGs and an eagerness to learn more. This practical introduction to soil is not just about surveying – it underpins our in-class teaching as concepts ranging from soil formation to the finer points of soil physics are now easier for students to grasp and appreciate. Every week another field practical builds on the last, covering soil formation, properties and processes in greater depth. They visit unique soils like the 'buried podzol of Teinland' (FitzPatrick, 1965) and a relic tropical soil containing Macaulayite (Wilson et al., 2018) that may be found on Mars. As the weather deteriorates, laboratory practicals show theory in action and teach analytical approaches.

While field and laboratory practicals are common at many institutions, threats come from cost efficiency drives, workloads and the availability of lecturers with the necessary expertise. Aberdeen has decades of soil science teaching, but increasingly soil science is one of many subjects in environmental science or geography degrees. We need to adapt to ensure that the next generation of soil scientists are attracted to the discipline and trained at sufficient depth. Teaching of soil science used to be more collegiate between institutions, with sharing of resources and academics rewarded for writing textbooks. In the late 1990s, several UK institutions came together to produce "Soil Surveyor – Computer-assisted Learning for Land Literacy" (Dawson et al., 1997). Newer approaches facilitate virtual teaching, such as an online textbook with accompanying videos by Selker and Or on "Soil Hydrology and Biophysics". The British Society of Soil Science addressed field based and surveying teaching gaps by offering 'Working with Soils' courses that benefit from demonstrators with extensive expertise.

Great potential exists to improve soil science teaching for broader impact and greater student engagement. To address gaps in resources and expertise, collaborative teaching between institutions facilitated by national soil science societies is one solution. Soil scientists have been slow to embrace digital teaching, hindered by publisher resistance to digital modernization, but the value would be immense. How should we proceed? We will present options for discussion.

paige.chyu@iswcr.cn

**ABSTRACT**

Early-career researchers (ECRs) face significant challenges in navigating the scholarly publication process, particularly in specialized fields such as soil and water conservation. This presentation draws on the editorial experience of International Soil and Water Conservation Research (ISWCR) to provide practical guidance for ECRs aiming to publish high-quality research. We first outline key steps for successful manuscript preparation, including aligning research questions with journal scope, structuring papers for clarity, and addressing reviewer feedback effectively. Emphasis is placed on the importance of rigorous methodology, transparent data reporting, and ethical compliance. Second, we highlight current hot topics in soil and water conservation that offer promising publication opportunities: (1) soil erosion modeling under climate change scenarios, (2) nature-based solutions for land degradation neutrality, (3) soil health indicators and their links to ecosystem services, (4) conservation agriculture in fragile ecosystems, and (5) integrated watershed management in the context of the UN Sustainable Development Goals. Finally, we discuss ISWCR's editorial policies that support ECRs, including constructive peer review, fast-track decisions, and open-access options. By bridging the gap between emerging researchers and the demands of high-impact journals, this presentation aims to empower the next generation of soil scientists to contribute meaningfully to global conservation efforts.

# Indigenous Agricultural Terraces in Mexico

**Javier Leonardo Toxqui-Roldán[1*], Carlos Alberto Ortiz-Solorio[1], and Ma. Del Carmen Gutiérrez-Castorena[1]**

[1] *Soil Genesis, Morphology and Classification Area, Edaphology Posgrate, Colegio de Postgraduados, Texcoco, Mexico.*

*toxqui.javier@colpos.mx

**ABSTRACT**

Agricultural terraces modify natural soil conditions to make them suitable for farming. Mexico is considered a center of origin for this technology. Sites with ancient and modern terraces are distributed throughout the country, particularly in arid and semi-arid regions. Furthermore, anthropological studies have highlighted the importance of this agricultural technology as a key component of the hydraulic works that enabled the development of a pre-Columbian civilization in Mexico. Despite their prevalence and historical significance, the soils of agricultural terraces and the local soil classifications, still used by some indigenous peoples in Mexico, have been understudied. This work aimed to describe and classify the soils of stone-wall bench terraces, document the indigenous soil classification of the Popoloca people, and characterize the agricultural terraces in a community in the southern part of the State of Puebla, Mexico. Soil description and classification were conducted according to World References Base (WRB) criteria in three runoff terrace systems approximately 100 years old. The indigenous soil classification was determined through an ethnopedological study that incorporated local knowledge via interviews, transect walks, and participatory mapping. The characterization of the terraces was achieved through farmer interviews, field surveys, and photointerpretation. Nine soil profiles within the agricultural terraces were classified as Terric Anthrosols. In addition, Eutric Leptosols, Eutric Regosols, and Pellic Vertisols were identified in natural soils using official pedological charts. The indigenous soil classification system, in turn, defines eight soil classes based on their agricultural suitability. Anthropogenic soils are distributed across 2578 hectares of slope and runoff terraces, featuring specialized structures for support and drainage. The terrace walls exhibit various construction styles and materials; however, inhabitants recognize a traditional stone-wall type known as *cuaxustle*, which is associated with the oldest terraces described by the community. According to the farmers, the formation of a surface horizon suitable for cultivating maize and beans can begin as soon as two years after a terrace is constructed. Furthermore, the communal labor organization of the Popoloca people helps reduce terrace labor costs through cooperation. It is concluded that agricultural terraces can generate quality agricultural soils in terraced areas, which help guarantee part of the community's food supply. The terraces have facilitated agricultural development in the study area, forming optimal soils within a relatively short period.

# Salary survey of soil science faculty in the United States of America: A gender comparison

**Xian Liu[1], Eric C. Brevik[1,2]*, and Amir Sadeghpour[1]**

[1] *School of Agricultural Sciences, Southern Illinois University, Carbondale, IL, USA*

[2] *School of Earth Systems and Sustainability, Southern Illinois University, Carbondale, IL, USA*

*Eric.Brevik@siu.edu

**ABSTRACT**

It is well established that women are often paid less than men for the same jobs in the United States of America (USA), but no survey of soil science salaries has been published. This study used publicly assessable databases to investigate the salaries of soil science faculty at colleges and universities. Salary data were collected for 2019 and 2022. Comparisons were made based on gender, land grant status, region, academic rank, and soil science specialization. Overall, men made more than women, but the gap shrunk from 12.8% in 2019 to 7.0% in 2022. Faculty at land grant institutions made more than those at non-land grant institutions and all faculty made more as their academic rank increased. The Southwest and New England regions had the highest salaries in both years, with a 2022 average above $132,000, while the Northwest and Southeast regions had the lowest averages. Most regions, except the South, had an increase in average salary from 2019 to 2022. The Northwest was the only region where women out-earned men, with a 7% difference in 2019 and 9% in 2022. The Great Lakes region showed huge improvement in gender equity with a gap that had nearly closed by 2022. New England, the Southwest, and the South had the largest salary gaps between women and men. Women trailed men for salary earnings at all academic ranks in 2019, but had caught or passed men at the instructor, assistant professor, and associate professor levels by 2022 and had narrowed the gap at the professor level. Soil physics faculty had the highest average salary in 2019 (soil chemistry was second), while soil chemistry faculty had the highest average salary in 2022 (soil physics was second). Soil physics and soil chemistry faculty positions in the USA are both dominated by men. Soil biology faculty had the lowest average salaries in both years of data collection. Soil biology is the only soil science subfield in the USA where there are as many women on faculty as men. Overall, the results of our study showed that women faculty members are still paid less than men, but the pay gap is decreasing and that gap has disappeared at the lower levels of soil science academia in the USA. This offers promise for a more equitable future for soil science faculty pay by gender in the USA.

# Crop identity modulates the homogenization of soil microbial functions induced by long-term fertilization

**Guangren Zheng[1*], Xu Chen[1], and Wenxiu Zou[1]**

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin 150081, China*

*zhengguangren@iga.ac.cn

**ABSTRACT**

Fertilization practices are crucial for crop yield but profoundly affect soil microbial composition and functions. However, how they reshape microbial ecological functions, and whether these vary with crop types, remains unclear. Utilizing an 18-year field experiment with continuous maize, soybean, and wheat cropping, this study integrated amplicon and metagenomic sequencing to analyze microbial responses to NPK fertilization. The results revealed that fertilization consistently narrowed microbial niche breadth. Bacterial niche breadth decreased significantly in wheat (0.428 to 0.225) and soybean (0.488 to 0.324), with a marginal change in maize (0.427 to 0.417). Fungal niche breadth reductions were most pronounced in wheat (0.301 to 0.083), followed by maize (0.425 to 0.296) and soybean (0.443 to 0.388). Crucially, the changes in microbial niche breadth were closely related to shifts in life history strategies. Fertilization simplified microbial metabolic functions, driving a shift in life history strategies characterized by weakened capacity for complex substrate metabolism across all three crops. Furthermore, the microbial functions in continuous soybean and maize cropping soils were biased toward environmental response, whereas those in continuous wheat cropping shifted toward nutrient cycling. PLS-SEM confirmed that fertilization and continuous cropping regulate microbial life history strategies by altering soil nutrient levels, which subsequently constrain microbial niche breadth. Overall, this study demonstrated that long-term mineral fertilization tended to homogenize soil microbial function. Crop type acted as a modulating factor of fertilization effects, with microorganisms in wheat systems showing higher sensitivity. These findings provide new insights into the mechanisms by which long-term fertilization and continuous cropping affect soil microbial ecological functions.

# Two-Eyed Soil Seeing: Bridging Indigenous Knowledge and Science for Soil Security

**Alex McBratney**

[1] *University of Sydney (School of Life and Environmental Sciences, Sydney Institute of Agriculture,, Sydney, Australia), Aroura, Soil & Soil Security Think Tank*

*alex.mcbratney@sydney.edu.au

**ABSTRACT**

Achieving global soil security requires not only scientific innovation but also the respectful integration of Indigenous Knowledge Systems (IKS)—deep, place-based understandings of soil cultivated through generations of observation, interaction, and stewardship. These holistic perspectives align closely with the five dimensions of soil security—capacity, condition, capital, codification, and connectivity—yet remain underrepresented in contemporary research, policy, and practice.

This presentation suggests a possible transdisciplinary framework recognising ethnopedology, the study of Indigenous and local soil knowledge, as a bridge between cultural insight and scientific analysis. Ethnopedology provides a powerful lens for understanding how Indigenous communities classify, manage, and value soils through environmental indicators, oral traditions, and spiritual relationships with the land. By integrating these approaches with modern soil science and the soil security framework, we can reveal complex soil processes and sustainable practices often overlooked in conventional frameworks.

Central to this integration is the principle of Two-Eyed Seeing (Etuaptmumk)—learning to view the world from one eye with the strengths of Indigenous knowledges and from the other with the strengths of Western science, and using both together for mutual benefit. Combined with knowledge co-production, this model promotes genuine partnership rather than assimilation, where Indigenous knowledge holders and scientists collaboratively design research questions, methods, and outcomes.

Practical applications include establishing data sovereignty protocols, supporting intergenerational knowledge transmission, and creating enduring platforms for dialogue and co-learning. Recent efforts to quantify the “connectivity” dimension of soil security through indicators of knowledge, action, and attitude offer a means to measure the impact of these collaborations.

By weaving ethnopedological insights with scientific inquiry through Two-Eyed Seeing, this framework strengthens connectivity, fosters equity, and cultivates shared responsibility for soil stewardship—reimagining soil not only as a biophysical resource but as a living bridge between cultures, knowledges, and generations.

## ABSTRACT

Subsoil constraints such as acidity, compaction, and poor water-holding capacity remain major challenges to crop productivity across many Western Australian soils, particularly in duplex (Kurosol) and deep sandy profiles. These limitations restrict root exploration, nutrient uptake, and water use efficiency, ultimately reducing yield potentials. To address these issues, two semi-controlled soil column experiments were conducted to examine how deep soil re-engineering—through loosening, liming, and clay incorporation—interacts with nitrogen (N) fertiliser to influence crop growth, root development, and soil properties. In an acidic Kurosol, deep liming markedly increased barley (*Hordeum vulgare* L.) root length, surface area, and volumetric root length density, allowing roots to access deeper soil layers and rely less on surface moisture. Biomass and grain yield rose sharply under limed treatments, with yield continuing to respond linearly to added N. In contrast, unlimed soils showed yield plateaus at higher N rates. A complementary study on a sandy soil showed that triticale (× *Triticosecale* Wittmack) responded strongly to soil re-engineering, particularly where lime and clay were combined. These treatments promoted deeper rooting, greater biomass, higher grain yield, and improved N recovery. Regression tree analyses pointed to N rate, soil pH, aluminium, and clay content as major factors controlling yield and root traits. Across both studies, integrated physical and chemical amelioration improved subsoil pH, reduced exchangeable aluminium, and enhanced overall water and nutrient capture. Together, the results indicate that deep-profile amelioration, through lime and clay incorporation combined with well-managed N supply can sustain root growth and improve fertiliser efficiency in constrained soils.

**ABSTRACT**

Mediterranean terraced landscapes document long-term human agency in mountainous environments, yet their soil histories remain poorly understood. The Castle of Montefalco (11th to 14th century A.D.) in central Italy is situated within a karst environment, surrounded by a system of walled terraces that date back to the Modern period, and possibly earlier. The construction of terraces reflects human efforts in creating flat land in mountainous regions for farming or agroforestry. An interdisciplinary geoarchaeological approach has been developed to capture the soil memory of terraces, integrating multiple scales of analysis from microscopic to landscape level. Soil micromorphology, image analysis of scanned thin sections, phytolith studies, µXRF geochemistry, and OSL profiling were combined to reconstruct formation processes and maintenance dynamics. Micromorphological evidence indicates biologically active soils with continuous bioturbation, while OSL depth profiles display a normal net signal progression, suggesting gradual sedimentation behind the terrace walls rather than abrupt anthropogenic dumping. The reconstruction of terrace fillings suggests the addition of reworked soils and rock fragments derived from nearby cherts and limestones. These findings contribute to understanding how soil processes, human management, and karst geomorphology interact to sustain agricultural practices over centuries.

# Oral Traditions from the Gangetic heartland of India

**Apoorva Singh**

*Research Associate, The Energy and Resources Institute, New Delhi, India*

apoorvasingh.1995@gmail.com

**ABSTRACT**

The scientific study of soil has historically revolved around the themes of soil genesis, taxonomy, and fertility enhancement, primarily to optimize agricultural productivity. However, diachronic studies in the social sciences show that soil figures prominently in human life worlds, both as a medium for cultivation, and as a source and symbol of a shared cultural identity. Epistemologies surrounding soil partake of religio-cultural interpretations that venerate soil as the foremost provider of food and nutrition and as a symbol of fertility. Vernacular literature and poetic traditions often give rise to indigenous soil concepts in which scientific acumen, ecological sensibilities and sustainable livelihood are indivisibly interwoven.

In Hindi, 'mitti'— derived from the Sanskrit word 'mrittika'—epitomizes both the existential and symbolic relationship between people and terrain. India's expansive geographical diversity and climatic heterogeneity have led to a rich array of vernacular soil nomenclatures - 'bhangar' denotes the old alluvial deposits, 'khadar' signifies fresh alluvial formations; 'regur,' is widely recognized as Black Cotton soil; and arid expanses are distinguished by stratified layers of 'kanker'. Soil diversity has necessitated a useful taxonomy that has incorporated traditional knowledge, transmitted it orally through proverbs and idioms and codified it in agricultural records of the state.

Ghagh, the illustrious seventeenth-century North Indian poet-philosopher, exemplifies this synthesis - his agrarian aphorisms, celebrated across the Hindi-speaking heartland, encapsulate empirical insights into soil dynamics, climatic exigencies, and the agronomic wisdom guiding pre-modern farming. Weather forecasts, predictions of rain, use of organic fertilisers in farming, behaviour of birds/cattle/insects prior to rain, interpreting the signs of the seasons, folk perceptions of astronomy and other facets of environmental knowledge systems are interwoven inseparably with everyday peasant life in the world of Gagh-Bhaddar proverbs or Dak vachan. He nudged for organic farming through "Wohi kisanon mein hai pura, Jo chodey haddi ka chura" ie the one who uses bone and flesh meal in his fields can be regarded as a genuine farmer. Similarly, on crop distancing he wrote "Gajar, ganji muri, Teeneu boway doori" ie radish, sweet potato and carrot should be sown at a distance. These oral traditions, far from being merely folkloric, encode pragmatic prescriptions and timing for agricultural practices.

My presentation will focus on illustrating this interplay between primordial and modern soil knowledge to initiate a dialogue that transcends disciplinary silos and revitalizes our approach towards soil stewardship in a rapidly changing ecological milieu.

# Traditional Ecological Wisdom: Bengali Proverbs and Their Insights into Soil Management

**Dr. Nairwita Bandyopadhyay[1]***

[1] **Head of the Department and Assistant Professor**

**Department of Geography, Haringhata Mahavidyalaya**

**University of Kalyani, India**

*nairwita@gmail.com

**ABSTRACT**

Bengali proverbs, accumulated over centuries of agrarian experience in the fertile deltaic plains of Bengal, covering both the states of West Bengal in India and Bangladesh, offer profound insights into soil science, water management, and sustainable agriculture. This folk wisdom, passed down through generations of farmers, reflects an intricate understanding of soil-water relationships that remains relevant to contemporary soil conservation discourse.

The proverb *'Mati ar jol mile shona pholai'*, that is *'Soil and water together yield gold'* encapsulates the fundamental principle of soil-water synergy in agricultural productivity. This traditional knowledge recognizes what modern pedology confirms: optimal soil moisture is essential for nutrient availability and crop success. Similarly, *'Je matite phoshol hoy, shei matike shomman dao'* which translates as *'Honor the soil that yields crops'* emphasizes soil stewardship, anticipating contemporary concepts of soil health management. Bengali wisdom also addresses soil fertility management. The saying *'Gobar shona, matir pran*' which means *'Cow dung is gold, the life of soil'*, highlights organic matter's critical role in maintaining soil vitality, predating scientific understanding of soil organic carbon and microbial communities. The proverb *'Tin bochhore tin phoshol, mati hoy pathor'* or that *'three crops in three years turns soil to stone'*, warns against soil exhaustion through continuous cropping without adequate regeneration—a concept now termed soil mining.

These proverbs collectively, and several others that I will talk about, demonstrate that Bengali agricultural communities possessed empirical knowledge of soil texture, structure, fertility cycles, erosion, and hydrological processes long before formal soil science emerged. Their wisdom emphasizes soil as a living system that requires respect and balanced management rather than mere extraction. In the context of the Soil Water Congress 2026, examining these traditional ecological knowledge systems offers valuable perspectives for sustainable soil management. As climate change intensifies pressure on soil and water resources, integrating time-tested indigenous wisdom with modern scientific approaches may provide holistic solutions for soil conservation, water retention, and agricultural sustainability in the Bengal delta and similar agroecological zones worldwide.

# Gendered Dimensions of Soil and Agricultural Practices in Rajasthan's Arid Landscapes

**Kanchan Mathur**
Prof. (former) and Officiating Director, Institute of Development Studies, Jaipur, Rajasthan -302004.
Email: kanchanmathur10@gmail.com

## ABSTRACT

Rajasthan's arid and semi-arid ecosystems, characterized by largely arid, fragile soils and recurrent droughts, pose significant challenges for sustainable agriculture. Within these landscapes, gender emerges as a critical yet under-explored determinant of soil management and agricultural resilience. This paper examines the intersection of gender, soil and sustainability through the lived experiences of women farmers in Rajasthan. Drawing on field-based insights and secondary evidence, it analyses how gendered divisions of labour and unequal access to education and technical knowhow, markets, land, quality agricultural inputs, extension services and awareness of government schemes shape soil health outcomes. Women, who constitute a major share of the agricultural workforce, are the custodians of indigenous soil-fertility practices and conservation knowledge - yet remain marginalised in formal decision-making and technological innovation.

Using a gender-transformative and intersectional lens, the paper situates soil conservation and enhancement and integrated soil health management within broader debates on climate adaptation, equity and sustainability. It argues that gender-responsive soil management through inclusive extension models, recognition of women's knowledge systems and equitable access to resources is essential for the restoration of degraded lands and enhancing productivity in both arid and non-arid regions. The findings call for integrating gender analysis into soil-science research, agricultural policy and climate-adaptation strategies to achieve the sustainable development goals (SDGs) on land, food-security and gender equality.

**Keywords:** Rajasthan, gender; soil management; women farmers; arid ecosystems; sustainable agriculture

# Profile of professor diversities (male and women) in Brazilian soil science

**Risely F Almeida[1*], Laires S. Reis[1]**

[12] *Universidade do Estado da Bahia, Juazeiro, Bahia, Brazil.*

*rizely@gmail.com

**ABSTRACT**

Innovative projects are the major challenges in Universities around the world, requiring strategies to increase the level of diversity and innovation in universities. The study hypothesized that the diversity of professors is an alternative to increase innovation in Brazilian soil science. Results showed that the team of postgraduate students is composed predominantly of Brazilians (mean: 97%) with low participation of foreigners. Programs of attractiveness are commonly used by traditional Universities in Europe, North America, and China to recruit students around the world. In Brazil, 3% of international students are represented mainly by students from Latin America. The team of professors/researchers is composed predominantly of Brazilians (mean: 99%) with low participation of foreigners. However, the greater part of professors/researchers obtained their doctoral (partial/total) in American or European Universities. The interdisciplinary and collaborative conditions are to increase the innovation in projects (Nyström et al. 2018). The different groups of partners increase productivity with a mutual benefit in the project (Cowie and Mcnae, 2017). The masculine predominance in the team of postgraduate students was common in the last decade, with 50% more men than women. However, in 2017, there was an equivalence of 54% and 46% of males and females, respectively, due to an increase of 40 % of the female presence in Brazilian Soil Science. This is a great indicator of diversity in the team of postgraduate students that brings a different perspective to research. Our study demonstrated that this gap is not more present among the postgraduate students. OECD (2011) demonstrated that in OECD countries, women graduates are the majority in the fields of education, health and welfare, and humanities and arts. While men dominate engineering, manufacturing, and construction. There was a masculine predominance in the team of professors/researchers, with a difference of 82% compared to female presence, where for every six professors/researchers male, there is one professor/researcher female. If we link the data from the student team, we can observe that there is an increase in women as postgraduate students, but this increase did not reflect on the presence in Academies. Probably, in the next years, we can see the number of women as professors/researchers as a consequence of the higher number of women with postgraduate degrees in soil science. According to Ceci and Williams (2010), the low women's presence is also due to them-decided child and family care, leaving the academy. We understand that the performance of the professor/researcher is not associated with gender but with the opportunity of work in a great group/university and the self-efficacy to develop research and publish papers. Based on the results, we conclude that the diversity of the team of students is high; there is a need to increase the diversity in the profile of professors/researchers who can contribute to increasing the number of patents in Brazilian soil science. However, even in a diverse team, the performance of students and professors/researchers is strongly related to the level of individuals: this holds for all fields, positions, gender, and age groups.

**ABSTRACT**

The teaching of Soil Science in Mexico is limited to a few university programs and to exceptionally rare secondary school systems. Moreover, the syllabi of soil-related courses and the current teaching resources in Mexico rarely keep pace with advances in soil science, and largely omit gender and diversity perspectives. Regions such as Latin America still have a male-dominated field, where most soil science teachers are male scholars (e.g., *Mexico*, Hernández *et al*., 2023; and *Brazil*, Wardzinski-Barbosa & de Araújo-Pedron, 2024). These gaps may exacerbate difficulties in transferring practical soil knowledge across diverse social contexts and reduce students' motivation to pursue careers in soil science. Here, we developed a series of audiovisual resources to enable students to engage with soils across diverse Mexican landscapes through multiple techniques and epistemologies of soil knowledge, fostering inclusion of diverse social, cultural, and gender perspectives in soil science education. Automated questionnaires were designed to assess the before-and-after process of students' knowledge acquisition, identify the main sources of learning, and evaluate their level of confidence in applying soil science concepts. The pedagogical design is based on situated and constructivist learning, emphasizing that soil knowledge may be improved through contextual practice, reflection, and collaboration at secondary and higher education systems. This project contributes to the National Autonomous University of Mexico's Educational Program (PAPIME PE102725, UNAM) and to the digital platform *Proyecto Suelox* (Institute of Geology – UNAM) by creating open-access educational materials while promoting inclusivity and contextualized soil science.

# Soil Justice: A Radical Black Marxist Framework for Addressing Soil Contamination

**Salvatore Engel-Di Mauro[1*] and Melanie Malone**

[1] *Department of Geography and Environmental Studies, State University of New York at New Paltz, New Paltz, NY, USA*

[2] *School of Interdisciplinary Arts and Sciences, University of Wahington at Bothell, Bothell, WA, USA*

*engeldis@newpaltz.edu

**ABSTRACT**

Soil contamination testing and monitoring is conducted in numerous locations for diverse reasons, including mandated cleanup and remediation of contaminated sites, built environment reconfiguration or expansion, and as part of negotiations for the transfer of properties. While soil testing and monitoring often become part of the political economy of legal or transactional structures to protect property owners from liability, and sometimes for larger public health studies designed to inform public agencies, what is less clear is how soil contamination monitoring benefits communities affected by soil contamination in places where they live, work, and play. Most soil contamination monitoring is conducted with due diligence and safety in mind, but the methods used rarely benefit communities or protect them from further exposure to contamination. Studies that engage with environmental justice in contaminated spaces help to illuminate why this conundrum exists. These include a lack of transparency from municipal governments when contaminant testing is conducted, poor regulation of contamination in general, and inadequate policy to prevent human exposure to contaminants. Yet, if soil contaminant monitoring were to contribute to improving social conditions, it would engage with transdisciplinary research that includes a broader array of methodologies and inquiries aligned with clear political commitments. The Black Radical Tradition and Marxism offer, in combination, such a possibility. A Radical Black Marxist framework is described and discussed relative to soil contamination to demonstrate how it enables greater engagement with the politics and values of those who are conducting soil contaminant monitoring and how it would be of more use to those impacted by contamination. Issues of upward translation and data sovereignty are discussed to illustrate the usefulness of Black Radical Marxism in addressing soil contamination more effectively than has so far been the case.

# Operationalizing the Soil Information System Framework: a methodological approach to strengthening collaboration and strategic development applied through country roadmap workshops

**T.I.S. van der Woude[1*], C. Khurshid[1], B.H. Colman[1], M. Allan[2], A. Valverde[2], L. Gatere[2], M. Parr [2], M. Coley[2], and F. van Egmond[1]**

*[1]ISRIC, Wageningen, the Netherlands*

*[2] CABI, Wallingford, the United Kingdom*

*thaisa.vanderwoude@isric.org

**ABSTRACT**

Developing a sustainable national Soil Information Systems (SIS) remains a critical challenge. Many countries lack systematic guidance on establishing and maintaining SIS that are technically robust and viable over the long term. To address this gap, the SIS Framework was developed as a structured methodological approach to assess, plan, and strengthen the enabling environment required for sustainable SIS development. The SIS framework extends beyond data availability and technical specifications - it incorporates financial, technological, institutional and capacity aspects that influence SIS resilience.

The SIS Framework is organized into four phases—initiation, planning and design, implementation, and operational—each comprising practical components with suggested activities, guiding questions, and recommended tools. Refined through iterative application and stakeholder feedback, the SIS framework provides an open-access, replicable methodology for identifying constraints, prioritizing interventions, aligning SIS design with national objectives, and promoting cross-sector partnerships.

The methodology has been applied through country-level roadmap workshops led by national agricultural institutes. These participatory workshops involve bringing together key SIS stakeholders—such as farmers, researchers, policymakers, or funders —in reviewing framework components such as envisioning, enabling environment, stakeholder needs, idealised system design, partnerships, data strategy, organizational plans and financial sustainability, culminating in a national SIS roadmap. This roadmap contains agreed next steps for collaboration between the key stakeholders for the development of the SIS. Structured feedback from each workshop improves its application in additional countries. Workshops have been conducted in Zambia -April 2024, Ghana -October 2024, Kenya -February 2025, Togo -June 2025, Liberia -August 2025, Sierra Leone -October 2025, and Nigeria -October 2025, with further deployments planned.

This presentation details the SIS Framework methodology, outlines the roadmap workshop process, and synthesizes lessons learned from national partners involved in its implementation.

# Soil Art in Action: Transdisciplinary Pedagogy and Community Practice in the Healing Garden Project

**Lipeng Jin**

[1]*Experimental Art School, Sichuan Fine Art Institute, Chongqing, China*

jin.lipeng@hotmail.com

**ABSTRACT**

How can a color heal our relationship with the Earth? The Healing Garden project at Sichuan Fine Arts Institute presents the "New Van Dyke Brown"—a transformative metaphor for a transdisciplinary language of soil. Historically, Van Dyke Brown was a pigment mined from peat soil. We invert this logic of extraction into a ritual of return: the rich humus we create from campus kitchen waste (over 28 tons converted) becomes our palette. Using this "life-brown" in local food producing and painting/healing performance, we transform art-making into an act of ecological reciprocity.

This artistic ritual anchors a cyclical pedagogy that bridges art, science, and community:

Creating the Pigment: Through community composting, Bokashi, and vermicomposting, we produce fertile humus—our "New Van Dyke Brown."

Painting the Landscape: This living pigment nourishes Hugelkultur mounds and food forests, where soil fertility becomes visible as biodiversity and abundance.

Completing the Cycle: In the Therapeutic Kitchen, the harvest is foraged, cooked, and shared, physically incorporating the soil's vitality into our community.

This closed loop—from waste to humus, to food, to body—bridges the "metabolic rift" through tangible repair, and grounds the ethic of "soil care" in actionable cycles. By the 23WCSS, we will present our co-created "Soil Lexicon," demonstrating how a shared language of soil emerges not from terminology, but from embodied, artistic, and community-engaged cycles of care. We offer a pedagogical model for a transdisciplinarity that is felt, lived, and grown.

**Keywords:** Language of Soil, Transdisciplinarity, Eco-Art, Metabolic Rift, Permaculture

# Soil Memory and Heritage: Foundations for Soil Literacy and the Codification of Soil Rights

**Edoardo A.C. Costantini**[1*]

[1] *Accademia Nazionale di Agricoltura, Bologna; Accademia dei Georgofili, Firenze; CNR-IBE, Sesto Fiorentino (FI)*

*E-mail eac.costantini@gmail.com

**ABSTRACT**

Soil literacy, the capacity to understand, interpret, and apply soil knowledge, requires more than scientific information: it depends on cultural, historical, and emotional connections that make soils visible and valued within society. This study examines how two complementary perspectives, soil memory and soil heritage, can strengthen soil literacy and support the codification of soil rights.

Soil memory refers to the long-term imprint of natural processes and human activities preserved in soil features, horizons, minerals, and organic markers. As an archive of environmental and cultural history, soil memory enhances scientific literacy by training observers to read soils as records of climate shifts, land-use changes, and ecological transformations. Its persistent traits constitute a form of natural capital, comparable to biodiversity, that merits protection, as soil self-organization produces unique and sometimes rare environmental legacies.

Soil heritage provides a parallel, culturally oriented perspective. It highlights soils of symbolic, ecological, or historical significance and situates them within landscapes, traditions, and identities. While soil memory deepens scientific understanding, soil heritage connects with society through emotional, cultural, and place-based values. It incorporates diverse ways of knowing soil, traditional, indigenous, sensory, and experiential, that complement scientific knowledge and help make soils relevant to citizens, educators, and decision-makers. In addition, by linking soils to quality foods (terroirs), land-based customs, and iconic landscapes, soil heritage serves as a powerful gateway to soil awareness.

Together, soil memory and soil heritage form two reinforcing pillars that broaden soil literacy beyond technical expertise. They also help to create conditions for recognizing soils as finite and irreplaceable entities whose protection may require both cultural norms and legal frameworks. Examples of legal personhood granted to natural entities illustrate how enhanced soil literacy can support the codification of nature's status within societal hierarchies, while also underscoring the central role of soil knowledge in informing conservation policy, from the design of regulatory frameworks and management plans to the long-term governance and effectiveness of nature reserves.

Ultimately, acknowledging soil memory and soil heritage as integral components of soil literacy can broaden public engagement, foster more sustainable soil management, and support emerging debates on the ethical and societal foundations of soil protection. In this context, the codification of soil rights offers a pathway to make the intrinsic and interconnected value of soils legible and actionable within policy, jurisprudence, and shared civic responsibility.

# Raising Soil Awareness through "Soil of the Year" Campaigns in Central Europe

*pecha@umk.pl

**ABSTRACT**

Public "Soil of the Year" initiatives have emerged in Central Europe as important tools for promoting soil literacy and strengthening public appreciation of soil diversity. Although the long-running German and Austrian campaigns began earlier, the region-wide landscape became more dynamic during the last decade: the Estonian "Soil of the Year" was launched in 2014, the Polish initiative in 2018, and the Slovenian and Hungarian programs in 2022. These national activities preceded and inspired the establishment of the global IUSS World Soil of the Year initiative, illustrating how regional experience contributed to the international recognition of soils as part of global natural heritage.

The selection of the Gleysol as the World Soil of the Year 2025—proposed by the Hungarian Soil Science Society—highlights this continuity and emphasizes the growing Central European contribution to soil awareness efforts. This paper provides a comparative overview of the Estonian, Hungarian, Polish, and Slovenian campaigns, focusing on their educational approaches, communication strategies, and societal relevance.

In addition, we aim to conduct an initial exploration of the online presence of these campaigns, including visibility patterns and forms of digital engagement. At this stage, the extent to which such activities translate into measurable increases in public awareness remains uncertain, yet mapping these trends may offer valuable insights into how soil-focused communication evolves across digital platforms.

**ABSTRACT**

In a world requiring **creativity, collaboration** and **innovation** to address the challenges of our changing planet, it is crucial for the Soil Science Society of America **(SSSA**), the American Society of Agronomy (**ASA**), and the Crop Science Society of America (**CSSA**) to develop robust programs and initiatives. The Societies (SSSA, ASA, CSSA) have recognized **Diversity, Equity**, and **Inclusion** (DEI) as a top strategic priority, with a focus on cultivating a welcoming and supportive culture within our professional societies. We acknowledge that enhancing diversity, equity, and inclusion fosters strength, creativity, and innovation in our scientific community.

The collective ASA, CSSA, SSSA Diversity, Equity, and Inclusion committee continues to expand its impact on the SSSA, ASA, and CSSA cultures, member experiences, and strategic priorities, while leading initiatives with a focus on inclusivity. The committee has made significant progress implementing recommendations from the 2022 DEI Recommendations Report. A Measuring Success report has recently been released to assess our progress. This report highlights the Societies' collective efforts and progress, aligning our metrics with the member experiences that shape them. Key features of the report include 1) a demographic summary (gender and ethnicity), 2) progress on the 2022 recommendations, 3) DEI-focused programming at the Annual Meeting (now CANVAS), 4) highlights from a recent DEI survey, and 5) future recommendations to continue advancement.

This presentation will highlight the Societies' collective work and provide an update on the progress achieved to date for this major initiative in fostering a more diverse, equitable, and inclusive community with SSSA, ASA, and CSSA.

*[3] Department of Agronomy, Iowa State University, Ames, IA, USA*
*[4] Soil Science Society of America, Madison, WI, USA*
*sdaroub@ufl.edu

**ABSTRACT**

The Soil Science Society of America (SSSA) is the leading scientific and professional organization in the United States (US) dedicated to the advancement and application of soil science as a foundation for life. SSSA aims to be a global leader advocating for soils through education and science and focusing on critical issues like food security, environmental quality, ecosystem sustainability, climate change, and human health. Along with its sister societies the American Society of Agronomy, and the Crop Society of America (ASA, CSSA), SSSA focuses on increasing engagement through workforce development, policy advocacy, certification programs and increasing the visibility of our sciences.

A significant and growing gap exists between the demand for and supply of expertise in our fields. Data from the U.S. Department of Agriculture show that graduates earning food/agriculture, natural resources, and environmental science degrees will only account for 61% of the demand for graduates with expertise in these areas. To address this challenge, the ASA is funding a two-year campaign dedicated to increasing awareness and interest in our sciences. The campaign aims to increase enrollment in agronomy, crop, and soil science programs at post-secondary institutions throughout the US. The goal is to develop a diverse workforce by educating students on career paths and highlighting the crucial role these professions play in ensuring food security, protecting the environment, and safeguarding human health.

The Societies (ASA, CSSA, SSSA) are committed to public outreach and policy advocacy. They actively reinforce their Science Policy activities to ensure the unique needs of soil science are represented to policymakers. This critical work includes engaging in advocacy for federal research programs related to agriculture and environmental sustainability, thereby supporting the foundational research necessary for global progress.

SSSA ensures the high standards of the profession through its certification programs. The Certified Professional Soil Scientist (CPSS) establishes and maintains high standards of knowledge, skills, and conduct for practitioners. Achieving the CPSS designation requires a bachelor's degree in soils, extensive coursework requirements, and successful completion of the Fundamentals of Soil Science exam. CPSS professionals are recognized as experts qualified to perform soil science work, such as land use evaluations and environmental consulting. Building on this success, SSSA is contributing to efforts within the IUSS Division 1 Working Group on International Accreditation with a goal of working with global partners to build an accreditation program for Soil Scientists. This program will be a trusted resource to the public for experienced certified soil scientists.

This presentation will highlight the accomplishments of SSSA in its major initiatives on workforce development, policy advocacy, and global certification efforts in soil science.

**ABSTRACT**

Pedology and Soil Education are soulmates: they complement each other and share common goals to promote knowledge, care, and love for soils. How can we care for something we don't understand? That is the key question.

Love for soil must be nurtured from early childhood. We can encourage children's first contact with soils of different textures and consistencies. How about moistening a sample of clay soil and turning it into play, as fun as modeling clay? In basic education, paints made from different soil colors should have a place alongside colored pencils. Looking at soil with imagination can be magical with pencil and paper, soil becomes poetry. As expressed by student Izabella Queiroz, who wrote that "soil is a love that must be returned"; a friend that nourishes and sustains us.The different Soil Orders, with their distinct features, can become fun characters. Who wouldn't be charmed by "Grandpa Lato," from the Fun Soil Profiles project, representing the LATOSSOLOS -Brazil's (SiBCS, 2025) most weathered soils? And so, we grow into adults - aware and responsible. We don't need to be pedologists or soil educators to value and care for our soils. This is a mission for everyone: to love, protect, and respect this living, essential resource, from which our food comes, and which plays multiple roles in nature. I invite you to see the soil with fresh eyes and to find, in the slopes by the roadside, precious life lessons. Walk barefoot on the earth, feel its energy. Never forget: the soil is alive. After all, what would our soils tell us if they could speak?

[2] *Department of Soil Science, Federal Rural University of Rio de Janeiro (UFRRJ) , Rio de Janeiro, Brazil)*

*E-mail: adriana.ribon@ueg.br

**ABSTRACT**

In Brazil, soils are classified according to the Brazilian Soil Classification System (SiBCS, 2025) into 13 soil Orders, described based on their chemical, physical, mineralogical, and morphological attributes. However, the teaching materials used in basic education do not provide updated information on Brazil's soil Orders and often avoid the appropriate nomenclature due to its complexity. To address this and simplify the understanding of the 13 soil Orders in a creative and engaging way, the "Fun Soil Profiles" Extension Project was created in Brazil in 2019. The project features playful characters representing each soil Order: Latossolos (Grandpa Lato), Neossolos (Little Liti), Espodossolos (Mr. Spodos), Nitossolos (Star), Gleissolos (Gleyson), Chernossolos (Madame Chernossólica), Organossolos (Little Monster Organo), Plintossolos (Plintita), Cambissolos (Cambi), Vertissolos (Super Vertinho), Argissolos (Argi), Luvissolos (Luvi), and Planossolos (Plano). Subsequently, 12 characters were created based on Soil Taxonomy (2022) to represent the 12 major soil orders found in different landscapes: Alfisols (Alfi), Andisols (Vulcano), Aridisols (Aridilson), Entisols (Baby), Gelisols (Gelinho), Histosols (Cramby), Inceptisols (Young), Mollisols (Uncle Moli), Oxisols (Grandma Oxídica), Spodosols (Mr. Spodos), Ultisols (Ulti), and Vertisols (Maravilha).To further expand the project, the current work presents 32 characters created based on the key features of the 32 References Soil Groups defined by the World References Base for Soil Resources (WRB, 2022): Histosols, Anthrosols, Technosols, Cryosols, Leptosols, Solonetz, Vertisols, Solonchaks, Gleysols, Andosols, Podzols, Plinthosols, Planosols, Stagnosols, Nitisols, Ferralsols, Chernozems, Kastanozems, Phaeozems, Umbrisols, Durisols, Gypsisols, Calcisols, Retisols, Acrisols, Lixisols, Alisols, Luvisols, Cambisols, Fluvisols, Arenosols, and Regosols. Thus, the "Fun Soil Profiles" become important tools for soil education from basic to higher education, helping to illustrate the different types of soils in Brazil and around the world, highlighting their most important characteristics through characters in a playful, enjoyable, creative, and engaging way.

# The Fun Soil Profiles: Characters for the YECS Working Group at WCSS 2026.

**A. RIBON**[1]

[1] *Department of Soil Science, University of Goiás (UEG), Goiás, Brazil)*

*E-mail: Adriana.ribon@ueg.br

**ABSTRACT**

With the aim of bringing young audiences closer to soil science in a playful, creative, and engaging way, two mascot characters were developed for the Young and Early Career Scientists Working Group at WCSS 2026. Dr. 土生 (Born from Soil) and the young student 地护士 (Nurse of Soils) represent the intergenerational spirit of this working group. Inspired by the World References Base for Soil Resources (WRB, 2022), these characters were designed with distinct shapes, colors, and personalities that reflect the main features of soils, making them easier to understand for children, youth, and adults. This proposal is part of the Brazilian initiative "Perfis de Solos Divertidos" (Fun Soil Profiles), which emerged from the national project Soil Education for All, active in Brazil since 2013. Dr. 土生 symbolizes the experienced soil science researcher and educator, while 地护士 represents a young student, connecting soil science concepts with different fields of knowledge and a critical view focused on soil health care. These mascots have been used in soil science events as educational tools, supporting outreach and the popularization of soil science from basic to higher education. This innovative approach strengthens the role of soil education in shaping young citizens who are aware of the importance of caring for and conserving the world's soils

E-mail Address of Presenting Author: Yuhao Dong (15136567528@163.com)

**ABSTRACT**

The continuous increase in agricultural mechanization has led to intensified soil compaction degradation. It is crucial for ensuring the sustainable development of national agriculture by addressing soil compaction. Salt-affected soils, which are important reserves for arable lands, have experienced an increase in agricultural use in response to national demand in China, leading to an increased soil compaction risk. However, current research on soil compaction is mainly focused on non salt-affected soils, resulting in a lack of understanding of the compaction process and regional spatial and temporal variation. This study aims to assess the current status and potential risk of soil compaction at the regional scale in Dongying, eastern China. A regional survey was conducted based on 76 sampling sites across three soil layers (0–15, 15–30, and 30–45 cm). Soil compaction was evaluated using penetration resistance, shear strength, saturated hydraulic conductivity, soil water retention characteristics, and uniaxial soil compression curves. Key parameters derived from compression curves were used to characterize soil mechanical strength and susceptibility to compaction. Clear vertical differentiation of soil compaction was observed, with subsurface layers exhibiting higher penetration resistance, shear strength, and compressibility than the surface layer, indicating the widespread presence of mechanically restrictive layers. The soil salinization had a significant influence on soil compaction status and spatial differentiation of farmland soil. The results highlight the coupled effects of mechanical loading, hydraulic and salinization limitations on soil structural stability. By integrating compression behavior with mechanical and hydraulic indicators, this study provides a physically grounded framework for regional assessment of soil compaction status and risk. The results contribute to a mechanistic understanding of soil compaction processes and support the identification of areas vulnerable to soil structural degradation in coastal agricultural regions.

5Masaryk University (Brno, Czechia)

*fenny.vanegmond@wur.nl

**ABSTRACT**

Soil as a science and the application of the insights, knowledge and data generated by or related to that science is a broad domain with many different subdomains, topics, adjacent domains, applications, and stakeholders. All these domains have their own agreed or de facto terminology that they use to communicate with each other, e.g. on research topics, concepts and procedures used, and apply in metadata, databases, knowledge documents. These are often agreed and written down in documents, such as the WRB and national soil classifications and description standards, soil legislation (e.g. the EU Soil Monitoring Law), ISO and GLOSOLAN lab procedures, etc. They can also be defined in projects or literature. In general they are described as glossaries in documents or on websites, which makes them human understandable but not easy to find, re-use, govern, maintain or cite.

To make the terminology, the glossaries, definitions and vocabularies of soil science and other domains machine readable, citable, easy to find, use and govern by the soil community, online vocabulary repositories or registries exist, e.g. AGROVOC[ https://www.fao.org/agrovoc/ ] and GEMET[ https://www.eionet.europa.eu/gemet/en/about/ ]. These repositories store the terms, definitions, relations to other terms, translations of terms in different natural languages, a link to the References (document) for the term and a unique identifier. Each repository has a webpage where users can consult the repository, and a governance body. The latter consists of domain experts who can decide on governance issues such as requests for additions, changes of terms, definitions, linkages etc. and may apply a hierarchy based on authoritativeness of terms. A proposal is to give pReferences to definitions and terms in legal documents, then adopted standards, then subcommunity de facto standards, literature Referencesd and project vocabularies.

At present, in the soil domain the last step of digitization, storage and governance of soil related terms in an online vocabulary repository is often not done yet, severely limiting soil information FAIRness (Findable, Accessible, Interoperable, Reusable). However, a few recent developments are promising. In the framework of the EU's Mission Soil, all Mission Soil projects collaborate in a Cluster on Knowledge and Data Management assisted technically by the SoilWise project. Within IUSS the WRB WG (governance and content) and the SIS WG (technical assistance) collaborate. At ISRIC increased attention to vocabularies allows to address remaining roadblocks. At the Global Soil Partnership (GSP) a GloSIS WG was created with vocabularies as subtopic. This increased attention, international collaboration and activity on the topic can lead to mature and useful soil vocabularies in a few years, significantly increasing the possible FAIRness of soil information.

jplhortamarques@gmail.com

**ABSTRACT**

This study analyzes the historical evolution of Soil Science in Portugal from the 19th century to the present. The central structural challenge identified throughout this period is summer water scarcity, a consequence of Portugal's Mediterranean climate (Köppen: Cs) and the limited water storage capacity of its soils. This issue is further exacerbated by low Soil Organic Matter (SOM) levels, shallow effective soil depth, and light textures.

Since the early research led by pioneers Ferreira Lapa (1823–1892) and Luís António Rebello da Silva (1855–1946), the chronic deficiency of SOM has been a primary driver of scientific inquiry. Influenced by breakthroughs in France, England, and later the USA, Portuguese research expanded into crop fertilization, soil conservation, and mapping. A major milestone was the 1950 Agrological Mission (Figure 1), which initiated the study of tropical soils under the leadership of Joaquim Botelho da Costa (1910–1965), the "Father of Soil Science in Portugal."

*Figure 2 Team of the Tropical Pedology Study Brigade from the Instituto Superior de Agronomia (Lisbon), comprising Rui Mayer, Botelho da Costa, Ário Azevedo, Rui Pinto Ricardo, and sixteen staff members; Angola, 1951.*

Despite the rise of soilless culture since the 1980s, soil remains the fundamental pillar for mitigating water scarcity. Current research focuses on enhancing soil fertility and crop yields as contingency measures against Global Change. Finally, the strong master-disciple continuity across generations has ensured efficient knowledge transfer, directly contributing to the evolution of plant production and human well-being in Portugal.

* yangsy@zju.edu.cn

**ABSTRACT**

The traditional concentration-based health risk assessment of heavy metal (HMs) pollution in soil has often overlooked the initial loading and toxicity differences of HMs from various sources. This oversight hinders effective identification of the risky source, complicating precise risk management of soil HMs pollution. This study applied a source-oriented health risk assessment framework that integrates source profiling, exposure risk assessment, and spatial cluster analysis. Taking the Shanghai City, the largest megacity in China as a case, the findings revealed that overall environmental quality of peri-urban agricultural soil in Shanghai remains good, though 3.03% of Cd concentrations exceeded the national References standards. Industrial & traffic activities, primarily contributing Hg, Cd, and Pb, accounted for the highest proportion (44.3%) of total metal concentrations and posed the greatest non-cancer risk (54.6% for children and 53.1% for adults). Notably, natural activities, mainly contributing Cr, ranked only third in concentration contribution (26.55%) but induced the highest cancer risk (58.55% for children and 57.08% for adults). These findings suggest that sources with lower concentration contributions may still pose significant health risk. Integrating source apportionment with health risk assessment can more precisely identify the risky source and target areas for mitigating the human health hazards.

## ABSTRACT

**Introduction**

Soil health is a continental priority to be addressed. African Union Member States have committed to coordinated action plan through the CAADP and Africa Fertilizer and Soil Health. The donor community has responded positively to addressing the challenges of soil information. Several initiatives addressing soil information systems have emerged in recent years. These include Soils for Africa Project, African Union Soil Observatory (AUSO), NORAD-CIFOR-ICRAF-VARDA Foundation-CA4SH, Development Gateway an IREX Venture, Food and Agriculture Organization Soilfer Project among others. Each of the initiatives is creating a dashboard or collaborating in the creation of dashboards. CSIR-Soil Research Institute in Ghana is pivotal in the implementation. Major challenges for successful creation of dashboards are data sharing, data quality and harmonization and co-creation of mutually beneficial collaborations. This article identifies challenges associated with dashboard creation for soil information systems and explore opportunities for creating co-benefits among international and local collaborators.

**Materials and methods**

The Projects goals, objectives, duration expected outputs and deliverables, alignment with global, regional and national agenda, donors, partners, capacity building opportunities, communication, infrastructural development and existence ofFAIR (**F**inadable, **A**ccesssible, **I**nteroperable, **R**eusable) data guidelines were reviewed.

**Discussion**

All the initiatives are delivering a dashboard of soil information in Ghana. AUSO dashboard is focusing on continental scale delivery, but national focus is a priority. All the initiatives involve active stakeholder engagement. This is generally good, but effort should be made to avoid stakeholder fatigue. A good stakeholder matrix aligning interest and initiatives goals is needed.

**Conclusion:**

FAIR data guidelines, capacity building/succession plan, regular training in data management are important for successful dashboard creation and mutually beneficial collaborations. All the initiatives involve CSIR-SRI. Infrastructure and capacity building efforts are needed for hosting the dashboards. Ghana could be prioritized for monitoring and evaluation of soil information in Africa.

# Community-based research and action for sustainable land use in the Ethiopian Rift Valley

**Awdenegest Moges[1], Euan Phimister[2,3], Wolde Mekuria[4], Ojongetakah Enokenwa Baa[4], Dominik Bittner[2], David Burslem[2], Grant A. ## ABSTRACT

Two linked collaborative research projects in Ethiopia will be presented that address land degradation, soil restoration, biodiversity and rural livelihoods through strong partnerships between Ethiopian institutions and UK-based researchers. Both initiatives exemplify community-led research, meaningful local engagement and capacity building with demonstrable impact.

The project, “Local-level land degradation assessment towards sustainable land management for improved livelihood in the Ethiopian Rift Valley” (REDAA-SMILE) uses community-based participatory approaches to co-develop action plans that respond to locally expressed needs. Through joint land degradation assessment and low-cost site-specific interventions, the project is actively achieving degraded land restoration and fostering business models that strengthen livelihoods—especially for women, youth and unemployed groups. The design explicitly integrates indigenous knowledge, local stakeholder perspectives and gender-sensitive strategies, ensuring that farmers understand both problems and solutions in their own contexts and can independently sustain and scale activities. This approach has already fostered local ownership and practical solutions to entrenched environmental challenges such as soil erosion and food insecurity.

The project, “Cataloguing and Rating of Opportunities for Side-lined Species in Restoration of Agriculturally Degraded Soils in Sub-Saharan Africa” (GCBC-CROSSROADS) explores harnessing native floral diversity to restore agriculturally degraded soils in Ethiopia. Combining systematic reviews, field and laboratory studies, socio-economic analysis and local community engagement, the project seeks to understand how these plants influence soil health, biodiversity, climate resilience and livelihoods. A key strength of this work is the integration of local ecological knowledge and farmer perspectives into scientific characterisation and modelling, reinforcing the relevance and uptake of restoration practices. Collaborative activities—including improving laboratory facilities in Ethiopia, joint field visits and bi-directional sharing of teaching —illustrate substantive capacity building and co-production of knowledge.

Both projects demonstrate successful institutional cooperation that values local leadership and indigenous knowledge, supports Ethiopian research capacity and yields insights relevant for scalable soil restoration and rural prosperity. The UK-funded SMILE project is notably led by the Ethiopian partners, underscoring the emphasis on local ownership in driving sustainable impact across ecosystems and communities.

# Viruses of nitrifying prokaryotes and their impact on soil nitrogen cycling

**Sungeun Lee[1], Eleftheria Bachtsevani[1], Christina Hazard[1], and Graeme W. Nicol[1*]**

[1] *Department of Microbial Ecology, University of Lyon, France*

*graeme.nicol@cnrs.fr

**ABSTRACT**

Viruses influence biogeochemical cycling through cell lysis and metabolic reprogramming, yet the consequences of virus–host interactions in soil remain poorly resolved in these complex, diverse ecosystems. We demonstrate that focusing on discrete, microbially-mediated biogeochemical processes provides a powerful framework for illuminating soil virus–host dynamics. Nitrification is a central process in the nitrogen cycle, regulating nitrogen availability while contributing to nitrous oxide emissions and nitrate leaching associated with inefficient fertiliser use in agriculture. Viruses of ammonia- and nitrite-oxidising microorganisms that perform nitrification have received comparatively little attention. This is likely, in part, due to cultivated strains being incapable of confluent growth on agar plates, limiting the use of plaque assays for isolating lytic viruses. Using a novel liquid-based approach with a pre-incubation step to enrich both active hosts and viruses, we cultivated viruses infecting a range of ammonia-oxidising archaea (AOA) and bacteria (AOB) strains, with stable cultures analysed using transmission electron microscopy and genome sequencing. Viruses of both AOA and AOB were diverse and belonged to multiple uncharacterised families, all possessing minimal similarity to cultivated virus References genomes. In agreement with our previous virus-targeted metagenomic analyses, AOA virus genomes are generally larger than AOB, and ranged in length from 39 to 160 kb and 36 to 51 kb, respectively. AOB virus infection resulted in typical virus-host dynamics associated with the lytic life cycle, whereas AOA viruses produced host growth dynamics associated with chronic infection and caused host cell gigantism. The cultivation of nitrifier viruses offers opportunities for the development of novel genetic tools and augmentation of nitrification rates in various ecosystems.

# How do nitrogen transformation processes affect nitrogen use efficiency in rice paddy

**Xiaoyuan Yan, Institute of Soil Science, Chinese Academy of Sciences** [1*]

[1] *Institute of Soil Science, Chinese Academy of Sciences*

**ABSTRACT**

The nitrogen (N) use efficiency (NUE) of cropping systems needs to be improved to achieve sustainable agricultural development. The NUE of rice production in China is known to be lower than that in other major rice-growing countries; however, there are large regional variations in NUE across the country, and the underlying mechanisms driving this variation remain poorly understood. We collected soils from 50 rice paddy fields in the main rice production areas of China, quantified the rates of N transformation, characterized the associated microbial communities to explore the linkage among environmental controls, process rates, the responsible communities and NUE. We show that NUE in Chinese rice paddies is strongly associated with the ammonium retention time and gross rates of oxidation of NH4+ and N mineralization; additionally, we propose that soil pH and microbial composition are major factors determining soil N transformation processes and NUE. In particular, the variation in NUE in the sampled soils was strongly associated with changes in the relative abundance of Nitrososphaerales, an archaeal order encompassing diverse ammonia oxidizers. These findings provide important insight regarding the mechanisms underlying the large regional variations of rice NUE in China and offer a blueprint for improving the management practices in rice production systems.

# Global Soil Nitrogen Budget and Pollution hotspots (1980–2022)

## ABSTRACT

Soils mediate the largest exchanges of reactive nitrogen (Nr) between the biosphere, atmosphere, and waters. Using the coupled human and natural system model CHANS-Globe, we construct a soil-centred global nitrogen budget for 1980–2022 that integrates mineralization, nitrification, denitrification, plant uptake, manure and fertilizer management, and soil–water solute transport. Harmonizing multi-source datasets and validating against soil, riverine, and atmospheric observations, we resolve trends in soil N stocks, soil-derived atmospheric emissions ($NH_3$, $NO_x$, $N_2O$), and nitrate leaching/runoff. Anthropogenic Nr inputs increased by 40-50% over four decades, accompanied by higher atmospheric emissions and intensified solute exports. Pollution hotspots are identified in East and South Asia, Western/Central Europe, the U.S. Corn Belt, parts of Latin America, and major African river basins, driven by high fertilizer intensity, concentrated livestock, drainage practices, and limited wastewater treatment. We estimate a global net soil N sink of 30–100 Tg N $yr^{-1}$, with pronounced regional redistribution and divergent soil states ranging from N saturation to N deficiency, implying tailored management needs. Portfolio interventions, e.g., 4R nutrient stewardship, inhibitors/slow-release fertilizers, cover crops, manure stabilization, and drainage control, can cut Nr losses while improving soil health and nitrogen use efficiency. This study quantifies key processes and imbalances in the global soil nitrogen cycle, guiding efforts to synergistically achieve food security and environmental protection.

## ABSTRACT

Entisols (commonly known as purple soils) in the Sichuan Basin of China are vital yet vulnerable agricultural resources, where significant nitrogen (N) loss poses a challenge. While surface N dynamics have been documented, a systematic understanding of N transformation patterns throughout the soil profile—and the role of mineral-microbial interactions in governing them—remains limited.

This research bridges this gap by investigating how the co-evolution of soil minerals and microbial communities regulates N transformation processes along profiles of Entisols derived from different parent materials (forming Calcareous, Neutral, and Acidic subtypes) under varying land-use types (Paddy, Dryland, Forest). We collected soil samples by genetic horizon from representative profiles in the hilly Sichuan Basin.

A multi-faceted analysis was performed on each horizon, encompassing: i) basic physicochemical properties, ii) mineralogical composition (characterized via XRD and FTIR), and iii) N transformation characteristics (quantifying gross mineralization, nitrification, and immobilization rates using $^{15}N$ isotopic tracing). To explicitly link mineralogy to microbial drivers, we analyzed the structure and functional potential of N-cycling microbial communities (targeting *amoA, nirS, nirK*, and *nosZ* genes) and related enzyme activities.

Our results demonstrate that profile-dependent evolution of distinct mineralogical assemblies (e.g., illite, smectite, kaolinite) and carbonate content acts as a primary environmental filter, shaping the ecological niches for N-cycling microorganisms. Specifically, the carbonate-buffered higher pH in calcareous subtypes selected for a bacterial-dominated nitrifying community (AOB), resulting in accelerated nitrification rates. Conversely, the mineralogy and inherent acidity of acidic subtypes favored archaeal ammonia oxidizers (*AOA*) and promoted greater N retention. This evidence shows that the soil mineral matrix directly and indirectly—through its control on pH and organic matter stabilization—orchestrates the microbial engine that drives N transformations.

By integrating mineralogical, microbiological, and process-rate data, this study establishes a mechanistic framework for the "Mineral-Microbial Interaction" pathway that controls N cycling during initial soil development. Our findings provide a scientific basis for designing precise N management strategies that account for subsurface biogeochemical heterogeneity in Entisols.

# Root-soil interactions govern soil organic nitrogen dynamics under acid rain and nitrogen deposition

**ABSTRACT**

Acid deposition and nitrogen (N) enrichment are major environmental stressors under anthropocene change, exerting severe negative impacts on N cycling in forest ecosystems. Fine roots, as the primary input source of soil organic nitrogen (SON), their decomposition process play a critical role in the formation and turnover of SON; However, how fine root decomposition mediates changes in root substrates and the soil microenvironment, thereby influencing SON dynamics under acid rain and N deposition, is still poorly understood. Here, we established an acid rain-nitrogen deposition simulation platform in subtropical Cunninghamia lanceolata plantations and conducted experiments using substrate regulation, environmental regulation, and in situ decomposition experiments to explore the interactive effects of fine root substrates and soil environments on SON dynamics. The results showed that fine root substrate treatments accelerated the decomposition of SON fractions, with SON fractions declining by 7–42% relative to the control. Soil microenvironmental changes had distinct effects: N addition increased accumulation of acid-hydrolyzable total nitrogen, amino sugar nitrogen, and acid-hydrolyzable ammonium nitrogen by an average of 15%, along with increased protease activity in higher-order roots. In contrast, acid rain treatment suppressed soil enzyme activities in lower-order roots, leading to a 20% increase in acid-hydrolyzable amino acid nitrogen content. Notably, root-derived substrates and soil environmental conditions acted synergistically to increase acid-hydrolyzable total nitrogen by 16–32% compared with the control. Redundancy analysis and random forest modeling identified soil pH, total N, and protease activities (acidic protease, chitinase, and aminopeptidase activities) as key predictors of SON transformation. Overall, our results suggest the need to consider interactive regulation of SON dynamics by fine root substrates and soil environmental conditions in climate change impact assessments of N cycling in terrestrial ecosystems.

# SmartField Solutions: Advancing $N_2O$ Mitigation in Danish Agriculture

**Leanne Peixoto[1], Meng Kong[1*], Ann Britt Værge[3], Klaus Butterbach-Bahl[1,2] and Christian Dold[1]**

*[1] Department of Agroecology, Aarhus University, AU Viborg, Denmark*

*2 Research Director Land-CRAFT; Aarhus, Denmark*

*[3]Danish Technological Institute, Aarhus, Denmark*

*mk@agro.au.dk

**ABSTRACT**

Denmark's ambitious target of reducing national greenhouse gas emissions by 70% by 2030 underscores the urgent need to mitigate nitrous oxide ($N_2O$) emissions from agriculture. This is because fertilized soils contribute approximately 80% of the country's $N_2O$ sources. As part of SmartField, an innovative climate platform aimed at reducing Danish agricultural $N_2O$ emissions, we investigated mitigation strategies in a grass-clover/maize rotation on sandy loam at Supersite A (Aarhus University, Denmark). Using a randomized complete block design (4 blocks, eight treatments, 32 plots of 15 × 3 m), we compared the use of cattle slurry and biogas digestate, each combined with either (i) the nitrification inhibitor 3,4-dimethylpyrazole phosphate (DMPP; Vizura®), (ii) a 20% reduction in N rate plus DMPP or (iii) an additive for slurry (Eminex®), against a no-nitrogen (N) control. Manures were injected in two to three applications between April and July 2025. High-frequency automated chambers monitored $N_2O$ fluxes, complemented by measurements of mineral N dynamics and N leaching using suction cups. The study tested three a-priori hypotheses: (H1) DMPP would reduce $N_2O$ emissions for both substrates; (H2) moderate reductions in N application rate and optimized timing would lower cumulative $N_2O$ emissions without compromising the N fertilizer replacement value; and (H3) the slurry additive would suppress short-term $N_2O$ peaks without increasing N leaching. By integrating gaseous flux measurements, leaching data, and agronomic performance, the experiment aimed to identify mitigation strategies that would avoid pollution swapping while remaining effective across various manure types and management practices.

**ABSTRACT**

Temperature sensitivity (Q10) of NO and $N_2O$ emissions are the core parameter to project future trajectories of soil nitrogen (N) dynamics in response to climate warming. However, spatial variations in Q10 and their underlying microbial pathways are unknown, hindering the ability of projection. We sampled 21 upland soils across a 4000-km transect in China and conducted incubations at 15 to 40 °C with $^{15}N$ tracer to quantify temperature response of process-specific NO and $N_2O$ emissions. We found that their optimal temperatures (Topt) exceeded 30°C and increased with mean annual site temperature. Q10 ranged widely from 1.3 to 5.7 (averaged 3.3) and 1.0 to 5.9 (averaged 3.5) for NO and $N_2O$, respectively, being higher in subtropical and warm temperate regions than others and being significantly higher than 2 as set in Earth system models. Using spatially variable Q10 values observed in this study would result in 10–40% larger NO and $N_2O$ emissions under Shared Socioeconomic Pathways (SSP) 1-2.6 to SSP5-8.5 scenarios by 2100, compared to those using a value of 2, suggesting previously substantial underestimation.

## ABSTRACT

China is the world's largest consumer of nitrogen (N) fertilizer in rice production, yet excessive application leads to low nitrogen use efficiency (NUE) and significant environmental risks. This study investigated optimized water and N management through a two-year experiment with bare field in 2020 and rice field in 2021 and HYDRUS-1D modeling, analyzing conventional flooding (CF) versus alternate wetting and drying (AWD) with 30-40% N reduction and their effects on dry matter weight (DMW), NUE, $NH_4^+$-N and $NO_3^-$-N migration. Results showed AWD enhanced soil redox **fluctuations**, boosting nitrification and increasing $NO_3^-$-N uptake to 25-30%, which was 11-16% with CF. Root water retention under AWD reduced N concentration at 30 cm depth by 70% versus bare soil. CF with 30% N reduction maintained high yield of 1000 grain weight = 22.31 g and peak NUE= 45.63%. 1-3 days after each fertilization were critical for $NH_4^+$-N leaching particularly when irrigation exceeded 2 cm· $d^{-1}$. Notably, reflooding after drainage in AWD spiked $NO_3^-$-N by 40%, primarily from oxidized adsorbed $NH_4^+$-N. The HYDRUS-1D model demonstrated high accuracy for simulating water and nitrogen transport in bare and rice fields, particularly under CF conditions. And the model successfully revealed rice's predominant absorption of $NH_4^+$-N and the phenomenon that AWD irrigation increases the proportion of $NO_3^-$-N uptake. **For sustainable rice production,** CF system with 20-25% N reduction was suggested to balance yield, NUE and environmental protection, providing a **scientific** basis for optimizing water and N management in rice fields.

## ABSTRACT

Enhanced anthropogenic nitrogen (N) deposition has intensified nitrous oxide ($N_2O$) emissions from forest soils. The increase in atmospheric $N_2O$ concentration not only exacerbate the greenhouse effect but also aggravates stratospheric ozone depletion. However, most previous studies in forest ecosystems have relied solely on understory N addition for N deposition simulation, overlooking the influence of the forest canopy. Moreover, the majority of these studies have focused exclusively on inorganic N, with limited research addressing organic N deposition. Although the total N deposition seems to be stabilized in recent years, emerging evidence shows that atmospheric N deposition hotspots are shifting from temperate to subtropical and tropical regions. Here we conducted an experiment in a subtropical Moso bamboo (*Phyllostachys edulis*) forest to compare the effects of different N deposition simulation approaches (canopy vs. understory) and N forms (inorganic vs. organic). Our findings demonstrated that the annual cumulative soil $N_2O$ emissions under understory inorganic N deposition were 25.1% higher than that under understory organic N deposition. In contrast, no significant difference was observed between canopy organic and inorganic N deposition. For different simulation approaches, annual cumulative soil $N_2O$ emissions were always markedly higher under understory N deposition compared to canopy N deposition, but prolonged N deposition diminished the differences between the two approaches. In addition, both inorganic and organic N deposition increased abiotic $N_2O$ production by 17.2% and 16.5%, respectively, but abiotic processes only contributed 14.5-16.2% of total $N_2O$ emissions. Microbial processes dominated $N_2O$ production in both inorganic and organic N treatments, with nitrifier denitrification accounting for 54.6-64.3%. Furthermore, regardless of N forms, ammonia oxidizing bacteria (AOB)-driven $N_2O$ production (42.9-48.1%) exceeded that of ammonia-oxidizing archaea (AOA). The $N_2O$ emission factor from N deposition ($EF_4$) under canopy N deposition (0.76%) was lower compared to understory N deposition (1.63%). Using $EF_4$ derived only from understory deposition would lead to an overestimation of soil N2O emissions from Chinese bamboo forests by ~2.29 Gg $yr^{-1}$. Overall, our findings demonstrate that understory-only N addition experiments may substantially overestimate regional $N_2O$ emissions, particularly when inorganic N is applied, and underscore the necessity of incorporating canopy processes in future assessments of atmospheric N deposition impacts.

*esangree@ucsc.edu

## ABSTRACT

Long-term nitrogen (N) budgets from organic lettuce systems in California's Central Coast reveal substantial unaccounted losses (up to 350 kg N/ha annually) that cannot be explained by conventional inorganic N pathways. An emerging view is that in organic systems, where fertilizers such as manure and compost are rich in organic N, dissolved organic nitrogen (DON) can represent a significant portion of dissolved N leaching losses, as much as 35% of total N leached (Liang et al. 2021). However, the factors controlling DON leaching remain poorly understood; soil texture is widely considered a primary determinant of N mobility, while management practices and soil organic matter characteristics have been proposed as potential controls. Here, we combined controlled greenhouse experiments with field observations across 28 commercial organic lettuce farms in the California Central Coast region to test whether texture predicts DON leaching risk and identify effective soil management strategies. Column experiments (n=150) demonstrated that sandy soils leached 5.7-fold more DON than clay soils (13.6 vs 2.4 kg N/ha, $p<0.001$), with DON comprising 39% of soluble N in sand versus only 5% in clay. However, field observations across farms spanning 6-60% clay revealed no detectable texture effect on DON leaching risks ($p=0.71$). Instead, soil management practices explained 32-fold more variance than texture, with crop diversity and cover cropping emerging as the strongest predictors. Additionally, mineral-associated organic matter nitrogen (MAOM-N) was also found as another strong predictor of reduced DON leaching risks ($p=0.026$); further, increased cover cropping was found to be highly correlated with increased MAOM-N (0.005). These findings show that while soil texture fundamentally controls DON mobility under controlled conditions, field-scale complexity renders it an unreliable predictor of actual leaching risk. These findings challenge texture-based risk frameworks and demonstrate that management interventions—particularly crop diversification, cover cropping, and optimized nitrogen application—provide substantial leverage for reducing DON losses across all soil types.

# Modeling soil HONO emissions

**Dianming Wu***

*Key Laboratory of Geographic Information Science (Ministry of Education), School of Geographical Sciences, East China Normal University, Shanghai, China*

*dmwu@geo.ecnu.edu.cn

**ABSTRACT**

Soil is a critical component in the Earth system, significantly influencing atmospheric chemistry and climate change. Soil nitrous acid (HONO) emissions represent a significant source of atmospheric HONO, directly impacting air quality and atmospheric chemical processes. However, due to the reactive nature of HONO, the influencing factors and mechanisms underlying its soil emissions remain controversial, which limits the estimation of regional soil emissions. This presentation focuses on the processes and mechanisms of soil HONO emissions, as well as data-driven, empirical, and process-based models for estimating soil HONO emissions, with the aim of providing scientific basis and support for reducing nitrogen loss and optimizing air quality.

# The process of dissimilatory nitrate reduction to ammonium mediated by microorganisms

**Xuejiao Huang**[1*], Yuwen Luo[1], Luo Luo[1],Zhenlun Li[2], Deti Xie[2]
[1] *Key Laboratory of (Guangxi) Agricultural Environment and Products Safety, College of Agronomy, Guangxi University, Nanning, 530004, China*
[2] *Chongqing Key Laboratory of Soil Multiscale Interfacial Process, Southwest University, Chongqing 400716, China*
*hxuejiao0412@sina.com

**ABSTRACT**

Microbially mediated dissimilatory nitrate reduction to ammonium (DNRA) plays a crucial role in maintaining nitrogen balance in soil ecosystems. Previous studies suggested that DNRA occurs exclusively under anaerobic conditions, and mechanistic research on DNRA has likewise been confined to anaerobic environments. Our group previously demonstrated that *Pseudomonas putida* Y-9 can perform DNRA under aerobic conditions, with the *nirBD* genes involved in the reduction of nitrite ($NO_2^-$-N) to ammonium ($NH_4^+$-N); however, the key subunits responsible remained unidentified.

In this study, we constructed *nirB* and *nirD* gene knockout strains (Δ*nirB*, Δ*nirD*) and complementary strains (Δ*nirB::nirB*, Δ*nirD::nirD*) using double homologous recombination and seamless cloning techniques. By employing $^{15}N$ isotope tracing, we investigated the transformation of nitrate ($NO_3^-$) and $NO_2^-$ by these strains. The results revealed that the aerobic DNRA process in strain Y-9 is co-regulated by the *nirB* and *nirD* genes (Table 1). Further research identified that four out of eight preserved strains (isolated from long-term flooded paddy fields) could reduce $NO_2^-$ to $NH_4^+$ under aerobic conditions. $^{15}N$ isotope tracing confirmed the aerobic DNRA capability of these four strains. Sequencing analysis showed that the four strains showed the same NirBD sequence with strain Y-9 (the similarity was about 94.61%) (Fig.1). Additionally, two strains capable of reducing $NO_3^-$ to $NH_4^+$ under aerobic conditions—*P. fluorescens* 2P24 and *Agrobacterium tumefaciens* M—were isolated from upland farmland soil. Genomic sequencing confirmed the presence of *nirBD* genes in both strains, indicating their ability to perform aerobic DNRA.

Based on these collective findings, we hypothesize that the aerobic DNRA process is widespread in the surface layer of upland soils with sufficient oxygen. Consequently, the team conducted a meta-analysis of the soil DNRA process in subtropical regions. This analysis revealed that the DNRA rates in four typical subtropical ecosystems followed the order: wetland > upland farmland > paddy field > forestland. Specifically, the DNRA rate in upland farmland soil was 0.57 ± 0.09 mg N/kg/d. Structural equation modeling indicated that the influence of environmental factors on the soil DNRA rate in subtropical regions decreased in the order: C/$NO_3^-$-N > pH > MAP (Mean Annual Precipitation) > MAT (Mean Annual Temperature) > $NH_4^+$-N. Notably, MAP primarily affected the DNRA rate indirectly by regulating soil pH (Fig.2). Furthermore, we collected typical subtropical lateritic red soils under different crop cultivations to analyze the community characteristics of DNRA bacteria and their correlations with soil environmental factors. The results showed that DNRA bacteria are ubiquitous in Guangxi's lateritic red soils. *Anaeromyxobacter* was the dominant genus within the DNRA bacterial community and was most significantly influenced by C/$NO_3^-$-N and pH (Fig.3).

This research enriches the understanding of microbial nitrogen cycling and provides a theoretical foundation for developing technologies aimed at regulating the DNRA process in subtropical soils to enhance nitrogen use efficiency.

**ABSTRACT**

The coupled carbon and nitrogen cycles, fundamental to Earth's life-support systems and biogeochemical processes, are increasingly disrupted by global change drivers, with far-reaching implications for the climate system, ecosystems, and human well-being. To support cost-effective global management of these cycles, we developed the Coupled Human and Natural Systems-Carbon and Nitrogen Cycles (CHANS-CN) model, a global-scale framework that quantifies carbon-nitrogen fluxes and examines their interactions across 14 human and natural subsystems while assessing the influences of climate change, human-land interactions, and international trade. Building on this model, we established a cost-benefit analysis framework to evaluate integrated carbon-nitrogen management strategies and introduced a nitrogen credit system designed to incentivize mitigation. Together, the CHANS-CN model, the analytical framework, and the credit system, supported by adaptive policy measures, provide a comprehensive scientific foundation for advancing global food security, environmental protection, and sustainable development through coordinated carbon and nitrogen management.

**ABSTRACT**

Rice sustains nearly half of the global population, yet its nitrogen (N) use efficiency remains low, undermining both food security and environmental integrity. Rice predominantly absorbs ammonium ($NH_4^+$), which is readily nitrified and lost through irrigation and drainage, posing a persistent management challenge. Integrating 1,756 paired field observations and global modelling, we show that maintaining soil $NH_4^+$ relative to conventional practices increases rice yield by 6-10% and N use efficiency by 18-33%, while reducing ammonia ($NH_3$) volatilization by 16-50%, nitrous oxide ($N_2O$) emissions by 25-49%, and methane ($CH_4$) emissions by 9-30%. This N transformation-based management could reduce global N fertilizer inputs by 1.4 ± 0.06 million tonnes (Tg), generate an additional 72 ± 13 Tg of rice, and lower $N_2O$, $CH_4$, and $NH_3$ emissions by 0.07 ± 0.02, 6.8 ± 2.0, and 0.6 ± 0.2 Tg, respectively, equivalent to an annual reduction of about 202 Tg $CO_2$-eq. The total social benefit is valued at US$51 ± 5 billion, including US$29 ± 2 billion in added food value, achieved with only US$1.6 ± 0.6 billion in fertilizer investment and US$0.9 ± 0.1 billion in transaction costs. Aligning N transformation processes with crop N pReferences thus represents a pivotal strategy for sustaining rice productivity while minimizing environmental impacts.

## ABSTRACT

Soil fertility, which involves physical, chemical, and biological processes, is critical in regulating plant nutrient supply. Efficient use of nutrients, such as nitrogen (N), and the minimization of nutrient losses to the environment depend on understanding the interactions between these processes. Effective management requires both temporal correspondence between crop demand and soil supply (*synchrony*) and the appropriate allocation of resources within the root zone (*synlocation*). However, spatiotemporal mismatches often occur between soil supply and plant demand. Consequently, achieving adequate *synchrony* and *synlocation* requires adjusting the N fertilization dose according to the functionality of the pore system. In this context, the objectives of this research are i) to determine the amount and source of mineral N stored within the plant available water porosity volume during the growing season under permanent pasture systems established on volcanic ash soil, and ii) to simulate the transport and storage of mineral N at the matric potentials of PAW (plant available water; ~100 kPa to 60 kPa) in volcanic ash soil.

To achieve these objectives, a four-year field experiment under rainfed conditions in the permanent pasture system will be carried out. Three N doses will be used: i) D1: 180 kg N $ha^{-1}$, ii) D2: 140 kg N $ha^{-1}$, iii) D3: 160 kg N $ha^{-1}$. Additionally, two application strategies will be considered: i) AS1: fertilizer applied at the beginning of the experiment, and ii) AS2: fertilizer applied two weeks after AS1. Urea enriched to 5% atoms in excess of $^{15}N$ will be added to the field experiment (microplot) to determine the movement of N in the soil profile. During the project, continuous soil water content will be measured by field sensors at 20, 40, and 60 cm depth. Soil solution samples will be collected by suction cups placed in the microplot at the studied soil depths to determine nitrate concentration. Sampling of aerial biomass will be collected seasonally. Also, both root exploration and root activity will be simultaneously determined across depths. To describe the characteristic temporal scales of soil water dynamics and related flow processes, the first-year preliminary results will be evaluated using wavelet analysis. Once the wavelet analysis is performed, mineral N data from suction cups and soil water content data at different tensions will be correlated.

These results will provide fundamental knowledge to understand how the soil's dynamic supply allows for both the storage of inorganic N over time and the movement of mineral N from the soil solution toward the roots, functions that are influenced by the soil's hydraulic properties. This understanding will enable us to adjust the nitrogen fertilization dose to efficiently use the available resources while maintaining the productive levels in agroecosystems.

## ABSTRACT

China is one of the largest producers and consumers of citrus. It is widely cultivated in Southwest China. To maintain a high yield, large amounts of chemical fertilizers are applied in citrus orchards. However, excessive fertilizer application leads to significant nitrogen (N) residue in soils, which is lost through runoff, leaching, ammonia volatilization, and denitrification (Li et al., 2024a). Soil moisture is also the main factor restricting citrus production. Moderate water stress can balance the vegetative growth and reproductive growth of fruit trees (Zhong et al., 2019). However, the citrus production area in Southwest China has been affected by seasonal drought and waterlogging disasters for a long time, which will cause the reduction of soil nutrient utilization and the destruction of the ecological environment (Cui et al., 2024). There are the most abundant microbial communities in soils, which play an important role in soil N cycling (Zhu et al., 2021). According to statistics, terrestrial ecosystems account for about 70% of global $N_2O$ emissions, of which at least 45% can be attributed to microbial N cycling processes (Jones et al., 2014), which is not conducive to farmland ecological balance and plant growth. Therefore, understanding the microbial mechanisms of N cycling under water and fertilizer deficit conditions is crucial for improving soil N availability and promoting citrus production in Southwest China.

Nitrogen is an essential nutrient for plant growth and basal metabolism. Plants' growth depends on available N forms ($NH_4^+$-N and $NO_3^-$-N) (Li et al., 2023). In agricultural ecosystems, the availability of N is a key factor restricting crop yield, which is controlled by the interaction between water-fertilizer management and microbial metabolism. The rhizosphere is a hot spot for nitrification and denitrification, which is different from bulk soils (Wang et al., 2017). Plant roots selectively recruit microbial communities in the rhizosphere, which play an important role in regulating soil N cycling (Schmidt et al., 2019). Soil N cycling is an important part of the biogeochemical cycle, which is mediated by various microorganisms, including N mineralization, N fixation, nitrification, and other redox reactions of various forms of N (Tu et al., 2017). During N fixation, nitrogenase, encoded by *nifH*, fixes atmospheric $N_2$ into a biologically usable form. Ammonia monooxygenase (AMO) is encoded by *amoABC* genes in ammonia-oxidizing bacteria (AOB) or archaea (AOA) (Shang et al., 2023). They catalyze the transformation of $NH_3$/$NH_4^+$ to $NH_2OH$ (Liu et al., 2023). Nitrite reduction in plants can stimulate $N_2O$ emission, which is mainly driven by Proteobacteria (Hou et al., 2019). Denitrification genes include nitrate reductase (*narG*), nitrite reductase (*nirS* and *nirK*), and nitrous oxide reductase (*nosZ*) (Nadeau et al., 2019). Among these, *nirS* and *nirK* catalyze the reduction of $NO_2^-$ to NO, and they are usually used as marker genes for denitrification (Ming et al., 2024). In addition, $NO_3^-$ may be reduced through other metabolic processes, including dissimilatory nitrate reduction (DNRA) and assimilatory nitrate reduction (ANRA) (Broman et al., 2021).

Water affects plant growth and biogeochemical cycles of all elements in terrestrial ecosystems. Soil N cycling is particularly sensitive to water availability. Extreme droughts significantly impact the pools, fluxes, and processes of terrestrial N cycling, leading to decreases in N mineralization and nitrification (Deng et al., 2021). However, excessive irrigation can accelerate microbial N turnover, increasing the potential for nitrate leaching and gaseous N emissions (He et al., 2022). Potassium (K) is a major osmotic regulator, enhancing the water uptake ability of plants under drought stress, which plays an important role in the transport of photosynthetic products, nutrient metabolism and physiological growth of fruit (Zhang et al., 2019). It is conducive to nutrient uptake, yield, and quality improvement of citrus fruit. Moderate K application also increased N use efficiency by interacting with $NH_4^+$ in soils and significantly affecting N transformation processes (Li et al., 2020). Moreover, the appropriate K fertilizer application also increased the diversity of bacterial community in soils, which can indirectly increase citrus fruit yield by regulating rhizosphere soil enzyme activity, organic matter, and N cycling (Li et al., 2023).

Water and f K fertilizer deficit regulation with drip irrigation ($WKDR_{DI}$) is a new technology that accurately and evenly transports water and nutrients to the plant root zone. It can create a moderate water and nutrient deficit environment during the key growth stages of citrus, stimulate the physiological adaptability of citrus trees, and regulate the rhizosphere microenvironment. However, systematic research on N cycling and the microbial mechanisms in citrus rhizosphere soils under $WKDR_{DI}$ is still underexplored. Therefore, in this study, a control treatment (CK) with full irrigation and fertilization, two degrees of water deficit treatments (20% and 40%), and three degrees of K fertilizer deficit treatments (20%, 40% and 60%) were set up at fruit expansion stage (stage III, early July to late October) and fruit maturation stage (stage IV, early November to late February), respectively. The specific treatment included 20% water deficit and 20% K deficit (HWHK), 20% water deficit and 40% K deficit (HWMK), 20% water deficit and 60% K deficit (HWLK), 40% water deficit and 20% K deficit (LWHK), 40% water deficit and 40% K deficit (LWMK), and 40% water deficit and 60% K deficit (LWLK). This study aims to: (1) clarify the effectiveness of soil inorganic N components under $WKDR_{DI}$ at fruit expansion and maturation stages; (2) reveal the abundance of N cycling functional genes and microbial communities under $WKDR_{DI}$ at fruit expansion and maturation stages; (3) explore the effect of soil inorganic N availability and rhizosphere microenvironment on citrus production under $WKDR_{DI}$.

Results showed that **$WKDR_{DI}$ improved soil ammonium availability by promoting the N fixation process and reducing denitrifiers at the citrus fruit expansion stage (stage III).** The fruit expansion stage (stage III) is crucial for fruit rapid growth and dry matter accumulation. Since N is the main component of protein, nucleic acid, and chlorophyll (Wang et al., 2024), the demand for N in citrus fruits increased at this stage, and the metabolism and transport of N in rhizosphere soils also increased simultaneously. Our study found soil $NH_4^+$-N and total inorganic N contents increased significantly under the III-HWHK treatment, which was significantly affected by the degree of water deficit. At the same time, the III-HWHK treatment can promote the N fixation process and related genes (*nifD* and *nifK*), which were significantly affected by the degree of water deficit. This treatment also inhibited denitrification by reducing the abundance of denitrification genes (*nirK*, *norB*, *norC,* and *nosZ*). Additionally, *Ochrobactrum*, *Rhizobium,* and *Achromobacter* were the main denitrifiers carrying *nirK* and *norB* genes, and their relative abundance decreased significantly under the III-HWHK treatment. This may be the main reason for inhibiting denitrification and promoting soil ammonium availability. On one hand, moderate irrigation was beneficial to soil permeability and decreased the relative abundance of *nirS*-type and *nirK*-type denitrifiers (Zhang et al., 2021), thus inhibiting denitrification. On the other hand, Moderate K fertilizer is beneficial for creating eutrophic environments in soils and significantly affects bacterial and fungal taxa essential for organic matter decomposition (Li et al., 2024b), thereby balancing the composition and content of available N in soils. Therefore, the III-HWHK treatment can effectively improve soil ammonium availability by promoting N fixation and increasing the relative abundance of related genes (*nifD* and *nifK*). The abundance of denitrification genes (*nirK*, *norB,* and *nosZ*) and denitrifying microbial communities (*Bradyrhizobium*, *Stenotrophomonas,* and *Cupriavidus*) at stage III were significantly reduced under this treatment, thereby inhibiting the soil denitrification process, and also improving ammonium availability.

**$WKDR_{DI}$ also improved soil nitrate availability by increasing the abundance of nitrifiers at the citrus fruit maturation stage (stage IV).** Citrus prefers nitrate during growth, the increase in soil nitrate availability is beneficial to citrus growth. In this study, soil $NO_3^-$-N content increased significantly under the IV-HWMK treatment. This may be due to soil nitrification process being significantly promoted under this treatment. Moderate water deficit created an aerobic environment conducive to nitrifiers in soils, facilitating the nitrification process (Bozal-Leorri et al., 2023). In addition, although $NO_3^-$-N is negatively charged and adsorbed on soil particles, it has strong mobility and migrates with water flow (Xiao et al., 2019), so that moderate water deficit can reduce the nitrate leaching to deeper soil layers while increasing nitrate availability in the upper soil (Chen et al., 2024). The relative abundances of *amoA*, *amoB*, *amoC,* and *hao* genes also showed an increasing trend under $WKDR_{DI}$, with the IV-HWMK treatment showing the most significant increase. The main reason is that AOA and AOB are sensitive to soil moisture and oxygen conditions (Yang et al., 2018). The change of soil moisture directly affects the abundance of ammonia oxidizing microorganisms. Moderate water deficit drove the activity of AOA and AOB, thus increasing the abundance of related genes and promoting nitrification. Importantly, moderate irrigation and K fertilizer application were beneficial to soil N mineralization, providing additional $NH_4^+$-N in soils (Barra et al., 2023). The increase of soil $NH_4^+$-N content will stimulate the reproduction of nitrifying microorganisms, increasing the abundance of nitrifying genes and promoting nitrification (Liu et al., 2024), and improving soil nitrate availability. In particular, we also found the relative abundance of *Nitrosocosmicus* carrying the *amoC* gene was significantly increased under the IV-HWMK treatment, which directly promoted the enhancement of nitrification, thus effectively improving the effectiveness of nitrate in citrus rhizosphere soils. Therefore, the IV-HWMK treatment could promote nitrification by increasing the abundance of the *amoC* gene and nitrifying microbial communities (*Cupriavidus*, *Streptomyces*, *Nitrosospira,* and *Nitrosocosmicus*), which were the main reasons for the improvement of soil nitrate availability.

Moreover, **$WKDR_{DI}$ promoted citrus production by improving rhizosphere microenvironment and soil nitrogen availability.** Soil microenvironment is regulated by rhizosphere microorganisms, which can directly or indirectly affect the growth and development of plants. Soil moisture and nutrient availability significantly affect N cycling by altering the metabolic activity of soil microorganisms (Shang et al., 2023). The treatment of III-HWHK and IV-HWMK significantly improved citrus yield characteristics, including yield, partial factor productivity from nitrogen ($PFP_N$), partial factor productivity from potassium ($PFP_K$), and irrigation water productivity ($WP_I$). These were achieved by increasing soil inorganic N availability. The main reason is that the increase in soil inorganic N availability can promote the accumulation of amino acid proline, promote cell division and expansion during fruit development, and facilitate the storage of N and carbon in fruits (de Carvalh et al., 2024). It also promotes the transfer of more available N to leaves, enhances photosynthesis, and continues to provide carbohydrates for the fruit (Chen et al., 2023). In addition, moderate water and K deficiency can accurately regulate the level of water and $K^+$ in soils, and promote the transfer of $K^+$ absorbed by citrus roots to fruits (Li et al., 2024c), and promote the sugar and acid metabolism in citrus fruits (Cui et al., 2024). Meanwhile, it also balances the osmotic concentration between the rhizosphere and root cells, which is conducive to the absorption and utilization of water by plants (Cui et al., 2023). Above all, the increase in inorganic N availability in soils under $WKDR_{DI}$ optimized fruit yield characteristics by regulating the synthesis of photosynthetic products, nutrient transport and distribution, and its adaptability to water stress in citrus fruits.

In summary, the treatment of III-HWHK and IV-HWMK at the key growth stages of citrus fruits can regulate rhizosphere N cycling microorganisms, increase fruit yield, and improve the water and nutrient use efficiency. These findings will enhance our understanding of the responses of N cycling in citrus rhizosphere soils to $WKDR_{DI}$, and provide a theoretical basis for the formulation of the best irrigation and K fertilizer regulation strategies in citrus production in Southwest China.

*elysiajade.lewis@studenti.unipd.it

## ABSTRACT

Agricultural soils are major sources of nitrous oxide ($N_2O$) emissions, primarily produced through denitrification and nitrification. However, the impact of soil compaction on $N_2O$ emissions remains debated. To address this, a two-year lysimeter experiment was conducted under five different cultivation systems with four replicates each: bare soil (BS), conventional agriculture (CV), conventional agriculture + cover crop (CC), conservation agriculture with shallow soil compaction (0-25 cm, CA1), and conservation agriculture with deep soil compaction (25-45 cm, CA2). Grain sorghum was grown in 2023, maize in 2024, and annual ryegrass served as the cover crop. Main crops received solid digestate fertilization at 300 kg $ha^{-1}$ annually. Continuous automatic measurements of $N_2O$ emissions were monitored using a non-steady state through-flow chamber system coupled with an FTIR gas analyzer, capturing up to seven flux measurements per chamber per day. Daily emissions were analyzed in four periods: post-fertilization, main crop growth, post-harvest, and cover crop growth. Concurrent measurements of NOx, water-filled pore space (WFPS; 0-15 cm) and soil temperature (0-30 cm) helped contextualize emission dynamics. Additionally, 280 soil samples were collected in each year within the 30 days following fertilization from 0-5 cm and 5-15 cm depths to analyze pH, ammonium ($NH_4$-N), nitrate ($NO_3$-N), and nitrite ($NO_2$-N) dynamics. $NH_4$-N concentrations peaked within three days following fertilization then declined rapidly, while $NO_3$-N concentration peaks were generally observed fourteen days after fertilization. Across all years, peak $N_2O$ emissions occurred within two weeks post-fertilization, with the highest emissions observed in CC in 2023 (1.02 kg $ha^{-1}$) and in CV in 2024 (5.15 kg $ha^{-1}$). The lowest emissions consistently appeared in CA2 (0.35 kg $ha^{-1}$ in 2023 and 1.24 kg $ha^{-1}$ in 2024). These results were also confirmed when considering the overall two-year period, underscoring the critical role of soil structure and cultivation methods in mitigating $N_2O$ emissions.

# Evaluating the Fate of Nitrate in Deep Soils Using Dual Isotopes

**Xia Zhu-Barker, Yanyu Deng, Randy Jackson**

*University of Wisconsin-Madison*

zhubarker@wisc.edu

**ABSTRACT**

Nitrogen (N) fertilizer use in agriculture significantly increases food supply at the expense of environmental degradation, such as nitrate ($NO_3^-$) leaching into ground water and nitrous oxide ($N_2O$) emissions as greenhouse gas (GHG) aggravating global warming. However, how land use and management influence the N dynamics in the soil profile and the fate of $NO_3^-$ in the system still remain unknown. To find the best mangement practice that can reduce nitrogen loss into the environment, we measured the concentration of $NO_3^-$ and its stable isotope abundance ($^{15}N$ and $^{18}O$), together with the potential denitrification rate across a four-foot (122 cm) soil profile under various cropping systems receiving cover crops, no-till, manure, organic, and pasture. Currently, we found dairy forage systems generally exhibit higher total denitrification rates to reduce $NO_3^-$ leaching risk compared to cash grain systems, while organic systems can significantly reduce $N_2O$ production in surface soils compared to other systems. The organic dairy forage system shows the most potential for nitrate attenuation, with the lowest associated cost of $N_2O$ emissions. Along with other environmental factors, we try to develop a mechanistic understanding of how land use and management regulate N cycling processes, providing more accurate estimates of cost efficiency in utilizing best management practices to meet agricultural and environmental goals.

**ABSTRACT**

Grasslands, as one of Earth's major ecosystems, are critical for sustaining biodiversity, ecosystem services, and global food security. However, their nitrogen cycles are increasingly influenced by climate change, including elevated atmospheric $CO_2$ ($eCO_2$), warming, and shifting precipitation regimes. These changes significantly affect grassland productivity and nitrogen dynamics, with substantial regional variations. Using a synthesis of over 5,000 experimental observations coupled with multiple ecosystem models, we investigated the impacts of climate drivers on nitrogen dynamics under the SSP2-4.5 scenario. Elevated $CO_2$ alone is projected to enhance global grassland net primary productivity (NPP) by 10% while reducing leaf nitrogen content by 8%, resulting in a net increase of 4 Tg $yr^{-1}$ increase in nitrogen harvest by 2050. Enhanced nitrogen use efficiency (+29%) and biological nitrogen fixation (+66%) under $eCO_2$ would reduce nitrogen surplus (-29 Tg $yr^{-1}$) and fertilizer demand (-9 Tg $yr^{-1}$), potentially mitigating nitrogen pollution and yielding economic benefits of 235 billion USD. Warming, as another driver, is projected to increase nitrogen inputs by 17 Tg $yr^{-1}$ and nitrogen harvest by 12 Tg $yr^{-1}$ but may exacerbate reactive nitrogen losses by 5 Tg $yr^{-1}$. Adaptation measures to minimize nitrogen leakage could deliver economic gains of 121 billion USD by 2050. Precipitation shifts further complicate nitrogen dynamics. Regions with increased precipitation, such as the United States and mid-to-high latitude Asia, could see nitrogen harvest rise by 16 Tg $yr^{-1}$, while areas facing reduced precipitation, including Sub-Saharan Africa and South Asia, risk a 9 Tg $yr^{-1}$ harvest decline. These imbalances could worsen global inequalities in nitrogen cycles and food security. Our findings highlight the need for improved representation of these complex interactions in ecosystem models to guide climate adaptation strategies. Timely, targeted interventions can help balance benefits and risks, safeguard ecosystem health, and support sustainable, equitable grassland management in a changing climate.

## ABSTRACT

Drought and human activities pose substantial threats to wetland ecosystems. As the largest wetland in Asia, its ecological process has been significantly affected by hydrological dynamics. While the nitrogen (N) cycle is one of the key components in wetland ecosystems; however, the Poyang Lake Wetland has received limited attention regarding how flooding duration during the dry season affects soil N transformation rates. Therefore, this study therefore focused on the Poyang Lake Wetland in the dry season to explore the impacts of flooding duration and temperature on soil N transformation rates, and to clarify the regulatory roles of soil physicochemical properties, enzyme activities, and microbial functional gene abundances. Fieldwork was conducted from January to March in 2021, and, five plant community transects were established along a natural flooding gradient with different dominant species: *Artemisia selengensis* community, *Phalaris arundinacea* community, *Carex cinerascens* community, *Eleocharis congesta* community, and mudflat. Field situ incubation experiments were carried out, and samples were taken to measure the soil and microorganisms. Analysis of variance, correlation analysis, and regression analysis were employed to discuss the relationships between flooding duration, temperature, and N transformation rates. Results showed that: 1) Prolonged flooding duration significantly elevated net N ammonification and mineralization rates, though its effect on net nitrification varied across months. 2) Flooding duration significantly increased soil moisture and pH, while ammonium and total inorganic N contents exhibited a pattern of initial increase followed by decline with prolonged flooding, with nitrate responses showing monthly variability. 3) Protease and urease activities decreased markedly with extended flooding duration, whereas N-acetyl-β-D-glucosaminidase activity and N gene abundances related to N transformation remained virtually unchanged. 4) This study demonstrates that the impacts of flooding duration and temperature on N transformations were primarily driven by shifts in soil physicochemical properties, with enzyme activities and microbial genes making very limit contributions. These findings had significant implications for the management and conservation of the Poyang Lake Wetland Ecosystem.

# Identifying the driving factors of soil nitrate nitrogen via MLs-GIS framework in an intensive plain agricultural area, China

## ABSTRACT

Excessive accumulation of nitrate nitrogen (*SNN*) in soil is a global ecological issue, with adverse effects on terrestrial and aquatic ecosystems, particularly in developed planting-breeding mixed areas with multiple sources and high input of nitrogen. Here, a total of 251 topsoil samples were collected from a typical agricultural planting area on the North China Plain, China. At the same time, a multisource data including N-fertilizer types and input, physicochemical properties of soil, topographic factors, spatial distance factors, land use and land cover, remote sensing factors, were constructed. Then, a framework combining machine learning models with spatial analysis by GIS (MLs-GIS) was built to clarify the fit of the spatial distribution and identify key factors influencing *SNN*. The results revealed that the content of *SNN* at different sites varied significantly (from 0.02 to 58.85 mg/kg). The *soil pH* ranged from 5.18 to 8.69, with an average value of 8.12. Field investigations revealed that the primary type of N fertilizer was ternary compound fertilizer followed by urea. Correlation analysis showed *soil pH* was significantly negative correlated with *SNN* ($p < 0.01$), but not significant for *chemical N fertilizer input* though a positive correlation relationship. According to the performance of the ML models, namely, the random forest (RF), GBDT, LightGBM and XGBoost, *soil pH* and *chemical N fertilizer input* were the main factors influencing *SNN*. The RF model exhibited the best performance, with the highest prediction accuracy ($R^2$ =0.64), and warrants increased attention in the management of agricultural nitrogen pollution. In summary, the MLs-GIS framework is efficient at identifying the key influencing factors and the spatial distribution of *SNN*. While, an existing limitation of the study is the insufficient incorporation of soil physicochemical properties, which may reduce the predictive performance of the models. These critical factors are closely related to the SNN content, such as the soil texture and soil bulk density, and should be included in model analysis in future steps.

## ABSTRACT

The impacts of elevated carbon dioxide ($eCO_2$) and warming on plant growth and soil nitrogen metabolism are complex, particularly as their interaction can present additive, synergistic, or antagonistic effects on different parameters. Dinitrogen ($N_2$) emission and ammonia ($NH_3$) volatilization represent major pathways of nitrogen loss in paddy fields. However, the responses of these two gaseous losses to the interaction between $eCO_2$ and warming, along with the relative contributions of soil-derived versus fertilizer-derived nitrogen remained a significant knowledge gap, undoubtedly poses a challenge for formulating effective nitrogen mitigation strategies under climate change scenarios. Our study addressed this by utilizing a Temperature and Free-Air $CO_2$ Enrichment (T-FACE) platform, integrated with a Membrane Inlet Mass Spectrometer (MIMS) enabling for the first time the in-situ observation of $N_2$ emission patterns in paddy under $eCO_2$ and warming while simultaneously monitoring $NH_3$ volatilization losses. Furthermore, we employed $^{15}N$-labeled urea to differentiate the contributions of native soil nitrogen and applied fertilizer to both $N_2$ emissions and $NH_3$ volatilization under simulated climate change. Additionally, we evaluated the mitigation efficacy of two conventional measures—biochar and nitrification inhibitors (DMPP) under these future climate scenarios. Through continuous monitoring over two rice growing seasons, our research revealed that $eCO_2$ alone stimulated $N_2$ emissions whereas warming alone suppressed it. Under the interaction, warming mitigated the promotional effect of $eCO_2$ on $N_2$ emissions. Conversely, $eCO_2$ alone inhibited $NH_3$ volatilization while warming alone promoted it. Their interaction revealed that $eCO_2$ alleviated the stimulatory effect of warming on $NH_3$ volatilization. Although the individual effects of $eCO_2$ and warming on $N_2$ and $NH_3$ were opposing, their combination ultimately led to an increase in the cumulative losses of both gases. Analysis across fertilization stages (basal, tillering, panicle) revealed a distinct trade-off: $NH_3$ volatilization decreased while $N_2$ emissions increased from the basal to the panicle stage. Under climate change, $NH_3$ volatilization primarily originated from the fertilizer. In contrast, the contribution of soil versus fertilizer to $N_2$ emissions was temperature-dependent: under $eCO_2$ without warming, the soil was the primary source of $N_2$, whereas under warming conditions, fertilizer became the major contributor. For mitigation, the DMPP was significantly superior to biochar in reducing the cumulative total of $N_2$ and $NH_3$ losses, primarily due to its substantial reduction of $N_2$ emissions. In conclusion, our research not only fills a critical international knowledge gap regarding in-situ $N_2$ losses from paddy under future climate scenarios but also provides a theoretical foundation for developing adaptive nitrogen management strategies to mitigate nitrogen losses in a changing climate.

**ABSTRACT**

Sloping farmland is a critical global agricultural resource for ensuring food security, but its topographic features (particularly slope) make it a hotspot for greenhouse gas (GHG) emissions ($CO_2$, $CH_4$, $N_2O$) and nitrogen pollution (e.g., leaching, runoff, and ammonia volatilization), posing significant ecological threats. Achieving green and sustainable development in these systems requires a systematic understanding and synergistic regulation of carbon and nitrogen cycles to maintain crop productivity while minimizing environmental impacts.

This study conducted a meta-analysis to integrate field experimental data from published studies worldwide, quantitatively evaluating the effects of management practices (e.g., conventional tillage, conservation tillage, optimized fertilization, terracing, cover crops, and biochar application) on GHG emissions, nitrogen loss, and crop productivity under varying slope conditions. Through rigorous literature screening, 535 independent cases were included to build a comprehensive database incorporating slope, management types, environmental variables (e.g., GHG fluxes, nitrogen loss, yield), and background factors (e.g., soil type, climate, crop species). Using random-effects models, effect sizes (e.g., response ratio, standardized mean difference) were calculated for key indicators. Subgroup analysis and meta-regression revealed interactions between slope and management practices, highlighting carbon-nitrogen synergy mechanisms. The results provide a scientific basis for optimizing region-specific management strategies to enhance pollution control, carbon sequestration, and emission reductions in sloping farmland systems.

# Feasibility of gypsum by-products as soil amendment to mitigate nitrous oxide emission from arable soil

**Chang Oh Hong[1]*and Mu Seong Kim[1]**

[1] Department of Life Science and Environmental Biochemistry, Pusan National University, Miryang, Republic of Korea

*soilchem@pusan.ac.kr

**ABSTRACT**

Sulfate ($SO_4^{2-}$) can act as alternative electron acceptors under anaerobic soil conditions, potentially suppressing nitrous oxide ($N_2O$) production by competing with nitrate ($NO_3^-$) during microbial respiration. The objectives of this study were 1) to evaluate the feasibility of $SO_4^{2-}$-containing industrial by-products as soil amendment to mitigate $N_2O$ emissions from arable soils and 2) to determine the most effective amendment. An incubation experiment was conducted using both soil orders, Inceptisol and Andisol. Ninety grams of air-dried soils were mixed with neutralized gypsum ($CaSO_4 \cdot 2H_2O$), phosphogypsum ($CaSO_4 \cdot CaHPO_4$), and calcium sulfate ($CaSO_4$) at a rate of 1% (*wt/wt*) and 1 g of urea fertilizer was added as a nitrogen source. Soil mixtures were incubated at 25°C for 4 weeks under controlled moisture conditions with water-filled pore space (WFPS) set at 30%, 60%, 90%, and 100% to simulate various soil moisture regimes. Daily $N_2O$ fluxes increased over time in all treatments with a remarkable peak observed approximately two weeks later, indicating a delayed microbial activity related to nitrogen transformations and $SO_4^{2-}$ utilization. Cumulative $N_2O$ emissions were significantly lower with $SO_4^{2-}$-amended soils compared to the control across all WFPS levels. Calcium sulfate showed the greatest mitigation effect, followed by neutralized gypsum and phosphogypsum. The mitigating effect of $SO_4^{2-}$ was attributed to its role as an alternative electron acceptor that inhibited denitrification or competed with $NO_3^-$ reduction, and an inverse relationship was observed between soil $NO_3^-$ concentrations and cumulative $N_2O$ emissions. Particularly in $SO_4^{2-}$ -treated soils, consistently higher $SO_4^{2-}$ levels were maintained throughout the incubation. This suggested that $SO_4^{2-}$ redirected microbial respiration away from $NO_3^-$ reduction, thereby reducing $N_2O$ production. Nitrous oxide emissions decreased with increasing WFPS in both soil orders, showing the greatest emissions at 30% WFPS and the least at 100%. At higher WFPS, residual $SO_4^{2-}$ concentrations declined, indicating enhanced microbial $SO_4^{2-}$ reduction under anaerobic conditions. Overall, these findings demonstrate that $SO_4^{2-}$ amendments, specifically industrial by-products such as phosphogypsum and neutralized gypsum, possess strong potential for $N_2O$ mitigation and sustainable resource recycling. Although calcium sulfate showed a slightly greater reduction in $N_2O$ emissions, both phosphogypsum and neutralized gypsum clearly reduced emissions compared to the control and exhibited comparable mitigation effects to each other. In addition, these gypsum by-products offer advantages in terms of cost-effectiveness and environmental sustainability, especially in Andisol, making them promising soil amendments for field application.

## ABSTRACT

Understanding the fate of high nitrate accumulated in soil profiles (legacy nitrogen; LN) of cereal lands converted from intensive orchards (OC) is important for N management and environmental protection. This study has quantified changes in water and nitrate contents in soil profiles after OC during summer fallow on the southern Loess Plateau. HYDRUS-1D model was used to simulate the changes of water and N in soil profiles. The results show that summer fallow significantly increased the total water storage in the 0–500 cm soil profile of the OC treatment. Water recovery reached to the depth of 440 cm after the fallow. The scenario analysis of different precipitation patterns revealed a significant correlation between LN leaching and precipitation patterns. The leaching of LN in the soil layers at 200–300, 300–400, and 400–500 cm was estimated to be 390, 297, and 113 kg N $ha^{-1}$, respectively. The model predicted that recovery depths of soil water content at the average precipitation scenario during the summer fallow after 10 years of OC reaches up to a depth of 15 m; the peak depth of LN after 15 years of OC can reach up to 10 m. It highlights that while converting old orchards to cereal land improves soil water recovery during summer fallow, it simultaneously increases N leaching into the deep soil profile, which diminishes crop-available nitrogen. Balancing the trade-off between soil water recovery and legacy nitrate leaching into deeper soil is a challenge.

## ABSTRACT

Agricultural activities, especially those with poorly managed irrigation, synthetic fertilizers and livestock manure, are major contributors to soil and groundwater pollution, mainly by $NO_3$. To address this, the European Union introduced the $NO_3$ Directive (91/676/EEC) in 1991 requiring monitoring, designation of $NO_3$ Vulnerable Zones, NVZs, and the adoption of good agricultural practices and action plans to prevent and reduce $NO_3$ Non-Point Source, NPS, pollution. Despite these measures, $NO_3$ levels in shallow groundwater remain high in Arborea area on Sardinia Island's west coast, Italy, with monitoring data showing an upward trend. The NVZ in the sandy Arborea Plain faces excessive nitrogen input due to intensive livestock and agriculture. This study aims to mitigate agricultural NPS $NO_3$ pollution by integrating Site-Specific Best Management Practices, SSBMPs, and cost-effective field-scale bioreactors, BRs, to attenuate and intercept $NO_3$ pollution. Three pilot fields were selected in Arborea. Soil, vegetation, groundwater, irrigation and fertilization data were collected from each of pilot fields. FLOWS physically-based agrohydrological model was used to: 1) evaluate and quantify the water and $NO_3$ leaching to the groundwater under current practices, and 2) optimize irrigation water to minimize $NO_3$ leaching. In each of the three pilot fields, an artificial subsurface drainage network was installed to collect the percolation fluxes and transport them to a bioreactor specifically installed for this study. The BRs were designed to treat drainage water anoxically to remove $NO_3$ in the porous medium made by filling an excavated pit (25 × 4 × 1.2 m) with eucalyptus woodchips. Inlet and outlet structures along with a monitoring system were installed in each BR to monitor water quality parameters, to collect water samples at the inlet and outlet and to control the hydraulic gradient to sustain an average residence time of 4 to 6 h. Laboratory analyses illustrated high BR performance, reaching 100% of $NO_3$ removal rates in two of the pilot BR and 89% in one. The three BR effectively treated 1222, 2929 and 1830 kg of $NO_3$ over the period of 4 months between June 1st and September 30th, 2025. The collected data were used as inputs to FLOWS model whose results showed significant potential reduction in water and $NO_3$ fluxes to groundwater by optimizing irrigation water or by supplying the daily evapotranspiration demand.

**ABSTRACT**

Biological nitrogen fixation (BNF), primarily mediated by symbiotic (SNF) and free-living (FLN) diazotrophs, constitutes a critical source of bioavailable nitrogen in agricultural systems. However, their simultaneous responses to intercropping remain poorly understood. Here, we simultaneously investigated the responses of SNF by Chinese milk vetch (*Astragalus sinicus* L.) and soil FLN to intercropping with silage maize (*Zea mays* L.), alongside analyses of soil N pools and microbial communities. Intercropping reduced the proportion of atmospheric $N_2$ fixed by milk vetch (Ndfa) but increased the dry matter yield of silage maize. While the total rate of soil FLN remained unchanged, intercropping significantly altered the partitioning of fixed N among key soil N pools: the organic, inorganic ($NH_4^+$ and $NO_3^-$), and microbial biomass N pools. Specifically, the rhizosphere of milk vetch exhibited an increase in microbial biomass N derived from FLN, whereas that of silage maize showed enhanced $NO_3^-$-N from FLN. These shifts occurred without major changes in bulk soil properties but were concomitant with distinct restructuring of the fungal, bacterial, and diazotrophic communities. Notably, the abundance of specific dominant diazotrophs (e.g., *Sinorhizobium*, *Bradyrhizobium*), bacteria (*Microvirga*, *Bacillus*), and fungi (e.g., *Fungi_gen_Incertae_sedis*) was positively correlated with the proportion of inorganic N derived from FLN. Our findings demonstrate that milk vetch-maize intercropping enhances N bioavailability from FLN in a plant-specific manner, offering a promising strategy to benefit silage maize productivity.

## ABSTRACT

In the humid southeastern US, winter wheat (*Triticum aestivum* L.) production faces a critical dual challenge: heavy winter rainfall (>900 mm) creates high-risk conditions for nitrogen (N) leaching, while rising input costs impede farm profitability. Current management practices often rely on fall-applied poultry litter (PL), yet a critical knowledge gap exists regarding the fate of this unaccounted-for N and the optimal strategies to mitigate N losses. This study integrated field-based N budgeting, process-based modeling (DSSAT-CERES-Wheat), and multi-criteria decision analysis (AHP-TOPSIS) to quantify the fate of unaccounted-for N through different loss pathways and identify regulatory management strategies that balance farm profitability with environmental sustainability. Using two years of field data and 32 years of historical climate simulations across contrasting yield zones (High-Yielding Zone [HYZ] and Low-Yielding Zone [LYZ]), we first quantified the stochasticity of N loss pathways. Field-calculated budget revealed substantial "unaccounted-for N" (90-160 kg[N] $ha^{-1}$), which model simulations validated was primarily driven by nitrate leaching (69±21 kg[N] $ha^{-1}$). These losses were highly dynamic and peaked in wet years (96±21 kg[N] $ha^{-1}$) and significantly exceeded volatilization (1.6±0.5 kg[N] $ha^{-1}$) and denitrification (0.7±0.2 kg[N] $ha^{-1}$). Across both yield zones, the dominant driver of N losses was the asynchrony between fall mineralization and crop uptake. We subsequently evaluated planting dates and N management strategies to mitigate these losses. Delaying planting from mid-October to late November reduced crop N uptake and increased leaching by 18-21%. Although the farmer's baseline practice (T1: 130 kg[N] $ha^{-1}$ UAN + 5 Mg $ha^{-1}$ PL-Fall) maximized yield, it was economically inefficient and amplified N loss risk. In contrast, the AHP-TOPSIS analysis revealed that transitioning to a split-application of UAN only (130 kg[N] $ha^{-1}$) reduced environmental N losses by 4-8 kg[N] $ha^{-1}$ while increasing net returns by 36-70% across both zones. This strategy rectified the supply-demand asynchrony without compromising yield stability. These findings demonstrate that soil N fate in winter wheat is governed by climate-driven hydrologic fluxes and management timings. The integrated DSSAT-AHP-TOPSIS framework provides a transferable approach for regulating N losses, informing policies on organic amendment timing, and guiding climate-smart, site-specific nitrogen management in high-rainfall agroecosystems.

## ABSTRACT

Nitrous oxide ($N_2O$) emissions from ruminant urine patches are a major source of greenhouse gases in grazed pasture systems. Regenerative agriculture (RA) has gained global attention for its potential to improve environmental sustainability compared with conventional agriculture (CA), yet field evidence of its effect on $N_2O$ emissions remains limited. This study compared $N_2O$ emissions from synthetic cow urine patches on two adjacent dairy farms in New Zealand, one managed under CA and the other under RA practices. The comparison considered two soil histories present on both farms, reflecting the time since conversion from forestry to pasture: 23 years for early-converted soils and 9 years for late-converted soils. Plot pairs representing early- and late-converted soils were established in four paddocks on each farm, and $N_2O$ emissions were monitored over 71 days using the static closed chamber method.

Our results showed that cumulative $N_2O$ emissions were 72% lower in regenerative pastures compared with conventional pastures, demonstrating a substantial mitigation potential under regenerative management. Soil history strongly influenced emission patterns within each farm. At the CA site, urine-induced emissions were 152% higher from early converted soil than late converted soil ($p < 0.001$), whereas at the RA site, late converted soil produced 223% higher emissions than early converted soil ($p < 0.001$). Emission factors reflected these trends, with the highest in early converted CA soil ($0.61\% \pm 0.42$) and the lowest in early converted RA soil ($0.04\% \pm 0.03$).

These findings provide field-based evidence that RA practices can substantially mitigate $N_2O$ emissions from pasture soils while maintaining productivity, highlighting their potential role in sustainable dairy farming systems.

## ABSTRACT

Paste fertilizer, a type of controlled-release fertilizer, is a high-concentration liquid compound fertilizer with a certain level of viscosity. It has gained attention because, unlike coated fertilizers that use plastic shells, it does not generate microplastics. However, no studies have investigated the temperature dependence of nitrogen mineralization from paste fertilizer. This study aimed to clarify the nitrogen mineralization rate and temperature dependency of paste fertilizer through kinetic analysis and to compare its behavior with conventional urea solution. A 12-week laboratory incubation experiment was conducted using three paddy soils from northeastern Japan: two Inceptisols (Yamagata and Aomori Prefectures) and one Andosol (Iwate Prefecture). Incubations were performed under flooded conditions at three temperatures (10°C, 20°C, and 30°C). 10-g subsamples soil (on an oven-dried basis) were weighted into 68-mL serum bottles with 9.6mg N addition and flooded by 10ml water. After 0, 7, 14, 28, 56, and 84 days of incubation, the samples were extracted with 30ml of 15% KCI solution to measure ammonium nitrogen ($NH_4^+$-N) from the mineralization process. Results showed that Total nitrogen (TN) across all soil experiment in 12 week observations for the paste fertilizer and urea maintain very similar and there is no fertilizer type caused TN loss. Based on the $NH_4^+$–N accumulation was consistently higher under urea than paste fertilizer, reflecting the faster hydrolysis and stronger temperature responsiveness of urea-derived nitrogen. In both Inceptisols, $NH_4^+$ accumulation increased with temperature, with the 30 °C treatments exhibiting the most rapid and pronounced mineralization, followed by moderate release at 20 °C and 10 °C. The Andosol soil showed the lowest overall ammonium levels due to its higher adsorption capacity. These characteristics suggested that potential advantages of paste fertilizer for minimizing early-season nitrogen losses in flooded paddy soils and improving nitrogen-use efficiency under variable temperature conditions.

**ABSTRACT**

Fairy ring fungi (FRF) are basidiomycete species that can form fairy rings characterized by a thriving concentric vegetation zone with high plant biomass. Nevertheless, how the presence of those FRF affects soil bioavailable C and N is poorly understood. Fungal and soil samples were collected from China, and their stable isotope characteristics were determined to elucidate the influence of fairy ring presence on carbon and nitrogen cycling in fungal-soil interactions. The results showed that there were substantial differences in $\delta^{13}C$ and $\delta^{15}N$ between fairy ring fungi and soil. The $\delta^{13}C$ values ranged from -22.12‰ to -16.44‰ in fungi and from -25.30‰ to -22.08‰ in soil. Similarly, the $\delta^{15}N$ values ranged from 4.91‰ to 12.75‰ in fungi and from 3.22‰ to 7.75‰ in soil. Notably, soil $\delta^{15}N$ was significantly higher inside the fairy ring than outside it. The presence of fairy ring fungi affected the carbon and nitrogen content of the surrounding soil and altered the abundance of stable isotopes, with different soil regions exhibiting distinct characteristics. Therefore, the presence of fairy rings plays a dominant role in fungal-soil interactions.

**Key words:**fairy ring; natural abundance of carbon and nitrogen isotopes; fungal-soil interaction; stable isotope ratio.

## ABSTRACT

Optimizing the nitrogen (N) synchrony between soil supply and crop demand underpins resource-efficient agricultural production, whereas conventional one-time fertilization typically induces a temporal mismatch that compromises N use efficiency (NUE). Although substituting chemical fertilizers with pig slurry holds considerable potential for intensifying N-related productivity of crops, its low carbon (C) content and abundant ammonium ($NH_4^+$-N) concentration elevate the risk of soil mineral N (MN) accumulation and associated losses. Integrating C-rich straw with pig slurry regulates the C:N stoichiometric ratio of exogenous inputs, potentially mitigating MN accumulation and supply-demand asynchrony across the maize growing season. However, the underlying microbial mechanisms remain unclear. Therefore, we conducted a field split-plot experiment comparing two straw management practices—straw mulching (SM) and no straw (NS)—combined with three pig slurry substitution ratios (0%, 20%, and 40%) to investigate soil N dynamics and metagenomic functional shifts throughout vegetative (seedling, jointing) and reproductive (blister, maturity) growth phases. Key findings were as follows: (I) compared to sole slurry substitution (NS-20%, NS-40%), combining straw with slurry (SM-20%, SM-40%) functioned as a distinct "phasic regulator", more effectively synchronizing soil N supply with crop demand by maintaining lower MN levels during the seedling stage and enhancing soil N availability during the blister stage; (II) mechanistically, the phasic regulation was driven by a functional restructuring of the soil microorganisms, where SM-20% and SM-40% reduced MN accumulation during the seedling stage by prioritizing assimilatory retention (e.g., enriched genes of *nirA*, *nasA*, *gs_K00266*) over dissimilatory turnover (e.g., enriched genes of *narG*, *narJ*, *gdh_K00261*) relative to NS-20% and NS-40%, while subsequently shifting toward N acquisition during the blister stage via the enrichment of N fixation (e.g., *nifW*, *nifK*, *nifD*) and organic N degradation (e.g., *gdh_K15371*) genes; (III) exogenous C:N stoichiometry primarily regulated microbial functional shifts by stimulating microbial biomass, a process coupled with an improved physicochemical environment (e.g., pH and moisture) fostered by straw addition; (IV) multidimensional assessment identified SM-20% as the optimal strategy, achieving higher maize productivity (increased yield and economic benefits by 4.6% and 5.4%, respectively) and lower MN-related environmental risks compared to SM-40%. By synthesizing these findings, a "Stoichiometric Adaptation Cascade" framework was proposed, delineating how exogenous input stoichiometry modulates the transition in soil N cycling across the maize growing season. Accordingly, regulating exogenous C:N stoichiometry through rational organic combination establishes a viable paradigm for tightening soil N cycling and promoting sustainable agriculture in intensive maize cultivation.

## ABSTRACT

Nitrous oxide ($N_2O$) is a potent greenhouse gas contributing to global warming and stratospheric ozone depletion. $N_2O$ is primarily produced through nitrification and denitrification, which are regulated by soil and environmental factors. Numerous studies have been conducted to investigate nitrification and denitrification processes, their controlling factors and their contributions to $N_2O$ production. However, it is still challenging to estimate the parameters of process-based models based solely on limited experimental data. A fixed ratio is used in these models to estimate the proportion of $N_2O$ emissions from nitrification and denitrification. These unknowns may also result in uncertain predictions of feedback to N management practices and environmental conditions.

The application of nitrification inhibitors (NIs) e.g., 3-methylpyrazole 1,2,4-triazole (3MPTZ), 3,4-dimethylpyrazole phosphate (DMPP), acetylene ($C_2H_2$) is widely used to reduce $N_2O$ emissions. NIs could delay the oxidation of $NH_4^+$ to hydroxylamine, the first step of nitrification, thus decreasing the amount of $NO_3^-$, which is susceptible to leaching and loss through denitrification. While many process-based models simulate $N_2O$ emissions, their capacity to represent NIs' impact on N cycling is constrained by the lack of an NI module and relevant parameters.

Data assimilation improves model accuracy and reliability by calibrating models against observations, integrating mechanistic models with experimental data to estimate unmeasurable parameters and reduce associated uncertainties for better forecasts. In this study, we incorporated data assimilation into a coupled carbon–nitrogen model to estimate soil nitrification, denitrification, $N_2O$ emissions, and their related parameters under various soil moisture levels (Water-filled pore space (WFPS) at 50% and 70%), incubation temperature (15, 25 and 35°C) and nitrification inhibitor application (DMPP, 3MPTZ and $C_2H_2$) in cereal and vegetable production systems in Australia.

We found that the contribution of nitrification to $N_2O$ emissions (i.e., the fraction of $N_2O$ emitted from nitrification, $f_{N2O_nit}$) decreased with increasing temperature and moisture content, whereas denitrification dominated $N_2O$ production (i.e., the fraction of $N_2O$ emitted from denitrification, $f_{N2O_dni}$) under 70% WFPS regardless of temperatures. Under fertilizer N application, the use of nitrification inhibitors decreased $f_{N2O_nit}$) but increased $f_{N2O_dni}$). The efficacy of nitrification inhibitors in mitigating $N_2O$ emissions varied with environmental conditions. In this study, we demonstrate the use of data assimilation to constrain key parameters for predicting nitrification, denitrification and associated $N_2O$ emissions in response to soil environments and management practices. Integrating this technique into ecosystem process-based models has the potential to enhance model accuracy by reducing uncertainties and biases.

## ABSTRACT

Microbial nitrogen use efficiency (NUE), which governs the partitioning of N between microbial growth and mineralization, determines soil N supply and retention in croplands. However, the mechanisms driving the response of microbial NUE to fertilization at regional scales remain uncertain. Using a dual-isotope ($^{18}O$ and $^{15}N$) labeling approach across 12 long-term experimental sites in China, we found fertilization significantly decreased microbial NUE (log-response, RR = -0.48 ± 0.45, $P < 0.05$) compared to the unfertilized control, with organic amendments (manure and straw) exerting a greater reduction (median RR = -0.61) than chemical fertilizer alone (median RR = -0.35). This reduction was mediated by an enhancement in microbial N-acquiring enzyme activity, which increased soil total dissolved N. The magnitude of microbial NUE reduction was predominantly regulated by changes in soil properties (e.g., soil pH and total dissolved N) and microbial physiological traits (e.g., extracellular enzyme activity and stoichiometry), which together explained 83.5% of the response variance. Organic inputs enhanced this suppression by more effectively alleviating soil C:N imbalance and P limitation, as reflected in a greater decrease in microbial enzyme vector angle. Furthermore, climate (mean annual temperature) contributed 12.3% to the explained variance and was negatively correlated with microbial NUE response, indicating that warmer conditions amplified the fertilization-induced decline in microbial NUE. Overall, these mechanistic insights provide a theoretical basis for harnessing organic amendment strategies to regulate microbial function and improve soil N supply in croplands of China, with potential implications for soil N fate and developing region-specific fertilization regimes.

# Effects of manure substitution on nitrous oxide emissions in a subtropical Ultisol

**Yongxin Lin* and Yuheng Cheng**

*Fujian Provincial Key Laboratory for Subtropical Resources and Environment, Fujian Normal University, Fuzhou, China*

*yxlin@fjnu.edu.cn

**ABSTRACT**

Manure substitution is widely promoted as a sustainable alternative to synthetic nitrogen (N) fertilization, yet its effects on nitrous oxide ($N_2O$) emissions remain highly variable, particularly in phosphorus (P)-limited subtropical soils. Here, we investigated how P availability mediates the response of $N_2O$ emissions to partial manure substitution by combining soils from a 21-year fertilization experiment with controlled laboratory incubations and $^{15}N$ tracing techniques. We compared two fertilization regimes: N-only and N plus P (NP), under which 30% of synthetic N was replaced by manure-N.

Manure substitution exerted contrasting effects on $N_2O$ emissions depending on P supply, increasing emissions under the N-only regime while reducing them under the NP regime. These divergent responses were closely linked to shifts in gross N transformation pathways. Under N-only conditions, manure substitution stimulated autotrophic nitrification and denitrification, enhancing $N_2O$ production. In contrast, under NP conditions, manure substitution reduced the contribution of heterotrophic nitrification to total $N_2O$ flux, despite unchanged process rates, coinciding with a significant enrichment of *nosZ* clade II genes.

Our findings demonstrate that the mitigation potential of manure substitution is strongly context dependent and critically regulated by P availability. By reshaping microbial N transformation pathways rather than uniformly suppressing $N_2O$ production, P supply determines both the direction and magnitude of $N_2O$ responses to organic fertilization in subtropical Ultisols.

**ABSTRACT**

With the continuous increase in nitrogen fertilizer application rates, environmental issues caused by nitrogen loss have become increasingly severe. In flooded paddy fields, ammonia ($NH_3$), nitrogen gas ($N_2$), and nitrous oxide ($N_2O$) emissions are recognized as the main pathways of nitrogen loss. Previous research has largely focused on optimizing nitrogen fertilizer management, while insufficient attention has been paid to the regulatory role of rice varieties themselves, the contributions of fertilizer and soil sources to gaseous nitrogen loss, and whether a trade-off exists between $NH_3$ and $N_2$ losses. This study investigated flooded rice in southern China, quantifying nitrogen uptake and emissions of $N_2$, $NH_3$, and $N_2O$ synchronously across different varieties throughout the entire growing season. Using $^{15}N$ isotope labeling techniques, the contributions of fertilizer and soil to $N_2$ and $NH_3$ losses were clarified, and the balance between their emissions was preliminarily explored. Pot experiments included three conventional varieties with significantly differing biomass levels, one nitrogen-efficient variety, and the nitrogen-efficient variety with a 20% nitrogen reduction treatment. Results showed that different varieties varied significantly in nitrogen uptake and utilization throughout the growing season, with higher-biomass varieties exhibiting greater nitrogen uptake capacity. Although total gaseous nitrogen loss showed no significant difference among the three conventional varieties, loss patterns varied across growth stages due to differences in nitrogen translocation capacity. Nitrogen-efficient genotypes reduced gaseous nitrogen ($NH_3$, $N_2$) loss by 13% and increased nitrogen retention in the soil. Under the 20% nitrogen reduction treatment, the nitrogen-efficient variety not only maintained stable yield but also increased nitrogen uptake by 10% while reducing soil nitrogen residue by 10%. The study further revealed significant varietal differences in the contributions to $N_2$ and $NH_3$ losses, with fertilizer and soil sources playing distinct roles depending on the variety. Nitrogen-efficient genotypes increased the fertilizer contribution to nitrogen loss, whereas the nitrogen reduction treatment lowered fertilizer-derived loss and raised the soil nitrogen contribution. A potential balance between $NH_3$ and $N_2$ losses was also preliminarily identified: $NH_3$ loss dominated during basal and tillering fertilization stages, while $N_2$ loss prevailed during panicle fertilization. This research highlights the potential of variety selection in reducing nitrogen loss and provides new insights for strategies that combine varietal improvement and optimized fertilization to minimize nitrogen loss.

* thishari2000@gmail.com

**ABSTRACT**

Nitrous oxide ($N_2O$) is a potent greenhouse gas that significantly contributes to global warming and climate change. Agricultural soils are among the main anthropogenic sources of $N_2O$, driven by nitrogen fertilization and soil moisture dynamics that influence microbial nitrification and denitrification. A microcosm study was conducted to estimate the $N_2O$ emission from intensively cultivated Alfisol and Ultisol collected from *Mahaillupallama* and *Nuwara Eliya*, Sri Lanka, respectively. Soil samples were incubated under two moisture levels, 60% and 90% water-filled pore space (WFPS), with three treatments: non-amended control, urea alone, and with a biological nitrification inhibitor added at 2% (v/w). Headspace gases were collected after 1, 5, 15, and 30 days and assessed for $N_2O$ concentration, while soils were assessed for ammonium ($NH_4^+$) and nitrate ($NO_3^-$) concentrations. Results revealed that urea application significantly increased ($p<0.05$) $N_2O$ emissions with peaks of 0.81 and 667.20 $N_2O$ µg/kg/h in Alfisol and Ultisol, respectively, at 90% moisture level until the 15$^{th}$ day. At 60% WFPS, a significant reduction ($p<0.05$) in $NH_4^+$ concentration and a simultaneous increase in $NO_3^-$ concentrations and $N_2O$ emission imply a significant contribution made via the nitrification pathway to the $N_2O$ emission in both soils. At the 90% WFPS, a simultaneous reduction in $NO_3^-$ concentrations and an increase in $N_2O$ emissions from both soils suggest a significant role played by denitrifiers in $N_2O$ emission. The biological inhibitor added to Alfisol led to an accumulation of $NH_4^+$ while reducing $NO_3^-$ concentration and $N_2O$ emission until the 15$^{th}$ day at both moisture levels. In contrast, inhibitory effects on nitrifiers were not evident in the Ultisol, and $N_2O$ emission increased partly due to an increase in the carbon substrate for denitrifiers. The maximum nitrification rate (Vmax) and the substrate saturation constant (Km) of Alfisol were 5.74 µg $NO_3^-$ N/kg/h and 0.84 µM, respectively, whereas in Ultisol, comparatively higher Vmax (46.94 µg $NO_3^-$ N/kg/h) and Km (1.03 µM) were reported. These results imply that the substrate affinity of nitrifying communities differed between the two soils, implying differences in the diversity of bacteria and archaea communities. The results emphasize the need of managing soil moisture content and substrate availability for biochemical pathways that produce $N_2O$, the possibility of using nitrification inhibitors to control $N_2O$ emission from the studied soils, taking microbial community characteristics into account.

## ABSTRACT

Nitrous oxide ($N_2O$) is a major long-lived greenhouse gas and an ozone-depleting substance. Soils are a key global source, and net $N_2O$ fluxes are governed by microbially mediated source-sink processes. The enzymatic steps most directly linked to $N_2O$ source and sink include the reduction of nitric oxide (NO) to $N_2O$ by nitric oxide reductase (NOR), followed by the reduction of $N_2O$ to dinitrogen ($N_2$) by nitrous oxide reductase (NosZ). Although research on NOR and NosZ diversity has expanded our view of potential microbial $N_2O$ sources and sinks, we still lack an integrated understanding of which taxa carry different NOR/NosZ types, how these taxa are distributed across habitats, and which genomic traits underpin their metabolic potential and environmental adaptation. These gaps limit the translation of microbial insights into actionable strategies for soil $N_2O$ mitigation.

Here, we integrate soil microbial genomes with environmental metadata at the global scale to identify NOR/NosZ-associated microorganisms and characterize their taxonomic diversity and ecological distributions. We then conduct comparative analyses of metabolic and adaptive signatures, evaluate their associations with environmental gradients, and identify functional modules and ecological strategies potentially underlying variation in soil $N_2O$ source-sink strength.

The results are expected to provide a foundation for screening and cultivating mitigation-oriented microorganisms. Guided by the identified taxa and genomic traits, candidates with high $N_2O$ mitigation potential and broad environmental tolerance will be prioritized, and targeted enrichment and isolation will be pursued. Together, these findings provide a theoretical basis for developing microbe-driven strategies to mitigate soil $N_2O$ emissions.

**ABSTRACT**

Nitrification inhibitors are widely used to reduce the loss of nitrogen fertiliser from soil and associated environmental impacts. Similar to urease inhibitors, proposals have been made to mandate their use in agricultural systems. However, the effectiveness of nitrification inhibitors remains highly variable, with inconsistent performance across soils and environmental conditions limiting confidence in their widespread adoption.

This presentation synthesises recent mechanistic insights and builds upon existing conceptual frameworks to examine how soil physical, chemical, and biological properties regulate nitrification inhibitor behaviour and efficacy. Key factors influencing performance are discussed, including soil pH, sorption processes, microbial activity, and environmental conditions that govern inhibitor persistence and bioavailability.

By integrating these mechanisms, this framework provides a structured basis for interpreting observed variability in nitrification inhibitor performance and highlights knowledge gaps requiring targeted investigation. The framework is intended to support more predictive use of nitrification inhibitors and to guide future experimental and modelling approaches aimed at improving nitrogen management across diverse soil systems.

## ABSTRACT

Nitrogen (N) cycling is fundamental to forest ecosystem functioning, with nitrate availability largely dictating N-loss from soils. Beyond leaching, microbial communities reduce nitrate via three competing dissimilatory pathways: denitrification (DNF; N loss to $N_2$ and $N_2O$), anaerobic ammonium oxidation (AMX; N loss to $N_2$), and dissimilatory nitrate reduction to ammonium (DNRA; N retention). Despite the ecological importance of these competing processes, their simultaneous quantification and the factors governing their partitioning remain poorly understood. Here, we integrated isotopic, modeling, and molecular approaches to assess nitrate partitioning along forest hillslope gradients. We found that the competition for nitrate was dominated by DNRA at the top of hillslopes (up to 74%), which decreased and in exchange for a higher contribution from DNF (up to 96%) when approaching the bottom of the hillslope. The magnitudes of DNRA and AMX rates (up to 3.6 and 5.8 μg N $g^{-1}$ $h^{-1}$, respectively) underscore their underestimated significance in forest N budgets. Notably, the N-limited forest partitioned more nitrate to DNRA (26.4%) compared to the N-rich forest (19.4%), indicating a microbial adaptation toward N conservation under nutrient scarcity. Moving forward, we will investigate the specific factors governing the competition among these three pathways, alongside the $N_2O$ and $N_2$ product stoichiometry of DNF. This will inform the development of N management strategies aimed at enhancing N-use efficiency and climate mitigation in forest and managed ecosystems.

**ABSTRACT**

Atmospheric nitrogen (N) deposition is an important N source for ecosystems in China in recent years, driven by reactive N emissions from agricultural and industrial production as well as transportation. The long-term variation of atmospheric N deposition at the watershed scale and its environmental impacts remain insufficiently explored in regions with high N deposition, such as Central China. This study investigates the spatio-temporal variation of atmospheric N deposition in an agricultural watershed in subtropical Central China from 2011 to 2025. Atmospheric wet and dry N deposition were measured at typical paddy field, tea field, and forest sites. We assessed the impacts of atmospheric N deposition on soil $N_2O$ emissions and riverine N export using $^{15}N$ isotopic tracing. The results showed that atmospheric N deposition ranged from 25.7 to 41.5 kg N $ha^{-1}$ $yr^{-1}$ across the ecosystems over the 15-year period. Dry N deposition showed a significant decreasing trend across all sites, while wet deposition showed no significant change. The reduced N fraction in total deposition exceeded 0.5 in all three land-use types. Notably, the ratio of reduced to oxidized N in paddy fields showed an increasing trend, indicating that agricultural emissions remain the primary source of regional deposition. The contribution of N deposition to $N_2O$ emissions was 0.14% in paddies and 0.72% in tea fields, slightly lower than the IPCC emission factors for fertilizer (0.3% and 1%, respectively). Natural $^{15}N$ tracing also showed that atmospheric N deposition contributed over 20% to riverine N in the watershed. This study demonstrates that atmospheric N deposition significantly affects soil $N_2O$ emissions and non-point source water pollution in subtropical Central China.

## ABSTRACT

Rice production underpins food security but relies heavily on nitrogen (N) fertilization, of which is lost from flooded paddies as gaseous emissions. Dinitrogen ($N_2$) represents the largest N loss, yet its sources remain poorly constrained because biological $N_2$ fluxes are difficult to quantify against the atmospheric background. Global N budgets and mitigation strategies typically attribute $N_2$ emissions mainly to fertilizer, largely overlooking soil N pools. Here we apply a novel in-situ $^{15}N$ tracing–membrane inlet mass spectrometry ($^{15}N$-MIMS) technique to simultaneously measure $N_2$, $NH_3$ and $N_2O$ emissions and partition their soil- versus fertilizer-derived origins across a full growing season in two rice cultivars. We find that soil organic nitrogen (SON) accounts for most $N_2$ emissions (72-75%), overturning the prevailing assumption that fertilizer dominates this loss pathway, which is independently confirmed by a 13-year long-term fertilization experiment. In contrast, $NH_3$ originates mainly from fertilizer (71-77%) and $N_2O$ derives from both sources in near-equal proportions. We identify a previously unrecognized microbial N pump in which rapid assimilation of fertilizer-derived $NH_4^+$ accelerates SON mineralization, fueling soil-sourced $N_2$ emissions and driving a seasonal shift from $NH_3$- to $N_2$-dominated N losses. Neglect SON contributions causes systematic overestimation of fertilizer-derived $N_2$ and $NH_3$ losses by ~26%. These findings fundamentally revise N budgets for flooded rice systems and demonstrate that fertilizer reduction alone is insufficient to curb N loss, highlighting the need to manage soil-microbe-plant interactions to sustain yields while minimizing environmental impacts.

# Nitrogen Characteristics and Sustainable Management in Global Sloping Croplands

**Wenjing Zhou[1*], Ouping Deng[2]**

[1] *College of Resources, Sichuan Agricultural University, Chengdu 611130, China.*

[2] *College of Resources, Sichuan Agricultural University, Chengdu 611130, China.*

*zhouwj@stu.sicau.edu.cn

**ABSTRACT**

Sloping croplands are vital for global food security yet represent a vulnerable nexus of soil erosion and nutrient loss. While the impacts of topography on local productivity are well-documented, a systematic global assessment of how slope gradients drive nitrogen (N) budgets and nitrogen use efficiency (NUE) remains a critical knowledge gap. This limitation hinders the development of spatially targeted policies for sustainable agricultural management.

To address this, we developed a global analytical framework integrating high-resolution land use data, topography, and N cycling processes. We mapped the spatiotemporal patterns of global sloping croplands and quantified N inputs, outputs, and NUE across slope classes using the Coupled Human and Natural Systems (CHANS) model. Furthermore, we designed optimization scenarios aligned with Sustainable Development Goals (SDGs), evaluating the potential of cropland reallocation (retiring steep-slope farming) and crop mix optimization to enhance productivity and NUE.

Our results reveal distinct topographic controls on the global N cycle: (1) Gradient Effect: Both N inputs and outputs decrease significantly with increasing slope. Crucially, N outputs decline faster than inputs, leading to a structural decline in NUE on steeper terrains. (2) Regional Disparity: Asia dominates global N output on sloping lands, whereas Africa and Oceania exhibit significantly lower intensities, highlighting diverse management challenges. (3) Optimization Potential: Scenario simulations demonstrate that reallocating cropland from steep to flatter terrains globally can substantially improve NUE and mitigate environmental N losses. However, regional-scale crop structure adjustments offer a more cost-effective and feasible pathway. This study uncovers the structural influence of slope on global N cycling and provides actionable scientific support for achieving sustainable agricultural transitions.

**ABSTRACT**

The application of biochar to improve soil fertility and productivity is a well-established practice; however, the impact of its C:N ratio and interaction with nitrogen (N) application rates on crop performance remains poorly understood. This study investigates N-enriched biochar (NB) with varying C:N ratios on N fractions, as well as maize and wheat growth and yield, providing novel insights into the relationships between biochar, N dynamics, and crop productivity. A pot experiment evaluated the effects of biochar type and N application rate on soil properties and crop performance. The treatments consisted of three biochar types [pristine biochar (PB), and two NB types (NB1 and NB2)], and non-biochar control (CK)combined with three N fertilizer rates: 100% (N100), 70% (N70), and 40% (N40) of the recommended dose. The results demonstrated that the NB1 and NB2 significantly enhanced soil N availability, indicated by increased $NO_3^-$-N and available N (AN) concentrations, alongside improved N use efficiency traits, regardless of the N application rate. Notably, the NB1 at N70 increased soil organic matter (SOM)by 20.5% in maize and 18.5% in wheat at maturity, respectively. Furthermore, NB1 at N70 also significantly elevated key enzymes activities N-acetyl-glucosaminidase (NAG) and leucine aminopeptidase (LAP) by 64.3% to 114.9% across growth stages and crops. The improved soil N dynamics and enzymatic activities directly enhanced crop growth and productivity. NB1 at N70 achieved the highest grain yield and harvest index (HI), with maize yields increasing by 44.5% and 42.9%, and wheat by 69.5% and 49.5%, respectively. Additionally, NB application improved photosynthetic efficiency and chlorophyll content, even under reduced N rates. These findings suggested that the applying NB1 at 70% of the recommended N rate can significantly improve soil N dynamics, enzymatic activities, and photosynthetic efficiency, ultimately promoting crop growth and yield.

# Nitrogen cycling in the soil-plant continuum in multispecies swards: insights from a miniature sward experiment

**Rifaath Hassan*, Clayton R. Butterly, Hang-Wei Hu and Helen Suter**

*School ofAgriculture Food and Ecosystem Sciences, University ofMelbourne, Melbourne, Australia*

**ABSTRACT**

Temperate grazing systems are shifting from perennial ryegrass (*Lolium perenne*; PRG) monocultures to multispecies swards to address limitations of poor persistence of PRG under drought and heat conditions. They are seen as unsustainable because of high seed costs and the need for nitrogen (N) fertilizers for yield. Similarly, in binary systems with grass and legumes, even though clover contributes additional N through biological nitrogen fixation (BNF), it often leads to a decline in clover persistence and overall sward diversity in high input systems. Research has shown that the multispecies plant's diverse functional traits may affect plant-soil nutrient utilization and water uptake. However, there is still much to learn about their role in influencing N use efficiency (NUE) and soil health within multispecies use in dairy farming. To address this, we conducted a yearlong macrocosm experiment using 6 common forage species consisting of grasses (PRG and cocksfoot); forbs (plantain and chicory) and legumes (white clover and red clover) grown in various combinations. The species effect and interactions were studied by investigating belowground N turnover in a legume-forb-grass system using a $^{15}N$ leaf labelling method. A single leaf of white clover was labelled with 98% enriched $^{15}N$ urea to trace the movement of N to its companions, PRG, cocksfoot, plantain and chicory and into the soil. Comparisons were made between individual plant pairing (i.e. clover-grass) and complex mixtures (i.e. clover-grass-plantain-chicory). We tested the hypothesis that multispecies swards improve N cycling efficiency compared to traditional PRG based systems based on their functional traits.

The finding will reveal ways to address challenges to manage more environmentally sustainable pastures while reducing reliance on N fertilizers and simultaneously improving herbage production, soil health, and pasture sustainability in the Australian dairy farming industry.

**ABSTRACT**

Agricultural soils are a major source of anthropogenic nitrous oxide ($N_2O$), but their $N_2O$ emission estimates are highly uncertain, mainly due to the complexity of nitrogen (N) processes. Most soil N models include only primary N processes such as nitrification and denitrification, which limits their ability to realistically simulate N transformations in soils and accurately estimate $N_2O$ emissions from soils. This study introduces a Microbial-Explicit Model incorporating Comprehensive Nitrogen processes (MEMCN) to evaluate and quantify the influences of various N processes on the production of $N_2O$ as well as NO and $N_2$, including nitrification, denitrification, anaerobic ammonium oxidation (ANAMMOX), dissimilatory nitrate reduction to ammonium (DNRA), mineralization, and microbial assimilation (i.e., growth) and death. The MEMCN was evaluated in laboratory experiments using agricultural soils with different levels of N additions under anaerobic and aerobic conditions, and reproduced well the dynamics of $NH_4^+$, $NO_3^-$, $NO_2^-$, NO, $N_2O$, and $N_2$. After nitrification and denitrification, ANAMMOX and assimilation were found to be most important in controlling N transformations in agricultural soils. ANAMMOX directly increased $N_2$ emissions by 139% at the beginning of the simulations (i.e., 48 h) under anaerobic conditions, while microbial assimilation indirectly reduced NO, $N_2O$, and $N_2$ emissions by 88%, 54%, and 58%, respectively, at the end of the simulations (i.e., 336 h) under aerobic conditions. Correspondingly, the biomass of ANAMMOX bacteria increased significantly at the beginning of the simulations under anaerobic conditions, while the biomass of nitrite oxidizing bacteria increased substantially under aerobic conditions. In contrast, DNRA, mineralization and microbial death had minor effect on soil N transformations, and the biomass of DNRA bacteria and heterotrophs did not change significantly during the simulations. Our study shows that it is necessary to include ANAMMOX and microbial assimilation in soil N models, while explicit simulation of microbial biomass dynamics may only be necessary if microbial biomass pools change significantly.

## ABSTRACT

Subtropical forests in South China receive high atmospheric nitrogen inputs. These inputs stimulate strong nitrous oxide ($N_2O$) production in soils and in the underlying critical zone. In karst landscapes, highly permeable subsurface pathways rapidly transfer soil nitrogen into shallow aquifers. Karst springs are now recognized as hotspots of indirect $N_2O$ emissions, while the processes that control the transport, transformation and release of soil derived $N_2O$ remain unclear. Hydrological connectivity between hillslope soils, the epikarst and springs is often ignored.

We investigated this problem along a hydrological transect at the Yaji Karst Experimental Site in Guilin, China. The transect connects forest soils, the epikarst zone and a perennial spring. Event based sampling captured conditions from dry baseflow to intense rainfall. We measured soil $N_2O$ fluxes, dissolved gases and inorganic nitrogen species, stable isotopes and microbial functional genes along the flow path. These observations describe the saturation state and isotopic evolution of $N_2O$ from soils to the spring outlet. We use this integrated dataset to reveal how hydrological regimes control soil derived $N_2O$ from production to emission. Storm driven hydrological connectivity can flush $N_2O$ that has accumulated in hillslope soils and shallow groundwater. The same events also change subsurface oxygen and substrate conditions and thus alter in situ $N_2O$ production and reduction.

The study links soil nitrogen transformations in the critical zone with indirect $N_2O$ emissions from karst springs. The results will enable refined $N_2O$ assessment in subtropical karst landscapes by linking production, transport and release, while characterizing divergent responses to different events.

*ruisheng.jiang@healthyphoton.com

**ABSTRACT**

As a significant greenhouse gas (GHG), nitrous oxide ($N_2O$) is primarily emitted through anthropogenic activities, with agriculture being the predominant source. These emissions often occur across large spatial scales. Beyond the effects of global warming, $N_2O$ is part of the reactive nitrogen (Nr) cycle, contributing to environmental problems such as water pollution, soil acidification, and biodiversity loss.

Monitoring $N_2O$ remains technically challenging due to its low atmospheric background (~330 ppb) and short-term, high-intensity emissions triggered by rainfall or fertilization. These spatiotemporal variabilities demand high-frequency, sensitive detection methods.

This work introduces an open-path $N_2O$ laser analyzer (Model: HT8500, HealthyPhoton Co., Ltd.) designed for future applications in $N_2O$ monitoring and EC flux measurements. The HT8500 utilizes an quantum cascade laser (QCL) to probe the mid-infrared transition of $N_2O$ at 4.54 μm. The specific absorption peak has the advantage that the density and spectroscopic effects compensate for each other, resulting in low temperature-related corrections in EC flux measurements. Laboratory experiments revealed that the HT8500 has a noise level of 0.3 ppbv at a 10-Hz sampling rate with a typical power consumption < 25 Watts.

A long-term field experiment based on the HT8500 over a bare agricultural field in Shandong, China was conducted to test “zero-flux” measurements and computations under different meteorological conditions. The field experiment demonstrated a detection limit of approximately 26.549 ug N $m^{-2} \cdot h^{-1}$, indicating that the low flux detection limit of HT8500 is similar to the commercial available chamber-based $N_2O$ flux measurement scenarios.

In the experiments conducted in Northeast China, the fertilization period was concluded, and the crops were basically mature. As temperatures decrease, the diurnal variation in $N_2O$ fluxes dropped significantly, indicating the influence of temperature on eddies when emission sources remain stable.

**ABSTRACT**

The widespread application of synthetic nitrogen (N) fertilizers, pivotal for boosting global food production, has come at a significant environmental cost. This is particularly true in China, where intensive agriculture has led to substantial emissions of reactive nitrogen (Nr), causing severe air and water pollution. Achieving food security while minimizing environmental risks remains a critical challenge. This study aims to quantify the historical trajectory of N flows in China and identify a sustainable pathway that reconciles these dual objectives. We constructed a long-term national N budget for the period 1961–2018 to analyze changes in N inputs, crop uptake, and environmental losses. Our findings reveal a growing disparity between actual N inputs and the levels required for both food production and environmental safety. The N inputs (including N fertilizer, manure, deposition and biological N fixation) necessary to meet China's food demand were 14, 21, 27, and 29 Tg N $yr^{-1}$ in 1961, 1980, 2000, and 2018, respectively. However, actual inputs surged to 4, 25, 39, and 48 Tg N $yr^{-1}$ for the same years, indicating significant over-application since 1980. Furthermore, since 2000, the actual inputs have consistently exceeded the critical environmental thresholds—35 Tg N $yr^{-1}$ to control ammonia emissions and protect air quality and biodiversity, and 28 Tg N $yr^{-1}$ to mitigate nitrate leaching and safeguard groundwater—thereby escalating environmental and health risks. We demonstrate that reducing N input from the current 48 Tg N $yr^{-1}$ to approximately 31 Tg N $yr^{-1}$ is achievable without compromising food security. This reduction can be realized through integrated strategies, including enhanced manure recycling, balanced fertilization, and improved soil-crop system management, which align with the principles of integrated nutrient management (INM). Such a transition would yield direct and indirect benefits estimated at EUR€30.4 (28.5–35.8) billion, substantially improving air and water quality, protecting ecosystems and human health, and advancing agricultural sustainability. This analysis provides a feasible 'win-win' roadmap for China's agricultural policy, emphasizing that the targets for required and critical N inputs are dynamic and can be optimized further through continued innovation in N management.

**Key words**: Historic N budget; Critical N inputs; Required N inputs; Soil-crop system management

# Cultivating Resilient Crops: Nitrogen Management for Climate and SDG Benefits

**J.K. Ladha**

Department of Plant Sciences, University of California, Davis, U.S.A.

**ABSTRACT**

Nitrogen (N) is a crucial element for supporting life on Earth. It is involved in a vital biological process, namely nitrogen fixation. While nitrogen plays a significant role in food production and is essential for sustaining ecosystems, it also contributes to climate change by releasing reactive N. Nitrogen indirectly impacts climate change through the release of combined forms of N notably nitrous oxide, and its effects on ecosystems. Therefore, it is imperative to manage N emissions and adopt sustainable practices to mitigate climate change and achieve global climate goals.

Increasing N-use efficiency in agriculture has significant potential to mitigate climate change and contribute to resilient crop production. The quest for appropriate N-management needs accounting for the N-surplus in a production system and evolving strategies for increasing nitrogen use efficiency. Much effort has been made to this effect with varying success. Cutting-edge technological options are although available on the horizon, the success lies in improved awareness among the policymakers, stakeholders, and farmers, and better research to quantify the linkage between N-management and the SDGs, collectively.

This presentation will analyze the (1) different sources of N inputs and outputs in global cereal production, (2) global trends of synthetic fertilizer N recovery efficiency and losses, (3) effect of long-term addition of synthetic N on soil N storage, and (4) proposes various strategies available to improve the use efficiency of N in different regions.

**ABSTRACT**

Nitrogen plays a critical role in Earth's biogeochemical cycles, acting both as an essential nutrient for life and an environmental pollutant. Managing nitrogen use within safe boundaries is crucial for achieving the Sustainable Development Goals, particularly under the pressures of a growing global population. Here we quantified the temporal dynamics in safe boundary for nitrogen input to the human-nature system in view of surface water quality in China, driven by changes in management practices and runoff over the period of 1980 to 2020. Insufficient nitrogen management in the human-nature system led to a reduction in the safe nitrogen boundary from 27 Tg N $yr^{-1}$ in 1980 to 17 Tg N $yr^{-1}$ in 2006. Subsequently, improvements in agricultural nitrogen use efficiency and urban waste management contributed to an expansion of this boundary, which reached 34 Tg N $yr^{-1}$ by 2020. Further integration of nitrogen management strategies spanning agriculture, urban waste, and human dietary patterns is needed to maintain nitrogen use within the established safe boundary by 2050, generating societal benefits of US$335 billion for ecosystems, human health, climate, and food supply, with associated implementation costs of US$106 billion. These findings demonstrate that improved nitrogen management practices can dynamically expand the safe operating space for higher nitrogen utilization to support human well-being while keeping nitrogen pollution within safe environmental limits.

**ABSTRACT**

Achieving the Sustainable Development Goals (SDGs) by 2030 is becoming difficult as global progress lags. Nitrogen is key to food security and environmental sustainability, making its management crucial for advancing multiple goals within the timeline. Here, we introduce an SDG-driven framework to evaluate nitrogen management under sustainable shared socioeconomic pathways. We show that meeting balanced and achievable targets, defined as an average nitrogen-related SDG index score above 75 with individual target scores exceeding 60, requires reducing global nitrogen emissions by 50 million tonnes (Tg) by 2030, 32% of 2020 levels, entailing decreases of 30 Tg in the atmosphere and 20 Tg in aquatic ecosystems. Existing technological strategies can deliver only half of the required mitigation, even with investments of $176 billion that yield economic benefits of $291 billion. This highlights that technologies alone are insufficient, and meaningful progress toward the SDGs depends on integrating mitigation techniques with broader socioeconomic transitions.

## ABSTRACT

The elimination of nitrate constitutes a fundamental prerequisite for the remediation of secondary salinization in protected agricultural soils. Microbial assimilation-driven nitrate immobilization serves as an efficient pathway for removing excess soil nitrate, a process modulated by carbon-based amendments. Nevertheless, the key microbial taxa responsible for active nitrate assimilation and their specific responses to diverse carbon source additions remain inadequately characterized. To address this knowledge gap, a $^{15}N$-labeled nitrate tracing experiment was conducted on secondary salinized soil supplemented with eight distinct carbon sources (no-carbon control, glucose, xylan, cellulose, wheat straw, corncob, wood flour, and cow dung). The results demonstrated that glucose and xylan amendments induced the most rapid and substantial elevation in the gross nitrate immobilization rate—exhibiting 162.29- and 175.29-fold increases relative to the control within 7 days. This was followed by cellulose (26.84-fold) and corncob (18.68-fold) amendments. Parallel trends were observed in nitrate depletion dynamics, with significantly reduced residual $NO_3^-$-N concentrations detected in soils amended with glucose or xylan. Concomitantly, these two carbon sources also led to heightened nitrate loss and nitrous oxide ($N_2O$) emissions. Stable isotope probing targeting $^{15}N$-labeled DNA uncovered distinct nitrate-assimilating microbial communities associated with high-immobilization carbon sources. Specifically, unclassified Halomonas and Photobacterium taxa dominated the microbial assemblages in glucose- and xylan-amended soils, while unclassified Cellvibrio and Streptomyces emerged as the predominant groups in cellulose- and corncob-amended soils, respectively. Path analysis revealed that the primary determinant influencing nitrate immobilization rates was the community-level ribosomal RNA operon copy number of nitrate-assimilating bacteria. This factor exerted a more pronounced effect than other ecological attributes, including microbial diversity indices, community composition, and the abundance of nitrate assimilation-related genes. Indices reflecting carbon source availability—such as initial dissolved organic carbon content and microbial carbon source utilization (assessed via $CO_2$ efflux)—indirectly enhanced nitrate immobilization rates by promoting ribosomal RNA operon copy number and the abundance of assimilation genes. Collectively, this study identifies key nitrate-assimilating bacterial taxa and highlights the community-level rrn copy number as a critical functional trait governing microbial nitrate immobilization processes in secondary salinized soils.

# Effects of film mulching and straw retention on soil labile nitrogen pool, enzymes and ammonia volatilization in the root zone of winter wheat

**Huitong Li[1]*, Shanshan Wang[1], and Wentao Dong[1]**

[1] *College of Life Sciences, Yan'an University, Yan'an, China*

**ABSTRACT**

Film mulching and straw returning are common conservation tillage measures in arid regions. A long-term experiment was conducted to investigate the effects soil labile nitrogen pools and soil enzyme activities have on ammonia volatilization in the root zone of winter wheat under film mulching and straw retention. The experiment was arranged in Cao Xinzhuang experimental Farm of Northwest A&F University in 2017. A split-zone experimental design was used in this experiment. The main zones were conventional cultivation, straw return, and film mulching, while the secondary zones were no nitrogen application, conventional nitrogen application, and 20% reduction of conventional nitrogen application . 0~20 cm of wheat root zone soil was collected 42, 166, 194, and 217 days after sowing of winter wheat in the fifth season and inter-root soil of wheat was collected 42 days after sowing to determine soil nitrate-ammonium nitrogen, microbial biomass nitrogen, soil nitrate reductase, hydroxylamine reductase, and urease activities. The ammonia volatilization from agricultural soils was also collected during the wheat season in order to analyze the response of ammonia volatilization to the cultivation pattern, soil labile N pools, and soil enzymes. The results found nitrogen application significantly increased the content of soil unstable nitrogen pool, soil enzyme activity and ammonia volatilization. Total season ammonia volatilization accumulation in wheat to be significantly lower ($P$<0.05) in the film mulching treatments (6.41~7.38 kg·hm$^{-2}$) than in the straw return (8.37~9.45 kg·hm$^{-2}$) and conventional tillage treatments (8.81~11.06 kg·hm$^{-2}$) with identical fertilization levels. The microbial biomass N content was found to be significantly higher ($P$<0.05) in the straw return treatment compared to the conventional tillage and film mulching treatments. Soil ammonia volatilization was found to have a significant positive correlation with soil ammonium nitrogen, microbial biomass nitrogen, and urease activity under straw return treatment ($P$<0.05). It also had a significant positive correlation with soil ammonium nitrogen, microbial biomass nitrogen, hydroxylamine reductase, and urease activity under mulch treatment ($P$<0.01). Under 20% nitrogen reduction treatment, film mulching and straw returning can reduce ammonia volatilization, increase soil unstable nitrogen pool content and soil enzyme activity. This study can provide theoretical support for subsequently reducing ammonia volatilization losses and improving the utilization of N fertilizer.

## ABSTRACT

Nitrate ($NO_3^-$) leaching is one of the major pathways of nitrogen loss from forest ecosystems and can degrade downstream water quality under elevated atmospheric nitrogen deposition. Soil $NO_3^-$ reflects a mixture derived from atmospheric $NO_3^-$ deposition and biologically nitrification, yet mechanisms governing which fractions of $NO_3^-$ are preferentially leached from forest soils remain unresolved. Conventional interpretations treat soil $NO_3^-$ as a homogeneously mixed pool and therefore assume that leached $NO_3^-$ inherits the source composition of bulk soils. This assumption is difficult to reconcile with hydrological evidence that preferential flow bypasses biogeochemically active microsites, decoupling transport from processing and potentially exporting a hydrologically accessible fraction of soil $NO_3^-$. Here, we develop a framework to quantify selective $NO_3^-$ leaching from forest soils using oxygen isotope anomaly ($\Delta^{17}O$), and partition soil $NO_3^-$ into two hydrologically distinct components: i) recycled $NO_3^-$ (r-$NO_3^-$) that has undergone microbial turnover and is retained in processing microsites, and ii) mobile $NO_3^-$ (m-$NO_3^-$) that is preferentially connected to rapid flow paths. Within this framework, $\Delta^{17}O$ not only enables direct source apportionment of $NO_3^-$ in both soils and streams but also acts as an integrative indicator of hydrological accessibility to leached $NO_3^-$. Using a global compilation of published $\Delta^{17}O$ data together with a forest investigation in a region under high atmospheric nitrogen deposition, we quantified the proportional contributions of m-$NO_3^-$ and r-$NO_3^-$ to stream exported $NO_3^-$, providing a leaching selectivity metric among forests. We further examined how leaching selectivity varies with key environmental controls, including atmospheric N deposition, precipitation regime, and soil properties. This work can help identify the conditions under which forests are more prone to $NO_3^-$ losses and increased downstream nitrogen pollution, and they support a more robust interpretation of environmental controls on nitrogen export.

## ABSTRACT

Atmospheric nitrous oxide ($N_2O$) concentrations have increased since the pre-industrial period. Climate change is driving more frequent and intense droughts across multiple seasons in dryland ecosystems worldwide, and anthropogenic activities has been elevating nitrogen (N) deposition. Grasslands potentially contribute 25% of natural soil $N_2O$ emissions globally. While the individual effects of drought and N deposition on grassland $N_2O$ emissions are relatively well-studied, the interactive effects of N deposition and drought period on $N_2O$ emissions remain poorly understood. Here, we conducted a two-year factorial experiment to elucidate whether and how N deposition modifies the effects of drought period on grassland $N_2O$ emissions. Drought treatments were imposed in early (E-Drought), late (L-Drought), and continuous (EL-Drought) throughout the growing season, each with and without N deposition, over two growing seasons. We found that drought impacts on soil $N_2O$ emissions in semi-arid grasslands strongly depended on the period of drought and N scenario. Without N deposition, E-Drought and EL-Drought increased emissions by 26% and 13% (effect sizes: +0.23 and +0.15), respectively. These effects were amplified by re-drought in the following year (effect sizes: +0.44 and +0.94). This is primarily due to reduced plant competition for soil NH4+, leading to higher NH4+ availability for ammonia-oxidizing archaea (AOA), subsequently promoting nitrification and $N_2O$ production. With N deposition, E-Drought and EL-Drought also increased $N_2O$, but with smaller effect sizes (+0.08 and +0.09). This dampened responses are mainly because the N deposition alleviated plant drought stress by improving plant physiological conditions, which enhanced plant N uptake and thereby reduced N availability for AOA in this N limited grassland. L-Drought reduced $N_2O$, with effect sizes increasing from -0.06 for the first drought to -0.34 for re-drought. Similar trends for L-Drought were also found under N scenario (Fig. 1). Our findings suggest that drought increases $N_2O$ emissions when occurring before peak plant biomass period. However, under elevated N deposition scenario in the future, drought effects would be masked. Thus, the impact of drought on $N_2O$ emissions in this grassland ecosystem may be less severe than predicted under scenarios of increasing N deposition, highlighting the importance of considering climate changes.

Fig.1 The conceptual framework of drought period effects on $N_2O$ emissions under N0 and N5 scenarios。

**ABSTRACT**

Free-living biological nitrogen ($N_2$) fixation is increasingly recognized as an important, yet poorly constrained, N input in flooded rice paddy soils. Here we synthesize results from a continental-scale survey across China and a mechanistic field experiment to elucidate the magnitude, controls, and molecular mechanisms sustaining free-living $N_2$ fixation in paddy ecosystems. Using $^{15}N_2$ isotope tracing, metagenomics, metatranscriptomics, and ultrahigh-resolution FT-ICR MS, we link large-scale environmental gradients with phenological dependent dissolved organic matter (DOM) transformations and methane ($CH_4$) cycling.

Our results showed across 50 paddy soils spanning 4000 km in China, potential free-living $N_2$ fixation rates averaged 24 nmol N $g^{-1}$ $h^{-1}$ and were approximately an order of magnitude higher than dissimilatory nitrate reduction to ammonium, comparable to or exceeding combined $N_2$ losses from denitrification and anammox. Longitude and soil organic carbon were the dominant abiotic predictors of fixation rates, whereas ammonium exerted no detectable inhibition. Metagenomic analyses revealed that heterotrophic diazotrophs commonly co-encoded genes for organic carbon oxidation and nitrate respiration, supporting an energy-coupled mechanism sustaining $N_2$ fixation under anaerobic conditions.

Field experiments further demonstrated strong phenological regulation of $N_2$ fixation, with rates peaking at the seedling stage and declining toward harvest. Transcriptional regulation, particularly *nifA* expression, rather than gene abundance, best explained temporal variability in $N_2$ fixation. FT-ICR MS revealed that $N_2$ fixation and *nifA* transcription were positively associated with specific DOM traits, especially tannin-like and carbohydrate-like compounds, higher O/C ratios, and elevated nominal oxidation state of carbon. Phenological dependent DOM transformations, including demethylation and decarboxylation of tannin-like molecules, appeared to create transient thermodynamically favorable niches for diazotrophs. Notably, $N_2$ fixation was tightly coupled with methane cycling. Methane emissions and methanotroph gene expression (*pmoA/B/C*) covaried with $N_2$ fixation, and $CH_4$ addition stimulated fixation in straw-amended soils. DOM compounds correlated simultaneously with $CH_4$ metabolism and diazotrophic activity, indicating indirect support of $N_2$ fixation via DOM-driven methanogenesis and methanotrophy.

In summary, these results identify paddy soils as hotspots of free-living $N_2$ fixation sustained by interactive controls of organic carbon availability, DOM chemodiversity, microbial transcriptional regulation, and methane metabolism. This integrated C–N–$CH_4$ framework advances mechanistic understanding of N retention in rice systems and highlights management opportunities to enhance biological N inputs while maintaining soil fertility.

**ABSTRACT**

Although nitrogen (N) is an essential nutrient for plant growth and agricultural productivity, increased N inputs lead to elevated N losses, resulting in detrimental environmental consequences. This mainly includes the emission of nitrous oxide ($N_2O$) and ammonia ($NH_3$) to the atmosphere and the leaching and runoff of nitrate (NO3-) into water bodies. These N losses give rise to a range of significant environmental issues, including climate warming, increased concentration of fine particulate matter (PM2.5) in the air, ozone depletion, water eutrophication, soil acidification and biodiversity losses[1]. Addressing these issues is crucial for mitigating climate change and promoting environmental sustainability. Inversely, To reconcile required N inputs for food production of an increasing population (also denoted as the just N and boundaries) with acceptable N losses to protect the environment, also denoted as safe N boundaries, it is crucial to enhance the nitrogen use efficiency (NUE) and thereby reduce N losses.

In this key note lecture, I first give an overview of the variation in safe N boundaries as compared to current N inputs and of the required NUE increase to reconcile food production (just N boundaries) with environmental protection (safe N boundaries) at global scale[2] and continental scale[3, 4]. I then discuss the potential to attain such an NUE increase by the adoption of sustainable nutrient, crop and soil management practices in agriculture systems[5] and thereby reduce N losses[6]. Nutrient management practices involve optimizing fertilizer types, application rates, timing and placement to align N supply with crop N demand, crop management practices include straw incorporation, cover cropping, and crop diversification and soil management practices includes Conservation tillage practices, such as reduced or zero tillage. In addition, the potential of enhanced nutrient recycling and of dietary change to close the gap between just and safe N boundaries is discussed.

**ABSTRACT**

The nitrogen (N) cycle in arid regions is highly sensitive to the degree of aridity. However, there remains considerable uncertainty regarding the distribution process between ammonium nitrogen ($NH_4^+$-N) and nitrate nitrogen ($NO_3^-$-N) in natural ecosystems. This knowledge gap limits our ability to predict the functional changes of ecosystems under intensified aridity. This study, based on large-scale field observation data from 120 plots spanning 2,000 kilometers east-west and 1,600 kilometers north-south in the typical arid region of Xinjiang, China, covering the complete desert-grassland-forest ecosystem, utilized linear mixed-effects models and structural equation models to analyze the spatial patterns, environmental thresholds, and driving pathways of nitrogen forms. The results showed that across the entire regional scale, soil inorganic nitrogen was dominated by $NH_4^+$-N, but gradually shifted to $NO_3^-$-N dominance during the transition from forest/grassland to desert. Along the aridity index gradient (AI = 0.03 to 0.5), both $NH_4^+$-N and $NO_3^-$-N exhibited significant nonlinear transitions, and these transitions had critical thresholds at soil water content (SWC = 0.5%) and soil pH = 8.55. Random forest and structural equation models indicated that $NH_4^+$-N was mainly regulated by soil chemical environment (pH) and vegetation productivity, while $NO_3^-$-N was dominated by water-salt conditions (SWC, EC) and climatic factors. Overall, the distribution of soil nitrogen forms in arid regions is driven by the "water-pH" synergy, which is the core mechanism for the process transformation of nitrogen cycling in arid ecosystems along the dry-wet gradient. This study quantified the environmental thresholds of this phase transition, not only filling the knowledge gap in the transformation mechanism of nitrogen forms in arid regions but also providing precise scientific basis for formulating ecosystem nutrient management and vegetation restoration strategies in response to climate change.

## ABSTRACT

Regenerative grazing systems, such as mob grazing, are characterized by short-duration, high-density stocking followed by extended rest periods, in contrast to conventional continuous grazing, where animals graze the same area for prolonged periods. Such system promises improvements in animal productivity, carbon sequestration and soil health, but their impact on emissions of the greenhouse gas nitrous oxide ($N_2O$) is unknown, raising concerns about whether such systems exacerbate or mitigate nitrogen losses from grazed grassland ecosystems, which are major agricultural sources of $N_2O$. This study investigated how contrasting grazing histories influence the temporal dynamics of urine-induced $N_2O$ emissions by using a combined 13C and 15N approach. We hypothesized that (1) grazing history would influence both the magnitude and timing of urine-induced $N_2O$ emission peaks, and (2) these temporal patterns may be further shaped by carbon availability, including contributions from plant-derived versus soil background carbon.

The experiment was conducted under fully controlled conditions as a greenhouse incubation using soil samples from two pastures with the same soil type but contrasting long-term grazing histories (continuous grazing and mob grazing). Ryegrass was grown in the soils to simulate plant–soil interactions. 15N-labelled synthetic urine (200 and 400 kg N ha-1 equivalent) was applied to quantify the contribution of urine-derived nitrogen to $N_2O$ emissions during both grazing and rest periods. Gas sampling was carried out on days 1, 2, 3, 6, 8, 10, 14, 21, 28, and 49 following the urine application, while destructive soil sampling was conducted on days 1, 3, 7, 14, 28, and 49 to monitor changes in soil inorganic nitrogen and other properties. The results revealed that soils with a continuous grazing history consistently exhibited early $N_2O$ and $^{15}N$-$N_2O$ peak fluxes and raised $N_2O/(N_2+N_2O)$ ratio2–3 days after urine application, whereas soils from the mob grazing management showed delayed peaks and ratio at approximately 7–8 days. These contrasting peak timings were reproducible and independent of N application or seasonal grazing status, suggesting that grazing history exerts an influence on the timing of peak $N_2O$ production and raises the possibility that factors beyond nitrogen transformations alone—such as carbon availability—may contribute to the observed emission dynamics.

To further investigate mechanisms underlying these consistent temporal differences in $N_2O$ emission peaks, a dual stable isotope experiment was conducted to explore whether peak $N_2O$ production was primarily associated with plant-derived C inputs or with SOM-C, since denitrification is a heterotrophic process, the supply of electron donors from carbon sources can directly affect $N_2O$ production and reduction. In this experiment, plants were pulse-labelled with $^{13}C$–$CO_2$, while the nitrogen fate was simultaneously traced using $^{15}N$-labelled synthetic urine. Results show that the C source related to $N_2O$ production and reduction varied with both grazing management and with time after the addition of $^{15}N$-urine.

Current results demonstrate that the timing of peak $N_2O$ fluxes varies depending on the grazing management. This is related to the source of C respired, suggesting different C utilisation during denitrification. These findings enhance our understanding of the regulation of $N_2O$ emissions from regenerative grazed systems, which can help inform their management for greenhouse gas mitigation and C sequestration.

# Role of particulate organic matter accrual in affecting $^{15}N$ fate to grain corn comparing long-term vs. first-time vs. no cover cropping

*E-mail: ypeng09@uoguelph.ca*

**ABSTRACT**

Long-term cover cropping increases soil organic matter (SOM); however, the effect of cover crop duration on nitrogen (N) uptake by subsequent crops remains unclear. We hypothesized greater N uptake by grain corn (*Zea mays* L.) with long-term cover cropping, due to both cover crop decomposition and increased mineralization of particulate and mineral-associated organic matter (POM and MAOM). To test this hypothesis, we introduced a novel experiment by growing cover crops for the first time on a sub-set of no cover crop plots to facilitate comparisons among long-term, first-time, and no cover cropping treatments. We applied $^{15}N$ (12 kg N $ha^{-1}$) in microplots after cover crop emergence and traced it into cover crops, corn, and soil (0–90 cm depth). During cover crop season (late fall and following spring), long-term and first-time cover cropping had about double the total $^{15}N$ recovery in cover crop biomass and soil, compared to no cover cropping where only 30% of $^{15}N$ applied was accounted for, indicating both long-term and first-time cover cropping are equally effective at reducing potential overwinter N losses. At corn harvest, long-term and first-time cover cropping had approximately ten times greater $^{15}N$ recovered in soil than in corn biomass, indicating cover crops likely contributed more to soil organic N retention than soil inorganic N supply to subsequent crops. Moreover, piecewise structural equation modeling demonstrated that POM, but not MAOM, was the main soil mineral N source for grain corn in the sandy loam site. Overall, our findings demonstrated that SOM accrual with long-term cover cropping boosted mineral N supply to the subsequent crop than either first-time or no cover cropping, as well as increased grain yield relative to no cover cropping, clearly underscoring that building-up SOM is critical for enhancing N availability in agroecosystems.

# Integrating Soil Remediation and Land Valuation: Evidence from the UK and China under an Environmental–Economic Framework

**Wang Feng**

*Soil Scientist and Real Estate Valuation Expert, RICS Member, Beijing, China*

wangfeng 8020@163.com

**ABSTRACT**

Soil contamination presents a persistent challenge to sustainable land use and urban regeneration. While remediation technologies have made it technically feasible to restore contaminated sites, their economic implications for land valuation remain insufficiently understood. This paper develops an integrated environmental–economic framework to examine how remediation cost, contamination risk, and location jointly influence land value. Drawing on comparative evidence from the United Kingdom and China, the study demonstrates that perceived contamination risk exerts a stronger negative impact than remediation cost, while location significantly moderates value recovery. The findings also highlight the decisive role of institutional frameworks in shaping market outcomes. By bridging soil remediation and land valuation, this research contributes to the development of a green valuation approach that incorporates environmental considerations into property appraisal.

Highlights

- Soil contamination significantly reduces land value.
- Contamination risk has a stronger impact than remediation cost.
- Location moderates the economic effects of contamination.
- Institutional frameworks shape land value recovery patterns.
- A green valuation framework is proposed for sustainable land use.

# Unpacking Cause and Effect in Soil Health Science

**Yang Lin**[1*]

[1] *Department of Soil, Water, and Ecosystem Sciences, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, Florida, USA*

*ylin2@ufl.edu

**ABSTRACT**

Soil health has become a cornerstone concept for advancing sustainable agricultural management. Great progress has been made in the last decade in understanding how environmental drivers and management practices influence soil health and how soil health indicators affect key ecosystem services such as crop yield and soil water storage. These are fundamentally causal questions that seek to identify true cause–effect relationships rather than simple correlations. In this presentation, I argue that our community should more explicitly embrace causal inference. I will explain why causality is central to both the definition and assessment of soil health, and how causal diagrams can clarify the relationships among soil health, its drivers, and ecosystem services. Using case studies, I will show how a causal inference framework could be applied to account for confounding factors and reveal the true effects of cropping systems on soil health. I will also discuss how this framework could reveal the causality between soil health and crop yield. These examples highlight the potential of causal inference to enhance both theoretical clarity and empirical rigor in soil health science.

*lino.sciurba@unipa.it

**ABSTRACT**

Over the last decade, large-scale surveys have significantly advanced our knowledge on soil microbial biodiversity and elucidated the main environmental drivers shaping its global distribution. Continent-scale studies (e.g., Maestre et al., 2015; Labouyrie et al., 2023; Christel et al., 2024) consistently identified soil pH, organic carbon content, and land use intensity as key determinants of microbial diversity and functionality. Despite their ecological and agricultural importance, Mediterranean areas remain markedly underrepresented in these surveys. Sicily, characterized by pronounced environmental heterogeneity and diverse agricultural practices, lacks comprehensive datasets that integrate microbial community profiles with soil physicochemical properties and degradation dynamics. This data gap hinders the development of reliable microbial indicators for soil health in a region highly vulnerable to climatic variability and anthropogenic pressures.

To fill in this gap, the SOILS4MED project employed a factorial experimental design (2×2×2) encompassing soil type (Chromic Luvisols *vs.* Vertisols), land use (arable *vs.* tree crops), and degradation status (degrading *vs.* stable/improving). A total of 200 topsoil samples (0-20 cm) are being analyzed using amplicon sequencing targeting bacterial 16S rRNA gene and fungal ITS region, alongside of physicochemical parameters, pH, SOC, C/N ratio, texture, bulk density and $CaCO_3$. The study investigates how soil characteristics, land use, and degradation influence the structure, composition, and potential functions of microbial communities, and microbial diversity. By correlating taxa with environmental variables and applying functional and network-based analyses, the research aims to elucidate the ecological relationships underpinning soil ecosystem functions. This integrated approach seeks to identify microbial indicators responsive to ecological gradients typical of Mediterranean soils. The organization and connectivity of microbial communities may serve as early-warning indicators of soil health, while network-based measures can reveal community complexity and resilience. Ultimately, the findings aim to strengthen soil health monitoring frameworks and promote sustainable soil management strategies across Mediterranean landscapes.

**ABSTRACT**

The Mediterranean Region is a climate and food-security hotspot where soils face converging pressures: land degradation, low organic carbon, water scarcity and rapidly intensifying droughts. Yet, despite decades of field campaigns and laboratory analyses, soil hydraulic information in the region remains scarce because most legacy measurements were never translated into operational water retention functions. Pedotransfer functions (PTFs) offer a cost-effective way to unlock this "sleeping" legacy, but widely used PTFs are largely trained on northern European data and perform poorly in the environmentally heterogeneous Mediterranean basin.

We addressed this gap by compiling a truly Mediterranean hydro-pedological dataset, integrating thousands of records from legacy sources in Italy, Greece, Jordan, Spain, Tunisia, Morocco, Egypt, Lebanon and Syria. Two complementary datasets were built: HYDRO-GRAV (n = 6,468; gravimetric water content) and HYDRO-VOL (n = 3,943; volumetric water content). On this basis, we developed PTF4MED, a family of pseudo-continuous hydro-PTFs that predict gravimetric or volumetric water content at any user-defined matric potential using only clay, sand, organic carbon and matric potential as inputs. Multiple Linear Regression and Multilayer Perceptron (MLP) models were trained with 100-iteration stratified Monte Carlo cross-validation; MLPs consistently outperformed linear models, with HYDRO-GRAV MLP achieving RMSE = 0.060 ± 0.002 and $R^2$ = 0.780 ± 0.016. When benchmarked against 12 widely used international PTFs, PTF4MED delivered higher accuracy at most investigated matric potentials, particularly around field capacity (−33 kPa) and permanent wilting point (−1,500 kPa).

PTF4MED is, to our knowledge, the first pseudo-continuous hydro-PTF framework specifically designed for the Mediterranean Region. Developed within the SOILS4MED initiative, it illustrates how harmonized legacy data can be converted into regional-specific inputs for modelling, irrigation planning and drought-risk assessment, strengthening the capacity of Mediterranean countries to manage soil and water in a rapidly changing climate.

**ABSTRACT**

Soil indicators are widely used while assessing aspects of soil such as health, quality, and function. Indicators help land managers, agricultural industries, and policy makers focus on how soils support particular goals, such as producing food, or filtering water. There are many indicators, gained in varied ways from simple observation to complex technical procedures. Crucially, indicators must be matched to their intended purpose and contextualized. The value of indicators depends on the unique attributes of farming systems, industries, and soils. Consequently, soil indicators are designed for different actors—farmers, agronomists, consultants, industry representatives, and researchers across diverse enterprises, production systems, and agroecological settings.

Some core indicators may be universally valued; however, a common set of indicators does not meet the needs of all actors. Financial institutions, while aware of soil's importance to farm performance, note that soil-health metrics require clearer, more familiar terminology for lending and investment decisions. This highlights a key divide: the metrics relevant to growers and those needed by investors can differ so much that they require translation to ensure alignment.

A further challenge lies in reporting soil investments that reward "best practice" rather than bio-physical outcomes. It remains unclear whether incentives should focus on practices, outcomes, or both—understood as "lead" and "lag" indicators. Communicating the distinction between these approaches and linking them within a unified framework will help bridge current gaps in soil indicator expectations across sectors.

We propose a Strategic Performance of Soil Management (SPSM) Reporting System to integrate these varied needs. Its purpose is to enable consistent reporting that is useful for land management decisions while also supporting investors such as financial institutions. This framework can help recognize and reward good soil management through incentives, including favorable lending terms.

**ABSTRACT**

Since 2020, Brazil has adopted soil bioanalysis (SoilBio) technology, an initiative that integrates two key soil enzymes—arylsulfatase (ARYL) and β-glucosidase (GLU)—into routine commercial soil analysis (Mendes et al, 2024). This approach has allowed SH monitoring at the farm scale by combining chemical and biological indicators within a Soil Quality Index (SQI) framework, which includes three soil functions: (F1) nutrient cycling, based on ARYL and GLU activities; (F2) nutrient storage, based on soil organic carbon (SOC) and potential cation exchange capacity (CEC); and (F3) nutrient supply, based on $Ca^{2+}$ , $Mg^{2+}$, $K^{+}$, P, pH, $H+Al^{3+}$, and $Al^{3+}$ .

SoilBio technology has been made accessible for farmers through the training of commercial soil testing laboratories by the Brazilian Agricultural Research Corporation (Embrapa) SoilBio Network. The reliability of the results across the country is ensured by the nationwide standardization of methods and protocols and appropriate proficiency testing.

In November 2025, at COP 30, Brazil launched the "Soil Health BR Platform: Resilient Soils and Sustainable Agricultural Systems", which already includes more than 56,000 samples collected across 1,450 municipalities. Built in partnership with 33 commercial laboratories integrated through a digital system, the platform consolidates dispersed laboratory data into a dynamic national database. This structure supports climate-smart agriculture, guides evidence-based public policy, and fosters the development of low-carbon food systems.

The resulting database combines enzymatic and chemical analyses with information on location (municipality level), crop type, and soil texture. Processing this dataset for large-scale SH assessments provides an unprecedented overview of soil health conditions across Brazilian regions, helping identify trends, patterns, and emerging challenges. In doing so, it contributes directly to improving the sustainable management of agricultural landscapes.

By making this national soil health database publicly available and continuously updated, Brazil takes an important step toward transparency and data-driven action.

The initiative targets policymakers, government representatives, the private sector, NGOs, international organizations, farmers, and researchers, as well as all those interested in sustainable agriculture, climate, and soil. Monitoring soil health stands as a strategic tool to ensure sustainable productivity and climate resilience, and the public release of the platform represents a landmark contribution to global agendas on climate, soil, and food security.

## ABSTRACT

Wengyuan County is the most important fruit sugarcane producing area in northern Guangdong. However, excessive and indiscriminate fertilization has caused soil health problem in some fields. The typical sampling points were identified by field survey in seven producing areas in Wengyuan, and the key soil properties such as bulk density, moisture content, pH, organic matter (OM), available nutrients and exchangeable ions were determined in this study. ArcGIS spatial interpolation was used to establish a soil health evaluation system and reveal county-wide sugarcane field soil quality status and spatial variability. The results showed that the sugarcane field soil is mainly sandy soil with loose texture. The average soil pH is 4.77, and the average contents of available N (AN), available P (AP) and available K (AK) are 184.45, 249.86 and 237.69 mg $kg^{-1}$, respectively, which are in an excessive state. The contents of OM and exchangeable Mg are 18.78 g $kg^{-1}$ and 0.54 cmol $kg^{-1}$, respectively, which are in a deficient state. The overall health level is below average, with serious acidification and unbalanced nutrients proportion. Spatially, the bulk density and AP were decreased from northwest to southeast, the moisture content, OM, exchangeable Ca and Mg content increase gradually from west to east, pH increases from the middle to the east and west, while AN and AK decrease from northeast to all around in Wengyuan. In view of these problems, we put forward comprehensive improvement strategy, including soil-test-based scientific fertilization, crop rotation, soil acidification adjustment and nutrient supplementation, in order to achieve the balance of soil nutrients and the sustainable development of fruit sugarcane industry in Wengyuan.

**Key words**: Fruit sugarcane; Soil health; Spatial variability; Improvement strategy

**ABSTRACT**

**ABSTRACT:** The sustainability of cultivated land systems relies on the synergy between current production functions and long-term ecological resilience. To clarify this relationship in the undulating plain area of northern Liaoning, this study constructs an evaluation index system that respectively characterizes the current quality conditions and long-term sustainable health potential of cultivated land. Through a comparative analysis of Network Analysis (NA) and Principal Component Analysis (PCA) for index weighting, coupled with bivariate spatial autocorrelation, this study reveals the complex spatial dependence mechanisms between cultivated land soil health and cultivated land soil quality. The results indicate: (1) NA significantly outperforms PCA in weight stability and evaluation accuracy, proving more suitable for analyzing the complex internal relationships within cultivated land systems; (2) Soil health is predominantly at fragile and sub-health levels (combined 53.99%), while soil quality is predominantly classified as third or fourth grade; (3) Globally, a weak negative spatial correlation exists between soil quality and soil health; (4) Local analysis identifies four spatial patterns: High-High (H-H) Excellent Zone, Low-Low (L-L) Degraded Zone, Low-High (L-H) False Fertility Overdraft Zone, and High-Low (H-L) Improvement Potential Zone. This study provides a solid spatial decision-making foundation for developing a future-oriented zoning governance system for cultivated land resources by accurately identifying their spatial synergy and trade-off relationships.

**ABSTRACT**

The present work aims to evaluate the soil health status in a semi-arid area of Morocco (El Koudia station) using the Cornell Comprehensive Assessment of Soil Health (CASH), in order to assess the soil's potential to promote crop productivity and environmental sustainability. The study comprehensively examined 11 soil health indicators encompassing physical, chemical and biological soil properties, including bulk density (Bd), available water capacity (AWC), wet aggregate stability (WAS), pH, active carbon (AC), organic matter (OM), soil protein index (SPI), soil respiration (Resp), phosphorus (P), potassium (K), and minor elements (Mg, Mn, Fe, and Zn).

In the El Koudia site, identified as a chromic Luvisol, Bd is moderate at 1.41 g/cm³ indicating a still balanced soil structure that supports good root development, with significant variations in AWC (0.17 g/g) and WAS (12.3b, 9.6a, and 9.1a for 0-5 cm, 10-15 cm, and 5-10 cm layers respectively). In contrast, most chemical indicators showed few differences related to depth, except for pH, P, and Zn, which varied significantly in the topsoil. Biological indicators revealed significant variations across depths, indicating richness, particularly in the upper layers with an active microbial community. Based on the Cornell soil health assessment, the El Koudia site reveals significant limitations, notably in WAS, SPI and pH. These challenges, resulting from prolonged intensive tillage and continuous mono-cropping practices, pose potential risks to agricultural production and ecological sustainability, emphasizing the necessity of efficient soil management strategies. With an overall score of 48, the El Koudia site fall in the medium range indicating room for improvement. Through this study, the comprehensive assessment of soil health of El Koudia site provides opportunities to deepen our understanding of soil quality, pinpoint targeted management interventions, and monitor progress over time.

# The Soil Health Indicator: A Scalable, Rapid Assessment Tool Linking Soil Science to Agricultural Sustainability

**J.A. Reijneveld[1]*, O. Oenema[2] and J. Bouma[2]**

[1] *Eurofins Agro Testing Competence Centre, Wageningen, The Netherlands*
[2] *Wageningen University & Research, Wageningen, The Netherlands*
arjan.reijneveld@ftbnl.eurofins.com

**ABSTRACT**

Conventional soil testing has long focused on fertilization and yield optimization, typically relying on a limited set of chemical parameters. However, sustainable land management requires a broader understanding of soil multifunctionality and its contribution to essential ecosystem services, including food production, water purification, climate mitigation, and biodiversity support. These services are directly linked to several UN Sustainable Development Goals. Despite this relevance, comprehensive soil health testing remains underutilized due to challenges in complexity, standardization, and cost.

To address these limitations, we developed a rapid and scalable soil health assessment tool—the Soil Health Indicator (SHI)—combining Near-Infrared Spectroscopy (NIRS) with multi-nutrient 0.01 M $CaCl_2$ and ICP-MS extraction. This approach enables simultaneous evaluation of physical, chemical, and biological indicators, including bioavailable heavy metals, thereby generating a far more complete soil profile than traditional testing methods that measure only a small subset of soil properties. The SHI thus provides a high-resolution, multi-indicator dataset that is suitable for large-scale monitoring programs and practical land user-level decision-making for agriculture but also for nature, forest and urban areas. The tool demonstrated high analytical performance, with coefficients of determination ($R2 \geq 0.88$) for most key soil parameters when compared with References laboratory methods. The approach has been evaluated across more than 15 countries, including regions in Europe, China, New Zealand, and Vietnam, covering a wide range of soil types and land-use systems

The SHI can be integrated with crop-protection residue analysis and soil physical indicators related to structure and moisture regimes, forming a comprehensive dataset for Living Lab case studies. Within these Living Labs, scientists, advisors, and farmers co-design sustainability strategies. Farms that meet defined thresholds for ecosystem services—including soil health—can be designated as “Lighthouses,” serving as replicable examples for similar agroecological zones. This threshold-based approach shifts policy focus from prescriptive management rules to performance-based sustainability outcomes.

The SHI’s scalability, rapid turnaround, and broad indicator coverage make it a practical tool for widespread adoption. Its transparency and simplicity support land user engagement, while its scientific robustness ensures relevance for policy, monitoring, and research. By enabling comprehensive soil health assessment at scale, the SHI provides a pathway to operationalize soil science for sustainable agriculture and the SDGs.

**ABSTRACT**

The RMQS framework is based on standardized sampling protocols and analytical methods, ensuring spatial and temporal comparability and supporting evidence-based public policies related to sustainable land management, climate change mitigation, and environmental and human health. A second national sampling campaign is currently underway in mainland France and the French West Indies, enabling robust assessment of long-term soil health trends.

To address the diversity of environmental conditions, the metropolitan RMQS model has been adapted to Overseas Territories, particularly tropical rainforests and mangrove ecosystems. In Guadeloupe, the monitoring network includes 60 sites covering a wide range of soil types and land uses, including agricultural systems, pastures, forests, and protected natural areas. The program benefits from strong local partnerships, notably with the Guadeloupe National Park, reinforcing its scientific relevance and societal impact. An extension of the network to 40 additional sites in Martinique is planned from 2026.

Soil health assessment encompasses a broad set of indicators, including soil biodiversity, pH, water holding capacity, contaminants, and soil organic carbon. Soil samples are archived in the European Soil Sample Repository (CEES), creating a unique soil legacy resource that supports future research, methodological harmonization, and long-term environmental assessments.

By integrating harmonized monitoring, soil information systems, and long-term soil archiving across temperate and tropical environments, the RMQS program provides a transferable framework for soil health monitoring that bridges science, policy, and society, contributing to sustainable soil and landscape management at national and international scales.

**ABSTRACT**

In North America, access to soil health testing for growers through commercial soil laboratories has been limited by laboratories' ability to consistently interpret soil health measurements. In addition, growers who wish to compare soil health results over time must use the same laboratory, as measurement methods vary across laboratories. To address these challenges, the Soil Health Institute (SHI) is developing an online soil health portal that will allow growers and advisors to create accounts, enter field-level management data, select sampling locations, print sample labels, ship samples to SHI partner laboratories, and receive regionally relevant soil health interpretations. Partner laboratories will be trained to analyze SHI's suite of essential soil health indicators, (soil organic carbon concentration, 24-hour carbon mineralization potential, and aggregate stability measured through slaking image analysis), along with particle size analysis and soil pH to support interpretation of results. Following initial training, partner laboratories will participate in an annual proficiency testing program to ensure that data generated across laboratories are interoperable and comparable. Resulting data will be modeled alongside SHI's benchmarking dataset, enabling growers to assess how their soil health compares with that of regional peers in similar cropping systems and to understand the potential trajectory of soil health improvement. In addition, collected management data will be used to calculate continuous soil health management indices, allowing growers to track how changes in management practices align with soil health principles over time. The portal will also provide regionally relevant educational resources and contact information for technical assistance to support growers and advisors seeking to improve soil health. By improving access to standardized, interpretable soil health data and regionally relevant educational materials, this platform will give growers and advisors greater confidence to implement management changes and evaluate their impacts on soil health.

*cmorgan@soilhealth institute.org

**ABSTRACT**

Soil health assessment frameworks are employed worldwide to translate soil measurements into benchmarks to inform management decisions, yet there have been few efforts to evaluate how different frameworks influence interpretation at regional scales. Using a single, management-explicit dataset from the Greater Golden Horseshoe region of Ontario, Canada, we compared two soil health assessment frameworks: the Soil Health Assessment and Plan (SHAP) approach and the Soil Health Institute (SHI) regional benchmarking approach. We evaluated the sensitivity and redundancy of the indicator sets, their responsiveness to management, and the influence of sampling design and statistical inference on farmer-level outcomes.

Carbon and nitrogen indicators exhibited substantial redundancy, while aggregate stability measured by image analysis was orthogonal to carbon indicators and robust to organic amendment effects. Management sensitivity varied among indicators, with all indicators except for aggregate stability by wet sieving showing management effects after accounting for inherent soil properties. Both frameworks displayed broadly similar rank ordering of scores and proportions of References, but interpretation of results varied between frameworks, with SHAP providing relatively poorer soil health scores compared to the SHI framework.

Categorical texture grouping in SHAP produced discontinuities in scoring at texture boundaries of up to 29 points (100-point scale) and did not significantly or practically reduce the influence of inherent soil properties. The SHI framework accounted for inherent soil properties using continuous variables, which did minimize texture effects for two out of three indicators. Most importantly, for the sake of interpretations, simulations demonstrated that the distribution of management types in the parent database influenced SHAP scoring curves. Conversely, the inclusion or References soils significantly influenced References-based benchmarks in the SHI framework. These findings show that outcomes of soil health assessment depend on framework design and assumptions as well as the soil measurements themselves. Explicit consideration of pedological context, experimental design, representation of soil management, and statistical inference is essential for ensuring soil health assessment is interpretable and actionable.

# The role of SOILS4MED project in promoting soil information in the Mediterranean and a unique case study from Apulia Region in Italy.

**Pandi Zdruli and Claudio Zucca**

*CIHEAM Mediterranean Agronomic Institute of Bari, Italy (SOILS4MED partner) presenter*

*University of Sassari, Italy (SOILS4MED coordinator)*

**ABSTRACT**

SOILS4MED shares the vision that is an urgent need to enhance in the Mediterranean the availability of soil data and information (SDI) and to harmonize methods towards standardized soil information systems as enabling conditions to protect and improve soil health and support policies to achieve land degradation neutrality and accomplishment of SDGs. SOILS4MED has the following objectives: 1) engage with stakeholders in line with the Living Lab approach and raise awareness on benefits deriving from increased investment in SDI; 2) develop policy relevant integrated indicator sets and monitoring protocols; 3) validate the protocols in study areas representing major agro-ecological regions and soil types, generating the first region-wide harmonized soil health dataset; 4) demonstrate the capacity of the produced SDI, integrated by legacy soil data, to feed state-of-the-art tools to support sustainable land management and to enhance soil mapping; and 5) implement standardized country-based SIS for effective management and use of SDI. SOILS4MED builds on the relevant work done by the FAO's Global Soil Partnership and the Joint Research Centre (JRC) of the European Commission and will provide support to the compilation of the Mediterranean Soil Atlas, supported by the JRC and FAO.

Part of the activities of the project is the Salento study site in Apulia Region in Italy where the soil samples are confronted with legacy soil data collected 30 years ago. The purpose is to assess the state of soil health and quantify changes in soil chemical, physical and biological properties. The area was badly affected by the bacteria Xylella Fastidiosa that has desiccated thousands of olive trees causing a severe environmental and socio-economic crisis, hence it is essential to develop sustainable soil management strategies to recover soil health and the oliviculture sector in the region.

**Key words:** Mediterranean, soil information, soil health, Apulia Region

SOILS4MED project is part of PRIMA programme supported by the European Union.

# Nature-based Solutions for Transforming Smallholder Agriculture in Highland Areas of Northern Thailand

**Nattaporn Prakongkep*, Monrawee Meetam, Sutdacha Khunthong and Wiwat Suaysom**

*Land Development Department, 2003/61 Phahonyothin Road, Ladyao, Chatuchak, Bangkok, 10900*

*E-mail nattaporn@ldd.go.th

**ABSTRACT**

In the past, some highland areas of Thailand were continuously used for shifting cultivation, particularly maize production for animal feed, leading to severe soil degradation and deforestation. Tea Oil and Plant Oils Development Center, the Chaipattana Foundation has implemented Nature-based Solutions (NbS) based on the principle of mutual support between people and forests to restore degraded land and promote sustainable agriculture. Smallholder farmers were encouraged to shift from maize to oil tea (*Camellia* spp.), a shrub suitable for sloping land that functions as a cover crop to reduce soil erosion and improve soil and water conservation (Liang et al., 2017).

Although oil tea leaf litter accumulated on the soil surface, decomposition was limited due to low soil biological activity. Despite relatively high nutrient levels in the topsoil, plant nutrient uptake remained constrained. A Fishbone Diagram (6M) analysis suggested that soil management strategies should rely on resources accessible to farmers. Field experiments showed that applying microbial products developed by the Land Development Department improved soil health and increased oil tea yield by up to 42%.

# Application of Dredged Soil Resource Utilization in Mangrove Habitat Improvement

**Li Yaohua**[1*]

[1] *Technology R&D Center, CCCC Guangzhou Water Transport Engineering Design and Research Institute Co., Ltd., Guangzhou, China*

* Email Address of Presenting Author: 1462609403@qq.com

**ABSTRACT**

Drawing on more than 30 marine ecological protection and restoration projects, CCCC Guangzhou Water Transport Engineering Design and Research Institute Co., Ltd. has cumulatively completed over 4,600 hectares of mangrove restoration. Focusing on the key entry point of beneficial reuse of dredged material, our company has continuously carried out research on critical technologies for coastal wetland ecological restoration, successfully overcoming key technical bottlenecks such as mangrove habitat creation in deep-water tidal flats and the improvement of dredged silt into suitable planting soil. Our company has formulated technical standards such as the Technical Guidelines for Mangrove Habitat Creation Using Dredged Material, providing replicable and scalable technical pathways and engineering paradigms for the synergistic advancement of beneficial reuse of dredged material and coastal ecological restoration. This presentation will focus on the technical pathways for beneficial reuse of dredged material , engineering application outcomes, and standardization efforts, and will systematically share our institute's practical experience and research achievements in soil ecological restoration and coastal wetland protection.

# Cover Crop-Driven Anaerobic Soil Disinfestation Enhances Weed Suppression and Collard Greens Productivity

**Mahmoud Rady[1]*, Matthew Cutulle[1], and Brian Ward[1]**

[1] *Department of Plant and Environmental Sciences, Clemson University, Charleston, USA*

* mrady@clemson.edu

**ABSTRACT**

Anaerobic soil disinfestation (ASD) is a sustainable pre-plant soil management technique, utilizing labile carbon incorporated into the soil profile, while relying on a consortium of soil microorganisms to create anaerobic conditions, suppressing soilborne pathogens and weeds while enhancing crop production. Traditional ASD relies on industrial inputs like chicken manure and molasses, which increase costs and carbon footprint, but the potential of cover crop "CC" residues as alternative carbon sources has not been thoroughly investigated in collard green (*Brassica oleracea* var. *viridis*) production. This study evaluated sunnhemp (*Crotalaria juncea*) and sorghum-sudangrass (*Sorghum bicolor* × *S. sudanese*) as *in situ* carbon sources for ASD in a greenhouse experiment. A factorial randomized complete block design tested four residue treatments (sunnhemp "SH", sorghum-sudangrass "SS", their 1:1 mixture "MX", and control bare-ground "BA") with three rates of conventional carbon inputs "CMM" (0%, 50%, and 100% of chicken manure at 20,000 kg/ha and molasses at 14,000 L/ha). After collecting soil and CC residues from field plots, they were mixed with CMM, saturated, and sealed in microcosms for 6 weeks, before transplanting collards to grow for 4 weeks in greenhouse conditions. Results showed that SH improved collard growth and yield while suppressing weeds without CMM. SS reduced soil pH from 6.0 to 5.3, significantly decreasing yellow nutsedge but also impairing collard vigor, likely due to allelopathy. SH and SS reduced corn spurry and eclipta weeds by 85–90% and increased collard biomass by 150–155% compared to the control, performing comparably to 100% CMM. In conclusion, SH residue effectively replaces industrial carbon sources in ASD, providing comparable weed suppression and crop growth benefits while reducing input costs. This approach offers a practical alternative for integrated weed management and enhanced crop productivity in southeastern vegetable production systems.

# Changes in Soil Bacterial and Fungal Community Characteristics in Response to Biochar Treatments

**Igor A. Yakovlev, Hege Særvold Steen, Inger Heldal, Jihong Liu Clarke, and Nicholas Clarke***

*Norwegian Institute of Bioeconomy Research, Ås, Norway*

*nicholas.clarke@nibio.no

**ABSTRACT**

To optimize biochar for improving soil health, crop production, and environmental benefits, we need to study changes in soil bacterial and fungal communities as a response to biochar treatments. This will enable us to determine the effects of biochar on nutrient cycling, plant-microbe interactions, and the functional responses of soil, as well as to formulate effective and soil-specific application strategies.

We carried out pot experiments with biochar (BC), NPK fertilizer and wheat in artificial soil, investigated changes in soil chemistry and microbiomes after biochar treatments, and functionally annotated differentially represented microbes. There were some significant differences of BC addition on soil C, N, C/N, pH and extractable (ammonium lactate) Al and K (but not on extractable P). Phenotypic analysis confirmed the best growth after addition of 5% BC with fertilizers. Without fertilizers, BC decreased plant growth. Ground biochar decreased growth. PCA and other analyses showed clear changes in microbiome communities during plant growth, i.e. between the start and end of the experiments. We did not find an influence of BC addition on the diversity and richness of microbial communities, both for fungi and bacteria. Most highly present microbes represent saprotrophic, organic degraders, symbiotic and mycorrhizal species, nitrogen fixing and antibiotic producers.

Future work might include expanding the work to long-term field trials using natural soils and potentially additional crops.

## ABSTRACT

Reducing reliance on synthetic nitrogen (N) fertiliser without compromising yield in intensively managed grasslands is essential for mitigating environmental impacts such as nitrous oxide emissions and nitrate leaching. Nature-based solutions such as multispecies mixtures of grasses, legumes and herbs can help achieve this goal. They can enhance yield (Grange *et al.*, 2021) and N use efficiency (Obasoro *et al.*, 2025) compared to grass monocultures receiving 150 and 100 kg N $ha^{-1}$ $yr^{-1}$ more N input, respectively.

In 2023, 50 experimental plots were established at AFBI Crossnacreevy on sandy silt loam soil to investigate how variations in mixture composition influence yield and N response efficiency (NRE). Proportions of three functional groups (FGs: two grasses, two legumes and two herbs) were systematically varied. Plant communities ranged from one to three FGs, with each FG proportion divided equally between the two species of that FG. Plots were randomly assigned one of two N fertiliser treatments: 0 and 150 kg N $ha^{-1}$ $yr^{-1}$ (0N and 150N). In 2024, six harvests were conducted to determine annual dry matter yield (DMY). Annual NRE was calculated for the 150N plots as the increase in herbage N offtake above the mean of the 0N treatment, divided by the amount of N fertiliser applied, and expressed as a percentage.

In both N treatments, higher legume proportions in mixtures increased DMY. The equi-proportional six-species mixture at 0N increased DMY by 75% and 47% ($P < 0.001$) compared to the two-species grass- and herb-only communities at 150N, respectively. NRE, calculated for the 150N treatment, was higher in the two-species legume-only community compared to the grass- and herb-only community ($P > 0.1$). However, when legumes were mixed with grasses in the six-species mixture, NRE was 13% lower than the grass-only community ($P > 0.1$), which may reflect N transfer from legumes to grasses, lowering the relative N offtake response to N fertiliser application.

The six-species mixture of grasses, legumes and herbs produced higher DMY at 0N, but its NRE at 150N tended to be lower than the grass-only community at 150N, likely reflecting enhanced N availability from legumes. This highlights the capacity of multispecies mixtures to enhance yield even at lower synthetic N inputs, potentially reducing the environmental impacts of intensive grassland systems.

# Synergistic Mitigation of Crop Rhizosphere Soil Microbial Nitrogen Limitation by Maize-Peanut Intercropping and Straw Return in Black Soil Region: Insights from Extracellular Enzyme Stoichiometry

**Qila Sa[1], Wei Qi[1], Jie Liang[2], Yujun Cao[2], Fanyun Yao[1,2*], Yongjun Wang[1,2*]**

*[1] College of Agronomy, Jilin Agricultural University, Changchun 130118, China*

## ABSTRACT

Soil extracellular enzyme stoichiometry is a key indicator for assessing microbial resource limitation. However, the characteristics of microbial resource limitation in rhizosphere soil under the combined measures of intercropping and straw return remain unclear. This study was conducted in the black soil region of Northeast China to explore the effects of intercropping and straw return on soil nutrients, microbial biomass, extracellular enzyme activities, and their C∶N∶P stoichiometry in the rhizosphere of maize and peanut. The average vector length (VL) of extracellular enzymes in the rhizosphere soil of maize and peanut was 1.68 and 1.57, with vector angles (VA) of 37.80° and 34.67°, respectively. This indicated that soil microorganisms in the rhizosphere of crops in the study area were co-limited by carbon (C) and nitrogen (N), and the N limitation of microorganisms in peanut rhizosphere was more significant. Compared with maize monocropping, the combined measure of intercropping and full straw return increased VA by 5 degrees, effectively alleviating rhizosphere soil N limitation. Compared with monocropping, the combined measure of intercropping and full straw return significantly increased the microbial biomass carbon-to-nitrogen ratio (MBC∶MBN) by 5.20% and the nitrogen-acquiring enzyme activity (NAG+LAP) by 32.59% in peanut rhizosphere soil. For maize rhizosphere, the promoting effects were more pronounced: carbon-acquiring enzyme activity (BG) increased by 94.23%, phosphorus-acquiring enzyme activity (AP) increased by 41.77%, while the ratios of carbon-to-nitrogen acquiring enzymes (BG∶(NAG+LAP)) and carbon-to-phosphorus acquiring enzymes (BG∶AP) increased by 44.40% and 35.38%, respectively. The extracellular enzyme C∶N∶P stoichiometry in the rhizosphere soil of maize and peanut was 1.33∶1.29∶1.00 and 0.89∶1.29∶1.00, respectively. In maize rhizosphere soil, the activities of carbon and phosphorus acquiring enzymes (BG, AP) were extremely significantly positively correlated with total nitrogen (TN), total phosphorus (TP), and MBC∶MBN ($P<0.01$). In peanut rhizosphere soil, the above enzyme activities, as well as VL and VA, were extremely significantly positively correlated with soil organic carbon (SOC), TN, TP, TN∶TP, SOC∶TP, and microbial biomass carbon, nitrogen, and phosphorus ($P<0.01$), with an overall stronger correlation than that in maize rhizosphere. Redundancy analysis (RDA) further revealed that microbial biomass nitrogen (MBN) was the key factor affecting microbial nutrient limitation, with an explanation rate of up to 54.6%. In conclusion, the extracellular enzyme stoichiometric characteristics of rhizosphere soil varied significantly between different crops. Intercropping had a stronger impact on rhizosphere microbial nutrient limitation than straw return, and their synergistic effect could significantly alleviate rhizosphere microbial N limitation by enhancing BG activity.

**ABSTRACT**

As climatic processes become increasingly unpredictable, drought events have emerged as one of the biggest challenges for modern maize (*Zea mays* L.) production. Particularly during early development stages, limited water availability can reduce important agronomic traits such as plant growth and grain yield. In commercial agriculture hybrid maize varieties are primarily grown to ensure high and predictable yields. However, these varieties often show low tolerance to fluctuating environmental conditions, making them more susceptible to substantial losses. To better understand and ultimately improve the drought resilience of maize varieties, it is essential to study the underlying mechanisms and adaptive strategies associated with root and rhizosphere traits.

To explore these questions, we combined a controlled greenhouse experiment with field trials to explore both controlled and real-world variability. In a high-throughput phenotyping setup, six varying maize genotypes – including landraces and modern hybrids - were grown under five distinct water regimes and two contrasting soil types. This allowed us to track differences in growth dynamics, root traits, and physiological responses. During the following growing season, two of these genotypes were further tested under varying field conditions in Bavaria. In the field trials monocropping and mixed-cropping systems were included, to examine how interactions between varieties influence water use, root development, and overall plant performance.

By linking results from both approaches, we aim to identify genotypes that consistently perform well under drought and to determine the root and rhizosphere traits that underpin this resilience. These findings should help guide breeding and management strategies and emphasize the potential of maize landraces as valuable genetic resources for developing varieties adapted to increasingly dry and variable climates.

# BIOCHAR AND COMPOST AS NATURE-POSITIVE SOLUTIONS TO SEMI-ARID AGRICULTURE: MULTI-LEVEL ASSESSMENTS OF SOIL HEALTH, NUTRIENT CYCLING, AND GREENHOUSE GAS EMISSIONS

**Rajan Ghimire, Sundar Sapkota, Juan P. Frene, and Piumi Madhuwanthi**

New Mexico State University, Agricultural Science Center, Clovis, NM, USA

**ABSTRACT**

Biochar and compost applications have been promoted as a nature-positive approach to improving soil health and reducing greenhouse gas (GHG) emissions; however, significant uncertainty exists in quantifying their role in soil health and productivity, nutrient retention and loss, as well as soil nitrous oxide ($N_2O$) emissions in depleted semi-arid soils. We evaluated soil health, C, N, and P cycling, and net GHG emissions through a series of laboratory, greenhouse, and field experiments. Laboratory assessment of soil $N_2O$ emissions from soils amended with biochar prepared from diverse agricultural and forest biomass shows that pinewood pyrolyzed at 700 °C (PB700) was the most efficient in reducing $N_2O$ emissions, with 24% less total cumulative $N_2O$ emissions than CTRL. In contrast, cattle manure pyrolyzed at 500 °C (CM500) resulted in 74% greater cumulative $N_2O$-N emissions than CTRL (10.4 mg kg $^{1}$) and 102% to 107% greater emissions than plant-based agricultural biochars. It also showed the largest labile nitrogen pool ($N_l$) in CM500 among all biochars, and the cumulative $N_2O$ emission was positively correlated with $N_l$ ($r = 0.85$; $p < 0.001$). Soil C mineralization was 5.5–17.6% lower with pinewood pyrolized at 500 °C than with others. Greenhouse assessment of soil health, C, N, and P cycling shows that an increase in SOC was positively related to biochar C, surface area, and pore volume. In the field experiment, biochar application reduced cumulative $N_2O$-N and $CH_4$-C emissions by 85% and 43%, respectively. Soil moisture was positively correlated with $N_2O$-N emissions ($R^2 = 0.39$), while soil temperature had the strongest correlation with $CH_4$-C emissions ($R^2 = 0.37$). Overall, biochar-treated soil had the lowest (43% less) net global warming potential (GWP) compared to compost-treated soil and 22% lower than CTRL. Biochar emerged as a promising soil amendment for semi-arid soils, enhancing C and N cycling, lowering GHG emissions, and GWP.

## ABSTRACT

With the intensification of global climate change and the impact of human activities, the ecological degradation problem in arid and semi-arid areas has become increasingly serious. In particular, the dry-hot valley areas represented by the Jinsha River, Nujiang, and Yuanjiang river basins in my country are facing severe ecological degradation problems such as poor soil, poor water retention, and severe erosion [1] due to high temperature and drought, low and concentrated precipitation, huge evaporation, and distinct dry and wet seasons [1]. As one of the key industries that support human survival and development, agricultural production is a core issue in the field of sustainable agricultural development. Endophytic plant growth promoting rhizobacteria (PGPRs), as an environmentally friendly microbial agent, provides a sustainable solution in enhancing plant stress resistance (such as drought, salinity) and promoting plant growth [3-4]. However, its survival rate and colonization ability are significantly affected by direct application due to the harsh environmental conditions of hot dry valleys. This study aims to develop a new, environmentally friendly hydrogel based on Tamarind Seed Polysaccharide (TSP) and sodium alginate (SA) to encapsulate PGPRs to improve its activity and function in the fragile ecological environment of hot dry valleys, and to enable efficient application in harsh environments. By utilizing the water retention properties of tamarind seed polysaccharide (water retention rate > 90%), the sustained release properties of sodium alginate (sustained release period ≥ 14 days), and the biological activity of PGPRs (survival rate > 80%), green and pollution-free microbial water retention growth promoters are developed to improve the stress resistance of crops, improve soil, and assist ecological restoration in hot dry valley areas. At the same time, China's abundant tamarind resources (annual output in Yunnan, Guangxi and other places >100,000 tons) are used to promote the high-value utilization of agricultural waste and realize the application of tamarind seed polysaccharide in the agricultural field for the first time.

We optimized the formula of TSP-SA-$CaCl_2$ hydrogel and systematically characterized its physical and chemical properties, including swelling ratio, water retention rate, mechanical strength and microstructure. The functional response mechanism of the TSP-SA composite hydrogel under simulated hot dry valley conditions (temperature 30-45°C, relative humidity 20-40%) was used to explore the growth-promoting mechanism and soil improvement effect of the composite hydrogel. Successfully developed 1-2 tamarind seed polysaccharide-

sodium alginate-PGPRs composite hydrogel formulas with good water retention properties, certain gel strength, high PGPRs encapsulation rate, high bacterial survival rate, and suitable for dry and hot valley areas. Elucidate the water and nutrient slow release dynamics and PGPRs C5 activity maintenance mechanism of tamarind seed polysaccharide-sodium alginate-PGPRs composite hydrogel under drought stress, and reveal its coupling mechanism to promote crop growth by improving the rhizosphere micro-area water and fertilizer environment.

In this study, for the first time, tamarind seed polysaccharide interacts with sodium alginate and calcium chloride to form a polymer hydrogel with a three-dimensional network structure through electrostatic attraction, ionic cross-linking and hydrogen bonding, and uses it as an encapsulation carrier for rhizosphere growth-promoting bacteria PGPRs. Through flat plate, potted and field experiments, the water retention and growth-promoting effect of polymer-encapsulated PGPRs hydrogel in various crops was explored, and its synergistic water retention and growth-promoting mechanism in hot dry valley areas was clarified, laying a theoretical foundation for the development of new and efficient agricultural preparations. It solves the outstanding problems of fragile ecological environment, drought and water shortage, and limited agricultural development, and provides a low-cost, environmentally friendly ecological restoration and agricultural production increase technical solution, which provides a theoretical and practical basis for the development of sustainable agriculture in arid and semi-arid areas, and helps rural revitalization and ecological civilization construction.

**ABSTRACT**

The common bean is considered the most important grain for direct human consumption. This crop is demanding in soil fertility, and its needs can be met with the use of different sources of fertilizer, such as chemical or organic. Fertilizers, in turn, affect soil microbiota, which performs several functions such as nutrient cycling and availability, and promotion of plant growth. Therefore, the aim of this work was to explore the effect of fertilization on common bean cultivation, soil nutrient content, and variation in soil bacterial taxonomy. Field experiments were conducted in a latosol area previously cultivated with soybean. For this study, common bean was grown without fertilization, with chemical fertilization (NPK 5:20:10), and with organic fertilization made from poultry litter containing 1.75% nitrogen. Organic fertilization was applied 20 days before sowing due to its slow mineralization. Cultivation occurred in the main season, sowing on November 5, 2021, and in the second crop season, sowing on January 21, 2024, using a randomized block design with four repetitions. Soil samples were collected at 0, 30, and 60 days after sowing (DAS) in each growing period. These samples were analyzed for chemical composition, microbial biomass carbon, basal respiration, and metabolic quotient. At 30 and 60 DAS, plant samples were collected to analyze plant tissue composition. Another soil sample was collected 60 DAS for soil metataxonomic analysis. For this analysis, amplicon sequencing of the hypervariable V4 region of the 16S rRNA gene was performed. Sequencing data were processed and analyzed on the EMBL MGnify platform. When plants reached harvest maturity, yield components were analyzed. Different fertilization treatments did not show significant differences in soil chemical parameters, plant tissue composition, and yield components in both tested seasons. This is probably due to the short evaluation period and the adequate soil conditions before the experiments were conducted. On the other hand, biological parameters were affected. Proteobacteria, Acidobacteria and Actinobacteria were the predominant phyla, and Candidatus *Udaeobacter*, *Sphingomonas*, *Bradyrhizobium* and *Pseudolabrys* were the predominant genera, regardless of treatment or growing season. However, organic fertilization showed greater diversity (Shannon index). In the second crop season, which is warmer and promotes greater microbial reproduction and activity, microbial communities were more complex, especially with organic fertilization. More complex networks result in greater resource efficiency, improving the stability of microbial communities. This shows that even in a short time, organic fertilization can improve the resilience of microbial communities by increasing their interactions and helping to prevent the loss of soil quality.

## ABSTRACT

Soybean (Glycine max L.) is one of the world's most important oilseed and protein-rich legume crops, contributing significantly to global agricultural economies, food industries, oil processing sectors, and livestock feeding systems. The design, manipulation, and application of nanoscale materials are all part of the cutting-edge and innovative field of nanotechnology (Ali *et al.* 2014; Agrahari and Dubey 2020). The Greek word "nano," which literally translates to "dwarf," is used to characterize materials that have at least one dimension of less than 100 nm. Nanotechnology is now present in every facet of daily life (Zulfiqar *et al.* 2019). It has increasingly turned to green or biogenic synthesis routes for nanomaterials, as these methods offer milder reaction conditions, reduced environmental footprint and the potential for biocompatibility when compare to the conventional chemical and physical methods (Antunes Filho *et al.,* 2023). In particular plant extract made synthesis of nanoparticles has become a preferred route because plant phytochemicals (flavonoids, terpenoids, alkaloids, polysaccharides) act both as reductants converting precursors into elemental or ionic nanomaterials, and as stabilizers or capping agents preventing aggregation (Huang *et al.,* 2007; Raj & Trivedi and Soni, 2022).

Nanotechnology has emerged as one of most dynamic areas in modern science due to its wide applications in medicine, agriculture, energy, and environmental remediation. While physical procedures emit harmful byproducts that harm the environment, chemical approaches use hazardous precursors to create nanoparticles. Therefore, it is imperative to employ eco-friendly, environmentally safe methods for the synthesis of nanoparticles (Bhardwaj *et al.,* 2020).By strengthening crop protection, boosting nutrient management, and fostering environmental sustainability, nanotechnology has enormous potential to transform agriculture (Sivarethinamohan and Sujatha, 2021).

In order to solve these problems, nano-engineered sulfur, also referred to as nano-sulphur or NS and consisting of particles typically smaller than 100 nm, has emerged as a game-changing technology. Because of their high surface-area-to-volume ratio, improved solubility, and better soil-plant interface interactions, these nanoparticles facilitate more effective sulfur transport and assimilation than bulk forms of S (Wang *et al.,* 2022; Mahajan *et al.,* 2023). For the production of proteins, lipids, vitamins, and compounds that improve plant flavor, sulfur is essential. Crop yield, seed quality metrics, and the amount of sulfur in seeds are closely related (Zenda *et al.,* 2021). Because of their special qualities, such as their large surface area and increased reactivity, nanomaterials are perfect for a variety of agricultural uses, such as controlling plant infections and releasing fertilizer slowly (Goswami *et al.,* 2022).

In order to create nanoparticles that can lower metal ions, scientists are constantly investigating different bacteria, fungi, and plants (Bansal *et al.,* 2014; Duhan *et al.,* 2017). The process is biofabrication of nanoparticles when any biological material or its byproduct is used to create the nanoparticles. These make use of bacteria and their extracts, fungi and their cell-free extracts, plant tissue extracts, and plant materials and their crude and solvent-specific extracts, whether organic or aqueous. Different metal and nonmetal salts are used to test these extracts. The bio fabrication process becomes somewhat uncontrollable when the biochemical content of extracts is derived from bacteria, fungi, animal tissue, or plants (Bansal *et al.,* 2014).Due to their distinct physicochemical and biological characteristics, including intense antibacterial activity, high surface reactivity, and prospective application in fertilizers, insecticides, and medication formulations, sulfur nanoparticles (SNPs) have garnered significant interest among the different nanomaterials. Sulfur nanoparticles are traditionally produced via physical and chemical processes that frequently need hazardous byproducts, significant energy consumption, and toxic reagents. Green or biogenic synthesis techniques employing plant-based biomolecules have been proposed as sustainable, economical, and environmentally friendly substitutes to address these shortcomings.

Using leaf extracts from four medicinal plants that demonstrated antibacterial activity with $Na_2Sx$, the SNP was synthesized. $Na_2Sx$ combines with sulfuric acid in an acidic environment to produce visible yellow precipitates. (Paralikar *et al.,* 2017). According to Akl M. Awwad et al. (2015), sulfur nanoparticles were successfully made from sodium thiosulfate in the presence of Albizia julibrissin fruit extract at room temperature. The final product was described as highly crystalline sulfur with high purity, a spherical shape, an average particle size of roughly 20 nm, and a particle size distribution between 10 and 100 nm.

Soybean (Glycine max L.) is a globally important oilseed crop that requires adequate sulfur for protein synthesis, lipid metabolism, and improved seed quality. However, sulfur deficiency is now widespread due to continuous cropping, resulting in reduced soybean yield and nutritional value. Conventional sulfur fertilizers often show low solubility, slow oxidation rates, and poor bioavailability, limiting their effectiveness for modern soybean production.

Nanotechnology has emerged as a promising tool to enhance nutrient delivery, but physical and chemical methods of nanoparticle synthesis generate hazardous by-products, require high energy, and pose environmental and health concerns. Green synthesis using plant extracts offers an alternative, yet challenges such as variability in phytochemical composition, lack of standardization, and limited understanding of nanoparticle–plant interactions hinder its widespread application.

Therefore, there is a critical need to develop and evaluate biogenic sulphur nanoparticles as an efficient, sustainable, and environmentally safe sulphur source for soybean crop. This study seeks to address these limitations by exploring green-synthesized sulphur nanoparticles and assessing their potential to improve soybean growth, yield, and sulphur-use efficiency.

The present investigation were conducted during *kharif* season of 2023-24 and 2024-25 at Akola, India. The experimental soil was medium deep black, swell shrink, montmorillonites mineralogy with clay texture and classified under Vertisol. It is located in the subtropical zone at 22°42' North latitude and 77°02' East longitude, with an elevation of 307.42 m above sea level and average annual rainfall is around 846.5 mm (33.33 inches).The climate of Akola is semi-arid and characterized by three distinct seasons viz., summer being hot and dry from march to May, warm and humid monsoon from June to October and winter with mild cold from November to February. Most of the rainfall received from south-west monsoon. The total rainfall received during the cropping season was 592.8 and 813.0 mm with 28 and 37 rainy days in the year 2023-24 and 2024-25, respectively. SNPs were prepared by using typical parts of plants such as pods, leaves, peels, barks and fruits. Due to multifarious phytoconstituents present in the plant extract and behaves as herbal reducing, capping and/or stabilizing agents, therefore there is no requirement to involve external pernicious stabilizing/capping substances.

**Synthesis of SNP's**

Sulfur nanoparticles (SNPs) were synthesized by dissolving 3.2 M of sodium thiosulfate (25 mL, $Na_2S_2O_3$) in 50 mL of neem (Azadirachta indica) leaf extract, followed by continuous stirring for 5 minutes at room temperature. The mixture was then diluted to a final volume of 100 mL using sterile distilled water. Subsequently, hydrochloric acid (HCl) was added dropwise under gentle stirring to facilitate uniform sulfur precipitation. In the presence of neem leaf extract and acidic conditions, sodium thiosulfate undergoes a disproportionation reaction, yielding elemental sulfur and sulfonic acid, according to the following reaction:

$Na_2S_2O_3 + 2HCL \rightarrow 2NaCl + S + SO_2 + H_2O$

The suspended sulfur particles obtained were separated by centrifugation at 1000 rpm for 5 minutes and then repeatedly washed with sterile distilled water to remove any biological materials. The sulfur nanoparticles after purification were dried in a vacuum at 80°C for 2 hr. The product was light yellow powder used for UV-Vis, NTA, Zeta potential, TEM, XRD, and FTIR analysis. The field experiment was laid with six (06) treatments and four (04) replications in Randomized Block Design (RBD). The treatment details were $T_1$: GRDF through urea, DAP and MOP, $T_2$: $T_1$ + Foliar application of 25 ppm nanosulphur at 30 and 45 DAS, $T_3$: $T_1$ + Foliar application of 50 ppm nanosulphur at 30 & 45 DAS, $T_4$: $T_1$ + Foliar application of 75 ppm nanosulphur at 30 & 45 DAS, $T_5$: GRDF + 30 kg S/ha (Bentonite sulphur) and $T_6$: Absolute control. Note: RDF is 30:60:30 N:P:K Kg $ha^{-1}$. In all the treatments RDF will be applied through Urea, DAP and MOP (S free), FYM application @ 5t/ha at the start of experiment.

**Structural and Stability Analysis SNP**

The SNP indicated the absorption maxima at 215 nm under UV- Visible light, size of nanoparticles is 86.22 nm was observed by NTA analysis. The stable SNP's were confirmed by average zeta potential value of -21.8 mv and standard deviation of 9.56 mV these values confirmed the stabilization of nanoparticles. The high negative zeta potential values for sulphur nanoparticles synthesized from A. *indica* indicated their strong stability characterization of SNP. The transmittance peaks were observed at 3445.98 $cm^{-1}$ represented the presence of N-H stretch of amines and amides,1641.49 $cm^{-1}$ C=O groups of aldehydes and ketones,1386.88 $cm^{-1}$ C-H stretch of alkanes,1126.48 $cm^{-1}$ represented presence of C-N stretch of amines and amides .The other minor peaks at 1018.46 $cm^{-1}$,650.04 $cm^{-1}$,480.30 $cm^{-1}$ and 421.46 $cm^{-1}$ were assigned to C-O alcoholic stretch C-H of alkenes ,aliphatic chloro- and aliphatic iodo-compounds respectively were present in capping layer and stabilization of sulphur nanoparticles showed on FTIR analysis. The miller indices were assigned to a specific bragg's diffraction angle at 2 theta as given here .The XRD spectrum indicated the typical miller indices for SNP's of Bragg's 2 theta values of 113 (15.38), 222 (23.07), 026 (25.83), 313 (28.66), 044 (31.39), 317 (37.03), 062 (42.78), 515 (47.75), 357 (51.23) and 175 (53.96).The miller indices indicated the formation of crystalline SNP's.(Joint committee on powder diffraction standard file no.04-0836) were showed in XRD analysis.

**Effect of SNP on growth, yield and quality of soybean**

The plant height and number of branches $plant^{-1}$ at 30 DAS is significant and highest were recorded in GRDF + 30 kg S/ha Bentonite sulphur. The plant height and number of branches $plant^{-1}$ at 45& 60 DAS is significant and higher were recorded in GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 & 45 DAS. The Dry matter accumulation (g) at 45 & 60 DAS is significant and higher were recorded in GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 and 45 DAS. The chlorophyll content index (mg/g) at 30 & 45 DAS is significant and higher were recorded in GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 & 45 DAS.

The number of pods $plant^{-1}$ is significant and higher were recorded in GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 and 45 DAS. The number of seed $pod^{-1}$ and seed index was non-significant. The protein content and oil content was significant and higher were recorded in GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 & 45 DAS ($T_4$).

**Effect of SNP on soil chemical properties and content and uptake of nutrient by soybean**

The chemical properties showed non-significant on soil pH, EC, organic carbon, available phosphorus, potassium, zinc, iron, manganese and copper, however significant effect on available nitrogen and sulphur were observed. Soil available N and S was significantly higher in GRDF through urea + foliar application of 75 ppm nano sulphur at 30 and 45 DAS. The effect of SNP on N and S content (seed and straw) were found to be significant. The effect of biogenic synthesized nano sulphur showed a significant effect on uptake of N, P and K in seed and straw with the GRDF through urea + Foliar application of 75 ppm nano sulphur at 30 and 45 DAS.

**CONCLUSION**

Based on the data generated during two years of experimentation it can be concluded that, biogenic synthesis of SNP's can suggest that many bio-constituents were present in A. *indica* leaf extract which were responsible for reduction, capping and stabilization of sulphur nanoparticles with eco-friendly nature and characterization of sulphur nanoparticle is with 86.22 nm, higher negative value of zeta potential, with different functional groups, polydispersed size and crystalline nature. Biogenic synthesis of nano sulphur application significant improved plant growth parameters, yield components and increased quality of protein and oil content. Biogenic synthesis of nano sulphur application increased the nutrient and uptake. Thus, it can be concluded that, application of biogenic synthesized nano sulphur significantly improved the growth, yield, quality, nutrient content and uptake.

## ABSTRACT

Plant growth-promoting bacteria (PGPB) are beneficial microbes that enhance plant growth and mitigate abiotic stress. The increasing use of PGPB in sustainable agriculture highlights the necessity to elucidate their roles in improving plant tolerance to drought and salinity. This study investigated the resilience of tomato plants inoculated with PGPB, with the goal of identifying potential biofertilizer candidates. Soil samples were collected from commercial fields in the semi-arid region of Northwest Victoria and analysed for physicochemical properties. Three *Bacillus* species were isolated and identified through 16S rRNA sequencing. The isolates were screened for key plant growth-promoting traits, including 1-aminocyclopropane-1-carboxylate (ACC) deaminase activity, nitrogen fixation, siderophore production, phosphorus solubilization, indole-3-acetic acid (IAA) production, and acid/base production. Firstly, tomato seedling growth was assessed in vitro using Murashige and Skoog medium inoculated with the three bacterial strains. The strains were subsequently applied to tomato plants grown hydroponically under controlled conditions and subjected to three levels of drought and salinity stress. After eight weeks, growth parameters were recorded. The endogenous hormones abscisic acid, IAA, salicylic acid, zeatin riboside, methyl jasmonate, and gibberellic acid were quantified in roots and leaves using a triple quadrupole mass spectrometry workflow. Statistical analyses were conducted using Minitab 19. Soils consisted of clay, sandy loam, and clay loam, with water content and organic carbon below optimal ranges, while potassium, calcium, magnesium, pH, and electrical conductivity exceeded recommended levels (based on Australian Wine Research Institute, 2023, guidelines). *Bacillus subtilis* and *Bacillus gibsonii* exhibited positive ACC deaminase activity, while *Bacillus mycoides* did not display notable plant growth-promoting characteristics. Under in vitro conditions, *B. gibsonii* significantly enhanced taproot elongation, while *B. subtilis* and *B. mycoides* significantly increased root branching. In the hydroponic experiment, significant differences were observed among treatments for shoot and root length and area. *B. gibsonii* promoted the highest plant growth under non-stressed conditions and improved root area under drought. Despite bacterial treatment, the shoot area declined with increasing drought intensity. Under salinity stress, plants treated with *B. gibsonii* and *B. subtilis* exhibited higher root and shoot areas than controls. Hormone profiling revealed distinct shifts in endogenous signalling following bacterial inoculation. In conclusion, the application of *B. gibsonii* and *B. subtilis* enhanced tomato growth under both normal and stress conditions, highlighting their potential as biofertilizer candidates for improving drought and salinity resilience in agriculture. Further studies are needed to validate their effectiveness under field conditions.

# Optimizing Soil Health in Tropical Peatlands through Coconut-based Agroforestry

**Safira Eka Aprianti[1], Nurul Ihsan Fawzi[1,2], Ilham Adi Santoso[2], Fransisca Simanjuntak[3], Putri Oktariani[2], Suwardi[2]**

[3] *Astra Agro Lestari Tbk, Jakarta, 13920 Indonesia*

*safira@tayjuhanafoundation.org

**ABSTRACT**

Agroforestry is increasingly recognized as a nature-based solution (NBS) to promote soil health and ecosystem resilience in degraded tropical peatlands, where long-term drainage and monoculture practices have accelerated nutrient loss, and biological decline. In Indonesia's vast coconut (*Cocos nucifera*) peat ecosystems, sustaining soil quality is vital, yet empirical, quantitative comparisons of soil health across land-use systems remain scarce, particularly using integrative indices that capture biological responses like microbial biomass carbon (MBC) in drained perennials. This study evaluates soil health via the Soil Quality Index (SQI) in coconut monoculture (CMC) and coconut agroforestry (CAF) systems in Indragiri Hilir Regency, Riau, the country's largest peat-based coconut region. Field sampling targeted 0-15 cm depth across four villages (Teluk Nibung, Kateman, Sungai Danai, Manunggal Jaya), with three replicates per land-use type. A Minimum Data Set (MDS) of physical (bulk density), chemical (pH, Na), and biological (MBC) indicators was derived via principal component analysis (PCA) for additive SQI computation. ANOVA revealed significant differences ($p<0.05$) only in pH, Na, and MBC, all higher in CAF, driving superior chemical stability and biological activity. Overall SQI was 57.68% in CAF versus 46.04% in CMC, signaling enhanced resilience against subsidence and nutrient leaching. These findings affirm CAF as a superior, diversified NBS over CMC, leveraging vegetation complexity for organic matter inputs and microbial enhancement. To optimize peat-based coconut sustainability, we recommend scaling intercropping with N-fixing species and monitoring MBC thresholds, potentially stabilizing yields and minimizing emissions. These measures contribute to socio-economic sustainability by supporting smallholder resilience amid fertilizer volatility.

# Ecological Regulation Function of Soil Microorganisms: Synergistic Effects of Arbuscular Mycorrhizal Fungi and Trichoderma in Biotic and Abiotic Stress Tolerance

**Zhipeng Hao[1*], Kangxu Zhang[1], Xin Zhang[1], and Baodong Chen[1]**

[1] *State Key Laboratory of Regional and Urban Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China*

*zphao@rcees.ac.cn

## ABSTRACT

Soil microorganisms, particularly arbuscular mycorrhizal fungi (*Rhizophagus irregularis*, AMF) and *Trichoderma harzianum* (Th), play critical roles in enhancing plant resilience to both biotic and abiotic stresses. These microbes improve nutrient acquisition, modulate immune responses, and help plants tolerate environmental stresses. This study investigates how the co-inoculation of AMF and Th enhances the resilience of two crop models—tomato (*Solanum lycopersicum*), which faces pathogen-induced stress, and licorice (*Glycyrrhiza uralensis*), a medicinal plant affected by drought stress. The findings highlight the ecological roles of these microorganisms in improving agricultural sustainability.

In the first experiment with tomato, we assessed the effects of AMF and Th on plants infected with *Fusarium oxysporum* (Fo), a common soil-borne pathogen. Both AMF and Th independently reduced *F. oxysporum* colonization, leading to a shift in the plant immune response from a jasmonic acid (JA)-dominant to a salicylic acid (SA)-dominant pathway. This immune shift, characterized by increased phenylalanine ammonia-lyase (PAL) and polyphenol oxidase (PPO) activities, resulted in enhanced disease resistance. However, while both microbes improved disease tolerance, co-inoculation did not result in an additive or synergistic effect on disease suppression, suggesting that microbial interactions may not always lead to enhanced disease control.

The second experiment focused on licorice, a medicinal plant valued for its bioactive compounds, glycyrrhizin and liquiritin. Inoculation with *R. irregularis* significantly improved licorice biomass, drought tolerance, and the production of secondary metabolites. Specifically, glycyrrhizin levels increased by 29.9%, and liquiritin production was 3.3 times higher under drought stress. Co-inoculation with *T. harzianum* further boosted glycyrrhizin yields by 93.7%, demonstrating a synergistic effect between the two microorganisms. Gene expression analysis revealed the upregulation of key biosynthetic genes, including *Squalene synthase* (*SQS1*) for glycyrrhizin and *Chalcone synthase* (*CHS*) for liquiritin. These results indicate that microbial inoculation enhances nutrient uptake and activates metabolic pathways for bioactive compound production.

This study underscores the ecological regulation functions of soil microorganisms in enhancing plant resilience to both biotic and abiotic stresses. The combined inoculation of AMF and Th significantly improved disease resistance in tomato and promoted drought tolerance and secondary metabolite production in licorice. These findings provide valuable insights into the use of microbial consortia to improve plant health and productivity, offering sustainable solutions for crop management, especially in arid and pathogen-prone environments.

# Identification of Bioplastic-associated Bacteria with Potential Degradative Activity in an Agricultural Soil System

**Zeyu Zhu[1*], Shruti Parikh[1], Adan Gallo Lopez [1], Christopher W Simmons [1]**

[1] *Department of Food Science and Technology, University of California, Davis, USA*

*Zeyzhu@ucdavis.edu

**ABSTRACT**

Modern agriculture is increasingly recognized as a major source of environmental plastic pollution due to the widespread use of polyethylene (PE) mulch films, which gradually fragment into microplastics that accumulate in soil and impair long-term soil health (Li et al., 2022). Biodegradable mulch films can serve as alternatives, however, achieving complete degradation of bioplastic (BP) materials in soil remains a significant challenge (Chia et al., 2021). In this study, we aim to identify soil microbial strains capable of degrading starch-based bioplastics used in biosolarization—a non-chemical pest management technique in which plastic films trap solar radiation to elevate soil temperatures, while organic amendments stimulate microbial activity and promote natural biopesticidal processes (Stapleton, 2000; Stapleton et al., 2016). We hypothesize that the selective conditions created by this system provide a suitable method to select for bioplastic-degrading bacteria. Initial *in vitro* assays show that 24 isolated strains exhibit varying starch-hydrolyzing ability based on halo diameters. These isolates were identified via 16S rRNA Sanger sequencing and characterized by colony morphology, with most belonging to the genus *Bacillus*. We are currently investigating whether these targeted microbial isolates can effectively degrade bioplastic mulch films in soil. Soil phytotoxicity will be evaluated through seedling germination assays to assess whether the resulting soil environment supports healthy plant growth. These results will provide a foundation to develop microbial inoculum to accelerate the breakdown of residual bioplastic fragments to prevent the accumulation of microplastics.

## ABSTRACT

Nature-positive farming, an approach that improves crop production while increasing resilience and harmony between nature and society, is expected to enhance soil health and increase soil water infiltration. However, limited research exists on the response of diverse nature-positive farming practices on soil health and soil water infiltration dynamics. This study assessed the impact of three nature-positive farming practices on soil water infiltration and the relationship with other soil properties. For this, soil water infiltration was measured using a SATURO dual-head infiltrometer, and selected soil health parameters were measured in soil samples collected from the 0-15 cm depth of the respective fields. The results show significantly greater water infiltration rates in nature-positive practices compared to their respective controls, with infiltration rates 86% to 198% higher in nature-positive management than in the controls. Identifying factors regulating infiltration rate using linear mixed-effects model shows 70 % of the total variation in infiltration was governed by soil health indicators, with water stable aggregates being the most critical factor, accounting for 49% of the total variation. Nature-positive management could be a sustainable solution to improve soil health and security in semi-arid agroecosystems, and the stability of soil aggregates plays a critical role in improving water functions, including soil water infiltration, regardless of the nature-positive practices.

## ABSTRACT

Vietnam is a leading global producer of Robusta coffee and black pepper; however, decades of monocropping and reliance on nitrogen-intensive fertilisers have accelerated soil acidification, nutrient imbalances, and outbreaks of soilborne pests and diseases. From this comprehensive study, survey results revealed low soil pH levels (4.5 to 5.5), low cation exchange capacity (8 cmol(+) $kg^{-1}$), depleted organic matter, and poor soil structure. Fusarium species were widespread, Phytophthora species were found in 70% of pepper fields, and plant-parasitic nematodes were present in 75% of farms. The incidence of these pathogens was strongly linked to low pH, high nitrogen and potassium levels, and low organic matter content.

To increase soil pH, dolomitic lime (2.5 t/ha) was applied. This raised soil pH by 0.45 units and reduced exchangeable cation levels; however, it had limited short-term effects on pathogen suppression. Applying coffee husk biochar (2.5 t/ha) improved nutrient retention and soil porosity, increased arbuscular mycorrhizal fungi colonisation (16%), reduced nematodes in black pepper (33%), and lowered the incidence of Phytophthora (41%). In field trials, the most effective commercial bioinoculants reduced the abundance of *Meloidogyne incognita* (75%) in coffee and *P. capsici/tropicali*s (59%) in black pepper, whilst also inhibiting Fusarium and other nematodes.

Overall, the use of lime, biochar, and commercial bioinoculants improved soil health and reduced disease pressure on Robusta coffee and black pepper plantations. Their integration presents a promising pathway to transition Vietnam's perennial crop systems from chemically intensive practices to biologically resilient production. Future research should prioritise large-scale, multi-site trials and investigate synergistic effects among amendments, inoculants, and diversified agroecosystems.

## ABSTRACT

### Introduction

Biochar, a carbon-rich material produced by the thermochemical conversion of organic matter, has gathered great interest as a soil amendment for agriculture for its ability to enhance crop yields, improve soil fertility, and sequester carbon (Schmidt et al., 2021). However, biochar uptake in Northern Irish agriculture is low due to lack of knowledge and regional research regarding it (Cox et al., 2025). In a meta-analysis, Jeffery et al. (2017) found no positive effect on crop yields in temperate regions, associating this effect with higher inherent soil fertility. Therefore, this study aimed to measure the impact of biochar on crop performance and soil properties over 3 years in Northern Ireland on soils with contrasting fertility status.

### Method

Two field sites (moderate and low soil fertility) were set up in May 2024 with three crops cycles – spring oats (2024), winter barley (2024-25) and perennial ryegrass (2025-2026), with 4 treatments: no biochar and fertiliser control (CTRL), fertilizer (NPK) only, and biochar with fertilizer (B+NPK) and without (B0). Wood based biochar, ground to ≤2 mm, was applied once in 2024 at 5 t $ha^{-1}$, and NPK was applied annually at crop requirement rates. Soils were sampled at harvest and analysed for a range of biophysiochemical properties.

### Results

The experiment is ongoing; results from the first two years show a slight, but non-significant, increase (3.5-5%) in total carbon in plots applied with biochar compared to those without. Soil pH declined in both sites under NPK and B+NPK compared to CTRL and B0 by ~0.2 units. Only the moderately fertile site showed a change in soil nutrients, with higher soil available P in the B+FERT treatment compared to B0. Crop yield was affected by fertilization, with B+NPK and NPK showing similarly high yields, whilst CTRL and B0 were significantly lower. This experiment demonstrates that the application of fertilizer had a greater effect on soil nutrients and crop yield compared to biochar addition, in both low and moderately fertile NI soils.

# Faba bean-wheat intercropping sustains soil water and nutrient cycling, and the carbon availability for microbes in the short term.

## ABSTRACT

Legume-cereal intercropping systems are anticipated to play a significant role in the sustainable intensification of crop production. Their main advantage is the increased yield per area, which results from the physiological complementarity of the two companion crops. However, it has not been fully elucidated how nutrients, and carbon (C) cycling are affected by this cropping system under field conditions at different phenological stages. To address this knowledge gap, an experiment was conducted in which winter wheat and faba bean were cultivated in field under varying nitrogen (N) fertilizer doses. Soil and plant sampling covered the whole plant-growth cycle. The central hypothesis posited that co-cultivation could enhance C sequestration in soil and promote nutrient cycling closure. Various soil N and C pools were quantified, alongside the availability of the other macro- and micro-nutrients. The microbial functional potential was evaluated through the analysis of the enzyme activities and C Use Efficiency. The findings revealed that the intercropping with faba bean sustained the N cycling comparably to the normal N dose applied for wheat. Intercropping enhanced the water and nutrient availability for plants at some phenological stages, especially close to the grain-filling one. This resulted in a significant reduction in the water use efficiency under intercropping without N fertilization. The soil phosphorous mineralization potential was also stimulated. Furthermore, the results indicate that the C availability for microbes was consistently higher in all the systems compared to the sole wheat without N application. Anyway, no changes were observed in the total soil organic C concentration. Overall, wheat-faba bean intercropping demonstrated considerable potential for reducing the reliance on N fertilizers, and for improving the energy and nutrient status for soil microbial communities.

# Evaluation of the soil quality improvement potential through basalt rock dust amendment

**Angelique Daniell[1]***

[1] *Unit for Environmental Sciences and Management, North-West University, Potchefstroom, South Africa*

*angelique.daniell@nwu.ac.za

## ABSTRACT

Improving food security strategies on highly degraded soils has become a significant challenge for South Africa. The need to secure food sources for the growing population under harsher climatic conditions is crucial. South Africa is one of the many water-scarce countries and is labeled the 30th driest country in the world. Numerous methods exist to enhance and maintain soil quality, including applying fertilizers and geological materials to the soil. Basalt has been the focus of numerous long-term studies on soil fertility. Soil plays a vital role in supporting life on Earth. They serve as a medium for plant growth, provide a habitat for soil organisms, regulate and purify water resources, and participate in various nutrient cycles, such as carbon and nitrogen, which help adapt the atmosphere. Worldwide, there is a decline in soil quality due to various anthropogenic and natural causes. If these problems can be addressed, the decline in soil nutrients, which impacts on the agricultural sector, could improve food security. One way to improve soil quality is through remineralization, which involves adding more weatherable, nutritive rock types such as mafic igneous rocks. In recent years, there has been growing interest in using basalt as a natural fertilizing agent to improve non-arable or depleted soils as an alternative to synthetic fertilizers. Previous studies have already demonstrated that using materials such as basalt can enhance the soil and crop quality. The weathering of rocks depends on factors such as the climatic conditions of the region and the physical and chemical properties of the rock. One-way soil quality can be improved by remineralization, which refers to the improvement of soil quality by adding more weatherable, nutritive rock types. Internationally, powdered rock such as basalt has been used by farmers as a natural way to improve soil root system development, increase crop yields, and aid in plant health and conditions. Basalt has given rise to the possibility of replacing synthetic fertilizers as natural amendments to improve non-arable soils. Previous studies showed that adding basalt might improve soil and crop quality. Agriculture and food production are integral to South Africa. One of the root causes of decreased food production per capita is the decline in soil quality and quantity. Contextualizing South Africa's relative scarcity of available agricultural land against the increasing demand for food production by a growing population, combined with water scarcity, it is necessary to search for innovative methods to improve the quality of soils deemed non-arable. Very little field research has been conducted on the effect of basaltic rock powder in agriculture under local South African conditions. Therefore, this project aims to determine the effectiveness of augmentation of soils with basaltic rock powder. The objective is to determine if adding powdered basalt contributes to soil fertility and increases crop yields under local climatic conditions when local basalt is used. This will be achieved by evaluating the chemical differences of local non-arable soils (sandy soils with low pH levels, low cation exchange capacity, and limited water holding capacity) augmented with powder basalt and those with no augmentation (controls).

The first part of the study focused on a comprehensive literature review to assess suitable methods and understand what methods will be fully appropriate for this study. Methods selected to achieve the aim of this project include the weathering of basalt and the elements released during a 20-week humidity cell experiment and pot field trials with different amounts of added basalt to investigate the chemical changes in the soil when augmented with basalt. In the first experimental phase, the focus was on the humidity cell experiment where basalt was used and evaluated by speeding up the weathering rate by creating an artificial environment for weathering and with the pH of the leachate measured weekly where upon Inductively Coupled Plasma Mass Spectrometry analysis was conducted on the leachates to determine the composition and amount of major and micro cations leached from the samples during the following weeks. The second part of the experimental phase of the study focused on pot field trails which were conducted by making use of two palatable grass species (i.e., *Brachiaria brizantha* and *Lolium multiflorum*) where the germination percentage, growth potential, photochemical efficiency, and elemental concentrations were analyzed when two different mixing ratios of basalt (i.e., one t/ha and three t/ha), were applied to a sandy growth medium, representative of non-arable soil. The soil characteristics that were evaluated included particle size distribution and total elemental concentrations for cations using Inductively Coupled Plasma Mass Spectrometry analysis. It was found that the concentrations of micronutrients released from the leachate were low and decreased with time, which is considered normal as nutrients released from the basalt will decrease as leaching continues. However, it was determined that, as the literature suggested, basalt has a high pH buffering capacity by increasing the pH of the leachate during the 20 weeks. When considering the macronutrients, calcium was the only nutrient that showed a significant difference from the control, meaning there were higher amounts of calcium released throughout the 20 weeks. Unfortunately, no phosphorus was detected in the leachate of the basalt samples, as suggested by the literature on similar studies done previously. The results of the micronutrients found that there was a significant difference between the control and basalt samples for vanadium, nickel, and zinc, where nickel and zinc had higher concentrations than the control leachate than that for basalt leachate. The results from the analysis indicated no clear conclusion that basalt amendment could contribute to vegetation growth on non-arable soils when considering the significant nutrients such as phosphorus and potassium, which are the primary nutrients added by synthetic fertilizers for higher production as these nutrients do not weather as quickly which makes it slower to be released for plant use. The results from the pot field trials showed some interesting findings, and it was observed that the one t/ha basalt amended samples performed better than the three t/ha and the control samples. The evidence suggests plant quality was improved to an extent, meaning that the control samples had the highest growth potential; however, when considering the germination percentage, the one t/ha basalt amended samples showed the best results. The results show significant changes and improvement in the soil and vegetation; however, the substantiation to replace synthetic fertilizers is not evident. Although the study showed that basalt can improve soil quality and fertility immediately, it is recommended that the study be expanded to evaluate the long-term use of basalt under natural field and climatic conditions to get a better view and understanding of how basalt amendment will influence soil quality and crop production in the long run.

# Comparison study on soil layer disturbance between vertical rotary tillage and horizontal rotary tillage

**Zhao Hongbo* Dang Lihua**

*College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling 712100, China;*

*zhaohb@nwafu.edu.cn*

## ABSTRACT

Vertical rotary tillage, with vertical rotation axis, could reduce soil layer disturbance as compared with horizontal rotary tillage in theory, thus reducing soil structure damage and improving soil health. However, this effect has rarely been studied quantitively. This study compared soil layer disturbance quantitively between vertical rotary tillage and horizontal rotary tillage based on DEM (Discrete Element Method) and soil bin test. Firstly, a soil bin test was conducted, the soil layer disturbance was calculated by tallying colored sand that has been buried and torque requirement was determined. Then, the DEM model was established, its parameter was calibrated by comparing torque requirement of vertical rotary tillage in experiment and simulation. Results showed that overall soil disturbance of vertical rotary tillage was 82.38% in experiment and 88.32% in simulation, significantly lower than horizontal rotary tillage of 88.69% in experiment and 93.47% in simulation, verified the assumed reducing effect in soil layer disturbance by vertical rotary tillage, although a large amount of soil was also buried into deeper soil layer by vertical rotary tillage. Besides, more soil particles have been buried into the shallow layer (3-7 cm) under horizontal rotary tillage, while more soil particles have been buried into the deep layer (11-15 cm) under vertical rotary tillage. The results could provide References for sustainable soil tillage operation and help to understand the soil disturbance process under rotary tillage.

**ABSTRACT**

The Living Lab (LL) concept is an approach to developing innovative solutions under real settings. End users and stakeholders collaborate to create, test, and implement new products, services, or processes. Since end users are involved in the LL as active partners, the solutions developed better respond to real needs. According to this concept, 100 LLs focused on soil health are expected to be established in Europe by 2030. Five of these labs are involved in the LivingSoiLL project, which seeks to develop and implement soil health-friendly solutions for permanent crops, such as vines, olives, hazelnuts, walnuts and apples. As part of the project, the Grójec LL focuses on apple orchards, representing the largest production area for this crop in Europe. The long-term use of monoculture, fertilization that is not adjusted to the needs, the multiple use of pesticides during the growing season, and the use of heavy machinery create a risk of soil compaction, deterioration of the its structure, loss of soil organic matter (SOM), an imbalance of elements, and contamination with biogenic substances, pesticides, and trace elements, and consequently limited biological activity and many related problems. Farmers reported these problems at the initial stage of the project as well. In the next phase, soil health-related problems were verified based on 9 experimental sites (EXPS), representing medium-quality soils (usually Luvisols) and varied production modes, fertilization practices, tree varieties and their ages. The soils were sampled in spring 2025 from 3 or 5 locations per EXPS, depending on its size. In order to ensure a complex assessment, the soils were sampled both from rows and interrows. Soil samples were taken from 0-10 cm, 10-20 cm and 20-30 cm in order to determine soil bulk density, particle-size distribution, total organic carbon (TOC) and total nitrogen (N) contents. Moreover soil samples from depth of 0-20 cm were taken from the same locations for more detailed analyses, including pH, content of trace elements and bioavailable forms of P, K, Mg, and N ($NH_4$-N, $NO_3$-N), content of pesticide residues, microbiome composition (fungi and bacteria), and composition of soil sorption complex. The results indicated varied nature and severity of soil health-related problems depending on the EXPS, and showing correlation with practices applied to date. The most significant challenges concern low content and (probably) poor quality SOM, compaction and poor structure, not suitable pH and nutrient imbalances (both deficiency and strong excess). The problem of soil contamination with trace elements and pesticide residues is low. Preliminary results indicate also some problems with soil microbiome, including its structure and other characteristics.

**ABSTRACT**

Scientific evaluating the ecosystem service value (ESV) of cover crop cultivation system can provide important References for the construction of conservation tillage pattern in Northeast China. Based on experimental analysis and the theory of ecosystem service value, we calculate the ESVs of intercropping maize with gramineous cover crop ryegrass, leguminous cover crops alfalfa and hairy vetch, with maize monocropping as the control. The ESV accounting includes product supply, gas regulation, nutrient cycling, and soil and water conservation value. Results show that ESVs of cover crop-maize intercropping are higher than that of maize monocropping, nutrient cycling value is the highest, followed by product supply value, accounting for 67.32% and 29.26% of total ESV. The nutrient cycling value of cover crop-maize intercropping is higher than that of maize monoculture. The product supply value of alfalfa-maize and hairy vetch-maize are significantly higher than that of ryegrass-maize, which increased by 18.67% and 21.03%, respectively. Cover crops planting has the potential to increase the value of gas regulation services, but has little impact on the value of soil and water conservation. Considering the ESVs, intercropping with leguminous cover crops obtain the greatest benefits.

# Agronomic constraints limit the climate change mitigation potential of winter cover crops in Europe

**Marti Vidal Morant[1], Sarah-Maria Scheid[1], Bas du Mortier[1],Charlotte van Haren[2], Allard de Wit[2] and Renske Hijbeek[1*]**

[1] *Plant Production Systems group, Wageningen University, Wageningen, the Netherlands*

[2] *Wageningen Environmental Research, Wageningen University, Wageningen, the Netherlands*

*Renske.hijbeek@wur.nl

**ABSTRACT**

Cover cropping is widely promoted as a promising practice for soil carbon sequestration in agricultural land. Yet, estimates for its greenhouse gas mitigation potential often overlook key factors limiting the feasibility of upscaling. As a result, current potentials may overestimate the climate change mitigation capacity of cover cropping. To support more realistic assessments, we developed and tested a framework to quantify the potential additional adoption of winter cover crops in three European countries: the Netherlands, Germany, and Spain. We addressed two key questions: (1) What is the potential for additional cover cropping based on current adoption? (2) What biophysical and socioeconomic factors influence further adoption?

Through an online survey of 321 farmers (Vidal Morant et al. 2026), we gathered data on crop rotations, current cover crop use, and agronomic constraints. The results show that most farmers already cultivate winter cover crops on at least part of their land in Germany (89 % of farmers) and the Netherlands (97 % of farmers), with only 11 % of arable land in Germany and 25 % in the Netherlands still available for further cover crop cultivation; most arable land is already covered in winter. Soil type, late harvests, and weather conditions were significant biophysical constraints to expansion in both countries. In Spain, no cover crop adoption was detected in rainfed arable systems, largely due to water scarcity. The farmers mentioned benefits such as improved soil health and reduced nitrate leaching as key drivers of adoption.

We conclude that the potential for additional carbon sequestration through cover cropping is limited. Taking into account agronomic factors is needed to bring greater realism to carbon sequestration potentials of soil management practices.

## ABSTRACT

Frequent and intensive tillage can lead to degradation of soil physical properties. No-tillage systems have emerged as an alternative to counteract the effects of excessive tillage. However, no-tillage systems have also been associated with increases in bulk density (BD), reduced water infiltration (WI), and higher soil penetration resistance (PR), among other degraded soil physical properties. Cover crops (CC) have gained relevance due to the multiple benefits they provide and because they occupy periods in the crop sequence during which environmental resources would otherwise remain unused if the soil were left fallow. Among these benefits, improvements in soil physical conditions have been documented in several studies. However, reported results are variable and depend on edaphoclimatic conditions, CC species used, and duration of implementation. Therefore, the objective of this study was to conduct a systematic review of experiments carried out in the Argentine Pampas to assess the impact of CC on BD, PR, WI, and aggregate stability (AS). Information from 23 field-based studies was compiled and analyzed. Cover crop species were grouped into grasses, legumes, grass-legume mixtures, and brassicas. Soil depths were classified as surface (0-5 or 0-10 cm) and subsurface (5-20 or 10-20 cm) layers; and duration of CC use was categorized as short-term (1 year) or medium- to long-term (>1 year). The effects of CC on soil physical properties were evaluated using relative changes between CC treatments and the fallow (control). On average, CC inclusion resulted in 1.7% decrease in BD (0.02 Mg $m^{-3}$) and 16.4% decrease in PR (349 kPa), while increasing WI by 58.9% (45 mm $h^{-1}$) and AS by 25%. No significant differences were detected among CC species, although grasses and brassicas tended to produce greater improvements in soil physical properties. Only PR showed a significantly greater reduction in the surface layer compared to the subsurface layer. In addition, both BD reduction and WI enhancement increased with the number of years of CC implementation. These findings highlight the potential of CC as a tool for improving soil physical properties and underscore the importance of integrating CC into agricultural systems to promote sustainable soil management and enhance overall soil health in the Argentine Pampas.

# Soil Natural Productivity: A Path to Self-Regeneration and Sustainability — Empirical Insights from Hechuren's "Natural Mulching and No-Tillage"

**Author: Yi Zhu**

Natural Mulching and No-Tillage Empirical Laboratory

Chongqing Hechuren Farming Culture Heritage and Development Center

Chongqing,China

Email:hcr0123@163.com

**ABSTRACT**

A smallholder in northern Chongqing has practiced “Huaxia Natural Ecological Farming” for 17 years, conducting a 15-year experiment in ‘Natural Mulching and No-Tillage’ on 9 mu of once-poor mountaintop land. Results show annual yields exceeding 580 kg/mu across over 70 varieties of daily essential food items: 49% grains and soybeans, 49% vegetables and fruits, and 2% oil crops. with income matching the local urban-rural average.

Drawing on Hou Guangjiong's bio-thermodynamic theory of soil fertility, natural no-tillage principles, mycological research, and paleontological evidence, we confirm that indigenous, diverse communities of soil microorganisms and soil fauna serve as the driving force and foundation of the soil life system and its natural productivity. These communities are crucial for restoring and maintaining soil fertility, enabling soil to resume its inherent role as a "renewable resource" rather than a "consumable item requiring constant repair" due to human food production.

Soil natural productivity is essentially the soil’s self-nourishing and regenerative capacity. This capacity is compromised by: (1) External chemicals, hormones, counter-natural interventions, invasive microbes, and monoculture practices, along with the loss of heirloom seeds (and their co-evolved fungal communities), all of which harm soil life and its balance; (2) Removing all weeds and crop residues, leaving soil bare and heavily tilled, causing chronic food scarcity and habitat loss for soil organisms, leading to severe decline.

Key to rebuilding this capacity: Abandoning non-natural inputs and methods while practicing diversified planting establishes natural mulching and no-tillage as the crucial mechanism for interaction, balance, and renewal in the soil life system.Its implementation activates the soil network's ancient, self-regulatory program, enabling natural pest suppression, stable nutrient supply, and system self-repair. A critical note: no-tillage is impossible without mulch, and all non-natural mulch materials must be prohibited.

Conclusion: Today, alongside global soil degradation, issues like environmental pollution, health problems, and food quality decline are prevalent. Unlike complex technological solutions that face public skepticismm, the principle of Natural Mulching and No-Tillage is rooted both in the 400-500 million-year-old "original plant-soil symbiosis" and the restarting of "soil's self-nourishing capacity," as well as in the Chinese cultural tradition of "following the Dao of nature and achieving harmony between heaven and humanity." Combined with practical farming experience, it is more visible, comprehensible, and trustworthy. With significant potential for soil and water conservation, drought and heat resilience, climate adaptation, and enhanced soil carbon sequestration, it represents a path aligned with Chinese modernization.

# Structured Mini-Dunes (SMDs): Engineered Soil Structures for Moisture Retention and Salinity Control in Arid Sabkha Soils

**AfrahAl-Shukaili[1*], HamedAl-Busaidi[1], Ali Al-Maktoumi[1,2], and Anvar Kacimov[1]**

[1] *Department ofSoils, Water and Agricultural Engineering, Sultan Qaboos University, Oman*

[2] *Water Research Centre, Sultan Qaboos University, Oman*

*a.alshukaili@squ.edu.om

**ABSTRACT**

Arid regions, covering 41% of Earth's land, face major barriers to sustainable agriculture from water scarcity, soil salinization, and shallow saline groundwater tables on sabkha flats. This study introduces Structured Mini-Dunes (SMDs) simple, layered sand-gravel mounds inspired by natural Nabkha dunes (Al-Shukaili et al., 2028) as low-cost, self-irrigating soil structures to boost moisture retention, block salt rise, and support plant growth without external water (see Fig. 1).

Two large prototypes (150 cm diameter, 50 cm height) were built in stainless-steel tanks with controlled water tables. Each featured a 20 cm gravel base ($d_{50} \approx 1$ cm), medium sand core ($d_{50} = 0.25$ mm), thin top gravel mulch, and optional 5 cm coarse sand outer layer ($d_{50} = 0.7$ mm) on the second. Decagon 5TE sensors at 25, 50, and 75 cm depths monitored volumetric water content ($\theta_v$, stabilizing at 0.074–0.10 $m^3/m^3$) and electrical conductivity (EC < 0.06 mS/cm in upper layers) over 7 months.

HYDRUS-2D models (Fig.2), calibrated by inverse HYDRUS- 1D van Genuchten estimates ($r^2 = 0.9995$, RMSE = 0.5785), matched field $\theta_v$ data closely, especially in upper layers. Simulations confirmed higher moisture on slopes than crests (like natural dunes), vapor condensation from humid air, and minimal coarse layer benefits, allowing cheap construction with local sands.

Grass naturally grew on SMD crests post-irrigation, proving self-sustainability. SMDs offer practical tools for desert revegetation, non-halophyte farming, and arid soil management.

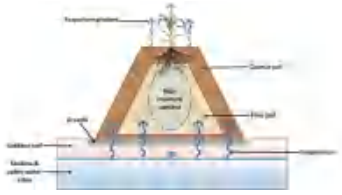

***Figure 1*** *A sketch of an axial cross-section of SMD*

*o42secaj@uco.es

**ABSTRACT**

Rhizospheric microorganisms represent a promising nature-based solution to enhance plant growth, soil functionality, and stress tolerance. The non-pathogenic strain *Fusarium oxysporum* FO12 was found to promote plant growth and induce iron (Fe) deficiency responses, but its performance and mechanisms involved under different soil types, fertilization strategies and inoculation methods remain unclear. This study aimed to (i) evaluate the ability of FO12 to solubilize phosphorus (P), Fe, and zinc (Zn) from mineral sources differing in crystallinity and solubility under calcareous (CAL) and non-calcareous (NCAL) conditions, and (ii) assess the effectiveness of two inoculation methods on plant growth, nutrient uptake, and soil properties in inoculated sunflower and wheat plants grown on contrasting soils and under different fertilization strategies. To this end, the solubilization capacity of FO12 was evaluated for phosphate rock (PR) and single superphosphate (S18) (P sources), ferrihydrite (Fh), hematite, and goethite (Fe sources), and $ZnSO_4$ and ZnO (Zn sources), with or without $CaCO_3$. In addition, *in vivo* experiments were developed with sunflower and wheat grown in CAL and NCAL soils, including two inoculation methods, i.e., direct soil application (St) and seed dressing (Sd) (first experiment), and four different fertilization strategies (full or P-, Fe-, Zn-deficient nutrient solution; second experiment). Analyses included soil pH, available P, Fe, and Zn in soil, plant mineral uptake, and phytohormone profiling. FO12 successfully solubilized 6 of the 8 mineral sources compared with non-inoculated controls, mainly through pH modulation (*in vitro*). This effect was more evident when the inherent solubility [PR (+ 33.6%), and ZnO (+ 110%)] or crystallinity [Fh (+ 1950%)] of the mineral source is low. Moreover, FO12 applied via St more effectively modified soil properties and increased nutrient uptake in NCAL, whereas Sd mainly affected plant physiology, increasing jasmonyl isoleucine (+ 511%) and ACC (+ 226%) while reducing indoleacetic acid (- 39%; *in vivo*). Furthermore, St applications improved soil nutrient phytoavailability and plant nutrient uptake increased up to 26.9% (P), 51.4% (Fe), and 85.4% (Zn), especially under no nutrient constraints (NCAL, full fertilization). Besides, FO12 enhanced Fe and Zn uptake in wheat grown on CAL soil under Fe- or Zn-deficient conditions. Overall, FO12 could act as a complement to fertilization strategies via direct soil nutrient mobilization and phytohormone modulation, but its performance is crop-soil-fertilization dependent and further evaluation to define optimal application conditions is required.

## ABSTRACT

Microbial activities involving the production and release of metabolites that stimulate plant growth and enhance plant health are considered key factors in biological soil fertilization. Among these, Plant Growth-Promoting Rhizobacteria (PGPR) represent one ofthe most widely implemented biotechnologies. This study determined the effect of a microbial consortium on biological activity (basal respiration), microbial biomass, and various ecophysiological indices (qMic, $qCO_2$, and $qCO_2$/C-organic) in soil cultivated under water deficit and inorganic fertilization. An experimental trial was conducted in San Juan de Lagunillas, Mérida, during a crop cycle of *Allium cepa*. The experiment followed a 2x4 bifactorial design in completely randomized split plots, testing water deficit, fertilization levels (0%, 50%, 100% NPK), and inoculation with a consortium of ME01 (*Rhizobium tropici*) and Leu2A (*Bradyrhizobium japonicum*). The rhizobial consortium increased microbial biomass at 0% NPK, thereby benefiting indigenous microbial communities and improving parameters such as the microbial quotient and metabolic quotient. Conversely, the 100% NPK dose induced metabolic stress in the inoculated bacteria, reducing the ecophysiological efficiency of the microbiota. These results suggest that microbial consortia may better withstand nutrient limitation periods due to the metabolic diversity provided by interspecies variety. Possibly, under water deficit conditions, increased enzymatic activity and organic acid production, coupled with root exudates, contribute to the drought tolerance of certain plant species. The proposed microbial consortium could serve as an alternative to improve soil quality and health under low-fertilizer conditions, particularly for drought-tolerant species in semi-arid regions.

**ABSTRACT**

Climate change is bringing opportunities and challenges to the agricultural sector in northern Canada, where the rate of warming is three times higher than the global rate (Bush and Lemmen, 2019). In the context of climate change, agricultural management mimicking nature is a climate-resilient approach for sustainable agriculture. Recognizing the importance of farmers' role in agricultural sustainability, the Canadian government launched the Peace Region Living Lab (PRLL, 2022-2027) to test better management practices (BMPs) and promote their wider adoption. Farmers in this Region are practicing cover cropping as one of the BMPs to improve soil health. Soils of this region are clay-rich and acidic in nature, with many challenges to crop production and soil health improvement. We assessed the effect of cover cropping on soil health in producers' farms participating in the PRLL, using soil samples collected in the first year of the project. Key soil health parameters, namely soil organic carbon (SOC) concentration, aggregate stability, and mineralizable carbon, were measured from the top (0–15 cm) soils. The SOC was determined by dry combustion using a LECO CN828 elemental analyzer. Aggregate stability was assessed using the SLAKES smartphone image-analysis application. Mineralizable carbon was quantified as $CO_2$ evolved over 24 h after rewetting air-dried soils, using an infrared gas analyzer (PP Systems' EGM-4). The SOC content ranged from 2.74 ± 0.81 to 3.18 ± 0.73% in cover-cropped farms, whereas 3.03 ± 0.57 to 4.01± 0.45% in conventionally cropped farms. Overall aggregate stability index was 0.61 ± 0.12 and did not differ between cover-cropped and conventional farms. Mineralizable carbon was numerically higher under conventionally managed farms than in cover-cropped farms, but the difference was not statistically significant. These results might indicate the fact that farmers have recently started cover cropping as a BMP to improve soil health in farms with poorer soils than the conventionally cropped, better farms. Effects of cover cropping will be re-assessed in soils collected at the end of the project period (2027) to determine clearly whether cover-cropping truly has an effect on soil health improvement in the Northwestern region of Canada.

## ABSTRACT

Cereal/legume intercropping is a typical and sustainable agricultural practice. Our previous field experiments indicated that maize/peanut intercropping with appropriate nitrogen reduction achieved a trade-off among soil biological health, soil multifunctionality and crop productivity, which is related to the differences in nitrogen use between cereals and legumes. Therefore, we further analyzed the influence of soil biota at different trophic levels in the intercropping system on nitrogen transfer between maize and peanut. Based on the field intercropping experiment, we conducted a pot experiment on maize/peanut intercropping with two N applications (conventional N and 20% N reduction). Four types of barriers were used in pots, including: solid barrier (no contact), 35 μm aperture nylon mesh barrier (allow nutrients, water and soil microbes contact), 100 μm aperture nylon mesh barrier (allow nutrients, water, soil microbes and soil nematode contact) and no barrier. $^{15}$N-urea was used to analyze the contribution of soil biota at different trophic levels to lateral nitrogen transfer in maize and peanut in intercropping systems, as well as the distribution of nitrogen fertilizer among crops, soil biota, and soil in intercropping systems. Results showed that nitrogen transfer occurred in both directions between maize and peanut. Under both N applications, the total nitrogen transferred from the peanut to the maize exhibited a nematode contribution rate of 2.76–3.11%; conversely, transferred from the maize to the peanut ranged from 1.94–3.73%. PCoA analysis showed that nematode community homogeneity increased significantly with decreasing barrier restrictiveness. Under both N application levels, no significant differences were observed in soil nematode abundance or diversity, or in the biomass of maize and peanut. Decreasing barrier restrictiveness had a considerable positive relation with total $^{15}$N transfer, and both were positively associated with maize and peanut biomass. Our findings emphasized that nitrogen transfer occurred not only from peanut to maize side but also from maize to peanut side, with soil fauna facilitating nitrogen transfer between neighboring plants. Maize/peanut intercropping reduced nitrogen limitation of the system and significantly increased crop productivity.

**ABSTRACT**

Nitrous oxide ($N_2O$) is a potent climate-active gas, and mitigating emissions is essential to achieving the 1.5°C climate target of the Paris Agreement. Agricultural soils are the dominant anthropogenic source of $N_2O$, yet most mitigation approaches focus on suppressing $N_2O$ production through fertilizer management, nitrification inhibitors, or reduced tillage. In contrast, nature-based strategies that enhance microbial $N_2O$ consumption remain largely overlooked [1, 2]. Recent advances have revised our understanding of the microbial $N_2O$ consumption process, revealing unexpected geochemical tolerance and previously unrecognized diversity among $N_2O$-reducing catalysts and microorganisms [3-5].

Effective microbially informed solutions — whether through managing indigenous communities or through the addition of non-native microbes (bioaugmentation) — require detailed knowledge of the ecophysiology of microorganisms capable of $N_2O$ reduction. pH is a major constraint on microbial $N_2O$ reduction, and well-studied $N_2O$-reducing microorganisms are thought to function only under circumneutral pH conditions. Here, cultivation experiments demonstrated the existence of $N_2O$-reducing acidophiles, including organisms harboring a novel $N_2O$ reductase that has been overlooked over decades. These findings substantially expand our understanding on the diversity and ecology breadth of $N_2O$-reducing microorganisms. Furthermore, cultivation experiments simulating realistic soil pH fluctuations uncovered a novel *Schinkia* species that maintains robust $N_2O$ reduction across a broad pH and salinity range, challenging the prevailing paradigm that $N_2O$ reducers endure narrow pH ranges and demonstrates that soil $N_2O$-reducing microbiomes possess substantial physiological flexibility to withstand dynamic acidity and salinity shifts. These findings provide new opportunities for leveraging microbial traits as nature-based solutions to reduce $N_2O$ emissions during climate-driven disturbance events (e.g., wetting–drying cycles), and strengthen the resilience of agricultural systems.

## ABSTRACT

Ecosystem functionality and essential services for human well-being have been degraded by intensively managed monoculture cropping systems. Intercropping may offer a means of maintaining and increasing agricultural soil multifunctionality (SMF) without reducing productivity. However, whether the maintained or enhanced SMF by intercropping is related to the potential function changes of soil microbiome driven by intercropping is poorly understood, limiting the optimization of these systems for sustainable intensification. Therefore, we investigated crop yields and SMF in a long-term field experiment established in 2009. The study evaluated soil physical structure stability, carbon, nitrogen, and phosphorus cycling, abiotic stress regulation and related functional genes under intercropping systems (chickpea/maize, faba bean/maize, oilseed rape/maize, and soybean/maize) and monocultures of the component crops at three phosphorus fertilizer application rates (0, 40, and 80 kg P $ha^{-1}$). Intercropping significantly increased crop grain yields and SMF by 27.3 and 34.6%, respectively, compared with the weighted mean values of monocultures, irrespective of phosphorus application rate. It also significantly increased the relative abundance of genes related to carbon-, nitrogen-, and phosphorus-cycling functions by 15.2%, 10.8%, and 26.3%, and the relative abundance of genes was related to weighted mean diameter of aggregates, soil compaction, total nitrogen, soil microbial biomass carbon, soil respiration, soil nitrate reductase, β-cellobiohydrolase and leucine aminopeptidase. There were synergies between soil carbon and nitrogen cycling and between physical structure stability and carbon or nitrogen cycling, and trade-offs were observed between physical structure stability and phosphorus cycling. The positive effect of intercropping on SMF was associated with enhanced enzyme activities and other soil properties and consequently increased crop yields. The results highlight the important role of intercropping in sustaining soil function and elucidate the mechanisms involved, offering novel insights into its role in reducing dependence on non-renewable phosphorus resources in agricultural ecosystems.

**ABSTRACT**

Copper (Cu) contamination in soils is an ubiquitous threat for agricultural practices using plant protection products containing this element, with vineyards achieving the highest concentrations of Cu in soils among other permanent crops in Europe (Ballabio et al., 2018). Vineyards deeply characterize the planted area in Portugal, making it a priority to investigate Cu contamination in these soils. Adding to this, in relation to other European topsoils, Portugal is one of the countries with the highest average values of Arsenic (As) (Fendrich et al., 2024).

Having said this, the case study of this work is set in a vineyard in the Douro Demarcated Region, where levels of Cu and As in soils were found to reach 132.62 and 1957.45 mg $kg^{-1}$, respectively. Trying to understand the possible consequences of such levels of Cu and As, grapevine leaves and grapes were sampled, and the levels of these elements were quantified. Results obtained for leaves indicate that they are accumulating As up to 14.40 mg $kg^{-1}$.

In order to improve soil health in this vineyard, phytoremediation emerged as a viable way to reduce the total or available contents of these contaminants in soils. For this purpose, four native plant species found already in this vineyard, which may act as hyperaccumulators or metallophytes, were used in laboratory assays to assess their capability of accumulating Cu and/or As. Preliminary results for one of the tested plants show its potential to be used as a phytostabilization strategy, due to its higher capability of accumulating these elements in roots than in shoots, with levels of Cu in roots reaching 67.23 mg $kg^{-1}$. For As, the same trend was found regarding the element's distribution in plant tissues, but with As levels in roots as high as 941.69 mg $kg^{-1}$. Overall, results so far point to a possible phytostabilization strategy of both Cu and As, which can be concomitantly applied with grapevine crops.

## ABSTRACT

Copper fungicides, in continuous use since the late 19th century to fight diseases like downy mildew, have caused toxic copper (Cu) accumulation in vineyard soils. Even though Cu is an essential nutrient, in excess it can trigger oxidative stress in grapevines, harming plant health. The impact that Cu has will depend on soil properties and management, often forcing the plant to activate its antioxidant and detoxification systems to survive. Additionally, transcriptional reprogramming involving genes related to metal transport, redox homeostasis, and stress signaling can occur due to this exposure. This work intended to evaluate how Cu availability modulated by amendment application translates into molecular and physiological responses in grapevine tissues combining soil Cu dynamics, plant Cu accumulation, oxidative stress indicators, and transcriptome analyses. For this, vine plants were placed in fresh soil collected in a vineyard from the Vinhos Verdes Region of Portugal, contaminated with different concentrations of Cu and amended with a mixture of pine bark and mussel shell. Samples of leaves and soil pore water were collected after six months (T1) and one year (T2) of exposure, whereas samples of soil and roots were collected in T2. In all samples, the pseudo-total concentration of Cu was analyzed by ICP-MS after Aqua Regia extraction, whereas oxidative stress (lipid peroxidation and hydrogen peroxide) and antioxidant-related parameters (proline and glutathione) were evaluated only on the leaves. The results obtained demonstrated that time had a significant effect on the response of grapevine to the treatments and that the presence of amendments had significant effects in some of the biomarkers analyzed. Additionally, RNA-seq analysis was performed in leaves and roots at both timepoints to investigate the transcriptional mechanisms underlying the observed physiological responses. Exposure time was confirmed as a major driver of transcriptional variation, in agreement with biomarker patterns. Copper exposure induced dose- and organ-dependent transcriptional responses, whereas amendments had a stronger impact in leaves at the later timepoint. Combined Cu and amendment treatments resulted in interaction effects, particularly at T2, indicating non-additive transcriptional responses. These findings highlight organ-specific nature of grapevine responses to Cu and soil amendments and emphasize the importance of carefully addressing soil management practices as they can also shape physiological and transcriptional stress responses in poorly known pathways.

**ABSTRACT**

Integrating perennial cover crop (PCC) into crop rotation is widely advocated for enhancing soil health. Yet, detecting short-term (< 5 years) PCC effect on soil health remains challenging primarily due to the slow response of soil properties, which can limit its widespread adoption. To address this gap, we evaluated the effect of three years of perennial clovers in Dresden Ontario, by comparing soil health indicators across treatments (PCC and no PCC(NOPCC)) and sampling locations (in rows where the main crops were planted and between rows that were either bare soil under NOPCC or perennial clovers). Soil samples (0–15 cm depth) were collected 10 times from 2021 to 2023 where the crop rotation was corn-edamame soybean-winter wheat. We used soil microbial quantitative PCR (11 functional genes and 3 taxonomic markers), standard soil chemistry assays (5 indicators and micronutrients), and standard soil health assays (8 indicators and quality ratings with associated micronutrients) to assess temporal changes to soil health. Generally, PCC supported greater microbial functional gene abundance than NOPCC, including genes linked to nitrogen (N fixation by 26–77%) and phosphorous (P mineralization by 23–65%) cycling. Among soil chemistry and soil health assays, potentially mineralizable N and Solvita $CO_2$-C were greater with PCC than NOPCC, but limited changes were observed in soil organic matter and micronutrients. These findings indicate that microbial functional genes and labile chemical indicators are sensitive and potential early indicators of soil health change in response to management practices. Moreover, the PCC effect on soil health was more pronounced for samples collected between crop rows than within rows, highlighting the importance of sampling location in soil health assessment. The study provides a robust framework for assessing short-term soil health response to management practice, emphasizing the value of integrating soil functional genes and of PCC adoption.

## ABSTRACT

Protected horticulture enhances land-use efficiency and food security in China. However, regional variations in farming systems and their socioeconomic impacts remain poorly quantified. Through large-scale surveys of smallholder farms (n = 246) and environmental sampling (n = 1,230) across China (longitude: 102.54°–122.97°E, latitude: 23.92°–41.97°N), we determined that this sector can deliver 37.2% of the national vegetable output on only 1.4% of China's arable land and achieve yields up to six times higher than those in open-field systems. We also identify seventeen distinct protected farming systems varying in five adaptation strategies: agroclimatic optimization, regional specialization, precise land use, use of marginal soils, and soil sustainability practices. Scenario modeling shows that by 2050, strategic production relocation to climatically suitable regions and optimization of these farming systems could further enhance land use efficiency, indicated by a decrease in land area of 7–49% while increasing farmer employment by 20–156%. Thus, diversified, small-scale farming systems represent a transformative pathway for sustainable intensification, offering scalable solutions to global food security with regional policy support.

**ABSTRACT**

Decades of continuous phosphorus (P) inputs in excess of soil P holding capacity – up to ~ 571 kg P $ha^{-1}$ versus ~ 117 kg P $ha^{-1}$ in open-field vegetable systems – has led to significant accumulations of total P (TP) and Olsen P, as high as ~ 397 kg $ha^{-1}$ and 115 mg $ha^{-1}$, respectively, in the surface soils of greenhouse vegetable production (GVP) systems in China. These figures suggest that vegetables are the primary P-consuming crops in China, given the markedly lower P application rates of 137.7 and 158.9 kg $ha^{-1}$ for wheat and rice, respectively. This substantial imbalance has saturated over 90% of surveyed GVP soils with P, especially in long-term production zones. The resulting decline in P use efficiency (PUE) increases the risk of P mobilization and eutrophication. Nonetheless, sustainable P management strategies remain largely unexplored in the Chinese GVP systems. To partially address this, a critical soil Olsen P value of 22 mg $kg^{-1}$ has been established for the five major GVP bases in China, above which the subsurface P leaching exceeds its threshold value of 0.1 mg $L^{-1}$ that can initiate eutrophication. In accordance, over 80% of GVP soils in China are at high risk for P mobilization, particularly the coarse-textured soils in northern regions. However, these thresholds must be calibrated regionally in response to the local soil properties and agricultural management practices. Alternatively, we recommend integrating organic amendments (e.g., manure, straw) as partial substitutes for chemical fertilizers to reduce long-term P accumulation. To further enhance P retention, GVP fields could incorporate tile drains equipped with P-sorbent materials. Such systems would trap P from soil leachates, enabling its recovery and reuse while preventing eutrophication risks. Collectively, these measures support sustainable P management and safeguard both vegetable production and environmental quality in China's intensively managed GVP.

## ABSTRACT

Vegetables have a weak capacity to absorb soil nutrients, and their nitrogen-use efficiency is generally low, with a high amount of non-point-source nitrogen pollution. Nevertheless, there are often stark differences in nitrogen-absorption efficiency among varieties of the same vegetable species. However, research focused on screening for high nitrogen-use efficiency varieties, with the goal of reducing nitrogen pollution associated with vegetable cultivation, has been scarce. We here conducted a comprehensive evaluation of 100 cabbage (Brassica oleracea var. capitata) varieties (30 late-maturing and 70 early-maturing), assessing their yield, nitrogen absorption, and nitrogen-use efficiency. Using principal-component analysis and cluster analysis, varieties were classified into high-, medium-, and low-scoring groups. Field validation demonstrated that high-scoring varieties achieved a clear 'win-win' outcome. Compared to low-scoring varieties, their yields increased by a remarkable 47% and 76% for early-maturing and late-maturing varieties, respectively. Simultaneously, environmental nitrogen losses were curtailed in high-scoring varieties, reducing nitrogen leaching by 26%–56% and nitrogen runoff by 21%–22%. Compared with low-scoring varieties, high-scoring varieties reduced leachate nitrogen concentration by 6 to 41% and decreased leachate volume by up to 40%. By contrast, high-scoring varieties did not significantly reduce runoff volume, but they lowered nitrogen concentration in the runoff by 3 to 42%. This environmental benefit was attributed to both a decrease in leachate volume and significantly lower nitrogen concentrations in both leachate and runoff water. The underlying mechanism appears to be the superior ability of the high score varieties' aboveground biomass to absorb, transform, and regulate nitrogen, while simultaneously reducing moisture migration in the soil through coverage, thereby decreasing the residual nitrogen in the soil available for loss. Our findings establish that screening for high nitrogen-use efficiency varieties is a powerful and sustainable strategy for cleaner vegetable production, offering a practical pathway to reconcile high productivity with environmental protection without additional economic inputs.

# Dose-Dependent Effects of Biochar on Physiological Metabolism and Fruit Quality in Tomatoes

**Baihui Li[1], Jie Zhang[1*], Tingting Chang[1], Hanyu Zheng[1], Ronglu Wu[1], Yidan Zhang[1], Menglu Wei[1], and Luman Sun[1]**

[1] *College of Agricultural Science and Engineering (Hohai University, Nanjing, China)*

* zhangjiejxd@hhu.edu.cn

**ABSTRACT**

Biochar has gained significant attention as a soil amendment for its potential in sustainable agriculture by enhancing soil properties and crop productivity. This study systematically evaluated the effects of different soil biochar application rates (0%, 1%, 3%, and 5% by mass) on tomato (Solanum lycopersicum L.) physiology, growth, yield, and fruit quality. The results demonstrated that biochar amendment significantly influenced plant physiology by modifying the rhizosphere environment. Applications of 1% and 3% biochar effectively enhanced the leaf net photosynthetic rate and chlorophyll content, promoted increases in plant height and stem diameter, and facilitated the translocation of photosynthetic assimilates to fruits, thereby increasing yield. Furthermore, biochar treatment profoundly improved fruit quality metabolism by concurrently elevating the contents of soluble sugars, soluble proteins, and ascorbic acid (vitamin C), while also regulating organic acid composition, which ultimately improved the nutritional value and flavor profile of the fruits. However, the highest application rate of 5% showed a diminishing or inhibitory effect on some parameters, indicating the existence of an optimal application threshold. Collectively, our findings identify 3% as the optimal biochar application rate for synergistically enhancing both yield and quality in tomato production, providing a practical strategy for sustainable horticultural management.

# Microplastics Engineer Denitrification Hotspots in the Plastisphere to Drive Soil $N_2O$ Emissions

**Yaqiong Hao[1], Ju Min[1*], Weiming Shi[1]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008*

*Email: jmin@issas.ac.cn

**ABSTRACT**

Biodegradable plastics are widely regarded as an ideal alternative for mitigating agricultural "white pollution"; however, the potential impacts and microbial mechanisms of their microplastic residues on soil nitrous oxide ($N_2O$) emissions remain unclear. Here, we selected two typical vegetable field soils and conducted a 120-day microcosm incubation experiment. By combining $N_2O$ natural abundance isotope tracing, high-throughput sequencing, and molecular biology techniques, we systematically compared the effects of biodegradable microplastics (PBAT) and conventional polyethylene (PE) on soil $N_2O$ emissions. The results indicated that, unlike chemically inert PE, biodegradable microplastics (PBAT) significantly stimulated $N_2O$ emissions in both soils, with cumulative emissions increasing by 325% to 1094% relative to the control (CK). An isotopic dual-endmember mixing model confirmed that bacterial denitrification was the dominant pathway for $N_2O$ production. Mechanistic investigations revealed that PBAT biodegradation triggered a significant cascade effect: the depolymerization released dissolved organic carbon (DOC), potentially serving as critical electron donors for heterotrophic microorganisms. Simultaneously, a specific "plastisphere" microenvironment formed on the PBAT surface, significantly enriching denitrification functional genes *(nirS, nirK, nosZ*), with abundances far exceeding those in the bulk soil. This synergy of "carbon enrichment" and "gene aggregation" likely engineered efficient denitrification hotspots within the plastisphere, thereby driving sustained and explosive $N_2O$ emissions. This study confirms that biodegradable microplastics are not "inert bystanders" in the soil nitrogen cycle. While mitigating plastic pollution, they may pose a risk of exacerbating climate change—a trade-off that warrants high priority in future environmental risk assessments.

# Mechanisms of nitrate accumulation in solar greenhouse with long-term high nitrogen inputs in the Loess Plateau of China

**Mingxia Yang[1, 2*], Xiaofang Deng[1, 2], and Jianbin Zhou[1,2]**

[1] *College of Natural Resources and Environment, Northwest A&F University, Shaanxi, China*

[2] *Key Laboratory of Plant Nutrition and the Agri-environment in Northwest China, Ministry of Agriculture, Shaanxi, China*

*yangmingxia@nwafu.edu.cn

**ABSTRACT**

The intensification of agricultural practices in the Loess Plateau region of China has led to widespread overuse of nitrogen fertilizers. Characterized by its deep soil layers and strong nitrification potential, this region promotes the rapid conversion of applied nitrogen into nitrate, which accumulates extensively within the soil profile. This substantial accumulation of soil nitrate represents a primary source of groundwater nitrate contamination. Understanding the sources and dynamics of nitrate in groundwater under sunlight greenhouse systems is therefore critical for developing targeted pollution control strategies and protecting the environment in intensively managed agricultural areas.

Through a combination of questionnaire surveys and soil sample analyses, we quantified nitrogen inputs and nitrate accumulation in a typical sunlight greenhouse system. The total annual nitrogen input was 1428 kg N $ha^{-1}$, comprising 814 kg N $ha^{-1}$ from chemical fertilizers and 614 kg N $ha^{-1}$ from organic manure (primarily cattle and chicken manure). This excessive nitrogen application resulted in a profound accumulation of nitrate ($NO_3^-$-N) in the 0-10 m soil profile, with an average reserve of 4168 kg N $ha^{-1}$ and a maximum reaching 6443 kg N $ha^{-1}$. Notably, significant nitrate levels (exceeding 20 kg N $ha^{-1}$) were detected even at a depth of 10 meters, indicating substantial leaching driven by high nitrogen inputs and intensive irrigation.

Analysis of 42 groundwater samples collected from the greenhouse area revealed an average nitrate concentration of 101 mg $L^{-1}$, with an alarming exceedance rate of 60% relative to national drinking water standards.

These findings highlight a severe risk of groundwater nitrate pollution associated with the high-input management practices in sunlight greenhouses. The study provides a theoretical foundation for implementing measures to reduce agricultural non-point source pollution and facilitates the pursuit of sustainable agricultural development in the region.

# Dynamics of soil salinization and its combined effect with nutrients on the microbial community in solar greenhouses

**Xiaofang Deng[1, 2*], Lin Ma[1, 2], and Mingxia Yang[1, 2]**

[1] *College of Natural Resources and Environment, Northwest A&F University, Shaanxi, China*

[2] *Key Laboratory of Plant Nutrition and the Agri-environment in Northwest China, Ministry of Agriculture, Shaanxi, China*

*dxf@nwafu.edu.cn

## ABSTRACT

Soil nutrient surplus and secondary salinization are common challenges in solar greenhouse (SG) systems. However, the dynamic changes of soil salinity with cropping duration and the combined effects of nutrients and salinity on the microbial community remain poorly understood. Therefore, we collected soil samples in SGs with varying cropping duration (2-3, 12-13, 21-22, and 30-31 years) and grain fields (control), and physicochemical properties, salinity, and microbial communities were measured.

Results showed that SG cultivation significantly reduced soil pH while increasing electrical conductivity (EC) and nutrient contents (mineral N, available P, available K). During the first 20 years of SG cultivation, the contents of TSS, total cations, and total anions in the topsoil exhibited a consistent increasing trend with cropping duration, peaking at approximately 11.44, 1.33, and 10.11 g $kg^{-1}$, respectively. Subsequently, all three parameters decreased significantly (Fig. 1). SG cultivation markedly altered the soil ion composition. It significantly reduced the proportional contributions of $Ca^{2+}$ and $HCO_3^-$, while progressively increasing the relative abundances of $Na^+$, $SO_4^{2-}$, and $NO_3^-$.

Fig. 1 The total concentrations and the compositions of cation (a) and anion (b) salinities in the topsoil (0-20 cm) and subsoil (20-40 cm) of solar greenhouses. Points represent mean values. Black error bars represent standard deviations.

Soil nutrients and salinity collectively reduced bacterial and fungal α-diversity. Fungal communities were less affected than bacteria. The relative abundance of salt-tolerant phyla (*Bacteroidota*, *Chloroflexota*, *Actinomycetota*) increased, while *Acidobacteriota* decreased. Our analysis revealed differing co-occurrence networks for bacteria and fungi across cultivation durations, indicating that SG practices altered potential interspecific interactions. In bacterial networks during the initial 20 years of SG cultivation, we observed a continuous increase in nodes, edges, clustering coefficient, and network density, concurrent with decreases in average path length, diameter, and modularity relative to grain fields. This indicates that SG cultivation increased the complexity of soil bacterial networks but reduced their stability (Fig. 2). Soil nutrient accumulation increased the complexity of the bacterial co-occurrence network, salinity compromised its stability.

Fig. 7 Mantel test (a) for bacteria and fungi in the topsoil (0-20 cm). Partial least squares path models (PLS-PM) show the effects of soil nutrient and salinity on the bacteria (b) and fungi (c) diversity and network.

In conclusion, long-term intensive SG management promotes nutrient accumulation and secondary salinization, altering microbial diversity, community structure, and network interactions, thereby threatening system sustainability. These findings highlight the need for optimized management practices to mitigate soil degradation in protected agriculture.

# Organic fertilizer improves soil carbon sequestration via macroaggregate formation in intensively vegetable cultivation system

**Lijun Ren[1, 2, *], Roland Bol[1], Lili Dong[2], Hongtao Zou[2]**

*[1] College of Land and Environment, Shenyang Agricultural University, Shenyang 110866, People's Republic of China*

*[2] bInstitute of Bio- and Geosciences (IBG), Forschungszentrum Jülich, Jülich 52428, Germany*

*E-mail Address: renlj1996@163.com

**ABSTRACT**

Intensive vegetable production systems play a critical role in ensuring vegetable security in China and globally by maximizing yield per unit area and improving the efficiency of land and resource use. However, long-term intensive vegetable production accelerates soil organic carbon (SOC) and structural degradation loss. The application of organic fertilizer is considered a key mitigation strategy. The SOC-driven mechanisms underlying carbon (C) stabilization, aggregate formation, and mineral associations, however remain unresolved. We therefore to evaluate their effects on SOC quality and stability as well as aggregate stability using a 7-year field experiment conducted in Shenyang, China, on a Humic Cambisols soil. Four fertilization treatments, no fertilizer (NF), chemical fertilizer (CF), organic fertilizer (BF), and chemical plus organic fertilizer (CBF) were examined, with all fertilized treatments receiving an equivalent nitrogen input of 300 kg N $hm^{-2}$. The results showed that BF and CBF treatments-significantly improved soil physical properties together with macroaggregates (> 0.25 mm) formation and stability. The former also increase total and water extractable SOC concentrations of the aggregates, particularly in macroaggregates. Furthermore, the soils receiving organic fertilizer had the lowest C emissions. Structural equation modeling further revealed that enhanced macroaggregate formation was the primary pathway that strengthened SOC stability and reduced C loss. Overall, organic fertilizer effectively improved soil structure, enhanced C sequestration, and mitigated C emissions, offering a scientifically robust strategy for the more sustainable management of global intensive vegetable production system.

# Enhanced soil ecosystem multifunctionality and microbial community shifts following spent mushroom substrate application in protected vineyards

**Xiaochi Ma [1*] and Yan Ma [1]**

[1] *National Agricultural Experimental Station for Agricultural Environment, Luhe, Institute of Agricultural Resources and Environment, Jiangsu Academy of Agricultural Sciences, Nanjing, Jiangsu Province 210014, China*

*E-mail Address: xiaochima@jaas.ac.cn

**ABSTRACT**

Soil multifunctionality and microbial diversity in agricultural ecosystems are influenced by fertilization. Spent mushroom substrates (SMS) have recently been used as organic fertilizers, but their effects on soil and microbial functions in orchard ecosystems remain understood. A two-year field study was conducted to compare the different types (*Agaricus bisporus* and *Pleurotus eryngii* substrates) and application rates (equal to 975, 1575 and 2250 kg N $ha^{-1}$ $yr^{-1}$) of SMS on soil multifunctionality and microbial community properties in protected vineyard soils. The application of *Pleurotus eryngii* substrate at a N input rate of 2250 kg $ha^{-1}$ $yr^{-1}$ significantly increased soil multifunctionality by 48.04% compared to non-fertilized soil, due to reduced soil bulk density, increased soil nutrient content and enhanced soil enzyme activity. Additionally, SMS application significantly improved bacterial diversity and altered bacterial and fungal community structures, with changes positively correlated with soil organic matter content. Furthermore, SMS amendment primarily increased the relative abundances of keystone species categorized as module and network hubs in the bacterial co-occurrence network. Compared to *Agaricus bisporus* substrate, the application of *Pleurotus eryngii* substrate increased the relative abundances of organisms involved in aromatic compound degradation (38.63-71.18%) and saprotroph (3.14-4.40%), while significantly reducing pathotrophic fungi by 59.96-64.76%. It is noteworthy that Cu and Cd accumulations were increased by 7.92-52.54% in vineyard soils treated with SMS. However, the type and application rate of SMS had divergent effects on Cr and Pb accumulations, suggesting that the better microporous structure of *Pleurotus eryngii* substrate helps bind and passivate heavy metal ions depending on the element type. The contents of Pb, Cd and Cu significantly influenced the diversity and composition of soil microbes. Overall, the proper use of SMS improves soil multifunctionality, and *Pleurotus eryngii* substrate application could further enhance microbial network structures and ecosystem functions in protected vineyard soils.

## ABSTRACT

In highly weathered acidic soils (pH<5.5), excessive hydrogen ions ($H^+$) exacerbate the devastation of *Fusarium* disease and cause progressive decline in growth and development, yield loss, and economic shelf life of black pepper farming. A two-cycle pot study was attempted to determine the effects of Calciprill and sodium silicate to ameliorate soil acidity in addition to improving silicon (Si) uptake and use efficiency in immature black pepper vines against *Fusarium* disease on an acidic soil (Bekenu series, *Typic Paleudults*). There were eight treatments evaluated in this study where the soil was treated with Calciprill at 90% and 100% calcium saturations (C90 and C100) combined with sodium silicate at 150 kg $ha^{-1}$ (S150), whereas the soils without any amendments (C0S0) were included as control treatments to reveal how severe the pathogen can affect the productivity of immature black vines. Some of the immature vines were solely added with chemical fertilizers (NPK) and inoculated with or without *Fusarium* disease (F0 or F1) in weekly basis up to eight weeks, followed by soil analysis, plant growth measurements, and disease incidence and severity index determinations. Regardless of F0 and F1, results revealed that the soils with Calciprill and sodium silicate (C90+S150 and C100+S150) significantly ameliorated acidity by increasing soil pH, exchangeable calcium ($Ca^{2+}$), and water-soluble Si besides suppressing exchangeable acidity and aluminium compared with C0S0 and NPK. In terms of plant growth, the use of amendments also significantly increased aboveground and underground biomass production. The use of Calciprill and sodium silicate does not only improve the Si uptake and use efficiency in immature black pepper vines, but it also effectively mitigates the devastation of *Fusarium* disease by significantly reducing the disease incidence and severity compared with those vines without the amendments and those with solely application of chemical fertilizers (C0S0F1 and NPKF1). We concluded that the combined use of Calcirpill at 90% and 100% calcium saturations and sodium silicate at 150 kg $ha^{-1}$ (C90+S150 and C100+S150) were effective in improving the productivity of acidic soils and mitigating the *Fusarium* disease infection in immature black vines. Further research such as Si absorption mechanisms by the black pepper vines and economic viability studies were recommended to further validate the findings of this pot study.

## ABSTRACT

Intensive protected agriculture plays a critical role in maintaining food security and ensuring a stable vegetable supply. However, its long-term reliance on high-input management practices often accelerates soil degradation and threatens sustainable development. To explore effective green soil strategies, this study used greenhouse cucumber (Cucumis sativus L.) as a model crop and conducted a controlled field experiment to assess the impacts of Bacillus subtilis (BS), biochar (BC), and their composite biochar-based microbial fertilizer (MF) applied at four rates on soil physicochemical and biological properties, as well as crop growth and yield. An integrative Soil Quality Index (SQI) framework combining K-means clustering, principal component analysis (PCA), and canonical correlation analysis (CCA) was developed to quantify soil quality. Furthermore, partial least squares structural equation modeling (PLS-SEM) was employed to elucidate the multi-pathway response mechanisms of the soil–crop systems. The results showed that MF treatment outperformed individual BS and BC treatments in improving soil structure, nutrient availability, and microbial activity. Specifically, MF reduced soil bulk density by 10.8% and enhanced field capacity and saturated water content by 19.0% and 28.1%, respectively. It also increased available phosphorus and potassium contents by 28.9% and 39.4%, elevated urease activity by 29.1%, significantly improved microbial diversity, as evidenced by higher Shannon and Chao1 indices ($p < 0.05$). The MF achieved the highest SQI (0.79), representing a 46.3% improvement over the control, and increased cucumber yield by 24.23%, significantly outperforming the BS and BC ($p < 0.05$). Moreover, PLS-SEM analysis further revealed that MF enhanced soil quality and crop yield primarily through three synergistic pathways: strengthening water-nitrogen coupling (path coefficient, $\beta = 0.968$), activating phosphorus and potassium pools ($\beta = 0.885$), and stimulating organic matter turnover and enzyme activity ($\beta = 0.790$). Overall, this study demonstrates that MF substantially enhances soil quality and cucumber yield through multi-dimensional synergistic mechanisms. The proposed data-driven SQI framework provides a robust and comprehensive approach for quantifying soil quality dynamics, offering both a theoretical basis and practical guidance for sustainable soil management in intensive agricultural systems.

**ABSTRACT**

Plastic greenhouse soils often accumulate salts and lose soil structure under long-term mineral fertilization, compromising soil health. We evaluated organic substitution (manure and straw) as a soil management practice and tested whether nematode community assembly links habitat restoration to soil multifunctionality. In a five-year tomato-cucumber rotation in a solar plastic greenhouse (Tianjin, China), we compared an unfertilized control (CK), mineral fertilizer (NPK), and three substitution regimes with equal total N inputs: 100% manure (OF), 50% manure + 50% mineral N (MOC), and 25% straw + 25% manure + 50% mineral N (MCS). We quantified soil salinity (total salt content), organic matter and aggregate stability, a multifunctionality-based soil health index, and nematode diversity, trophic composition, co-occurrence networks and assembly (betaNTI; iCAMP). Relative to NPK, organic substitution increased soil organic matter by 33-48% (23.6 to 31.4-34.9 g $kg^{-1}$), improved physical structure (water-stable macroaggregates >0.25 mm: 0.93 to 0.97-0.98; bulk density: 0.94 to 0.81-0.85 g $cm^{-3}$), and reduced soil salinity by 53-62% (0.58 to 0.22-0.27). These habitat improvements increased nematode taxonomic and phylogenetic diversity, reduced plant-parasitic dominance and strengthened food-web complexity (denser, more modular networks). Null-model analyses indicated a shift from stochastic turnover under NPK to stronger heterogeneous selection under organic substitution. Soil multifunctionality increased with nematode taxonomic and phylogenetic diversity and with a higher beneficial-to-plant-parasitic balance, whereas functional richness showed little response. A PLS path model explained 81% of multifunctionality variation and supported a management cascade from improved soil chemical/physical conditions to nematode community restructuring and higher multifunctionality. Together, our results provide management-relevant, indicator-based evidence that partial-to-full organic substitution can reverse secondary salinization and structural degradation in plastic greenhouses without significant loss of crop-support indicators, and that nematode metrics can serve as practical bioindicators for soil health monitoring and optimization of fertilization practices in protected vegetable production.

# Cadmium Uptake by Maize Grown with Microplastics and Their Effect on Water Content and Grain Quality

**ABSTRACT**

Microplastics are a vector for heavy metal uptake into roots and shoots of grain crops. However, it is not known if they increase uptake into the grain. Therefore, the main objective of this experiment was to determine if grain of maize (*Zea mays* L.) had more cadmium (Cd) in it when grown with microplastics in the soil than when grown without microplastics. The microplastic used was polyethylene glycol, a hydrophilic polymer. Hydrophilic polymers have long been used to retain moisture in the soil. However, the soil water status in the presence of hydrophilic microplastics has not been reported. Therefore, a second objective of this experiment was to determine the water content of a root medium with and without polyethylene glycol when maize was grown in it. The effect of microplastics on grain quality is essentially unknown. A third objective was to determine the effect of microplastics on protein in maize grain. Maize was grown for 112 days under greenhouse conditions in pots (22 cm diameter; 20.5 cm height; with drainage holes) that contained a peat-based, commercial potting soil. The microplastic was polyethylene glycol (PEG) with molecular weight of 8000. There were four treatments: control pots watered with tap water; pots watered with 100 µg/mL Cd; pots watered with a 2% PEG solution; and pots watered with a 2% PEG solution plus 100 µg/mL Cd. It was a randomized complete block experiment with four blocks. Pots were irrigated with the same amount of irrigating solution. At harvest, Cd concentration in the grain of maize grown with PEG and Cd in the soil was 1.6 times higher than the Cd concentration in grain of maize grown just with Cd (94.7 and 57.4 µg/g, respectively). At harvest, height (+ standard error) of the plants was as follows: controls: 131.9+4.1 cm; no PEG, Cd: 107.6+2.8 cm; PEG, no Cd: 131.1+3.1 cm; PEG, with Cd: 100.9+3.0 cm. Throughout the experiment, pots with PEG in the soil retained more water than pots without PEG. Average gravimetric soil water content during the experiment was as follows: controls: 355.7+27.2%; no PEG, with Cd: 381.1+25.0%; PEG, no Cd: 532.0+18.5%; PEG, with Cd: 577.7+13.9%. At harvest, the protein in the grain was as follows: controls, 18.98+1.51%; no PEG, with Cd: 20.97+1.04%; PEG, no Cd: 25.39+1.11; PEG, with Cd: 30.30+1.25%. The results showed that PEG increased Cd concentration in the maize grain. Cadmium in the irrigating solution reduced height at harvest by about 30 cm compared to the control plants. The presence of PEG in the root medium increased the gravimetric water content by 1.5 times and protein in the grain by 1.4 times.

# Strategies to reduce cadmium and arsenic accumulation in rice to protect human health

**Fang-Jie Zhao**[1*]

[1] *College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing, China*

*E-mail: Fangjie.Zhao@njau.edu.cn

**ABSTRACT**

Rice is a staple food for about half of the global population, for whom rice is also a major dietary source of the toxic metal cadmium (Cd) and metalloid arsenic (As). Contamination of paddy soils with Cd and As is a common problem in some areas of Asian countries, resulting in elevated dietary exposure to Cd and As and significant health risk for the local residents. It is therefore imperative to develop strategies to limit Cd and As accumulation in rice. Substantial progress has been made in recent years on understanding of the biogeochemistry of As and Cd in paddy soils, providing a basis for controlling their bioavailability in soil, although the opposite biogeochemical behaviours of the two trace metal/metalloid in response to fluctuating redox status make it difficult to reduce the bioavailability of both elements simultaneously. Strategies have also been developed to limit the uptake or translocation of Cd and As by rice through plant breeding or biotechnology, based on recent progress on understanding the molecular mechanisms of their uptake, translocation and detoxification. These progresses and future research needs will be discussed in the presentation.

# Ecological and Human Health Risks of Heavy Metals in Coastal Sediments of Grand Bahama Island

**Williamson Gustave[1*] and Antonio J. Cadet[1]**

[1] *School of Chemistry, Environmental & Life Sciences, University of the Bahamas, Nassau, Bahamas*

* *Williamson.Gustave@ub.edu.bs*

**ABSTRACT**

This study quantified the concentrations of selected heavy metals, chromium (Cr), manganese (Mn), nickel (Ni), cadmium (Cd), antimony (Sb), lead (Pb), copper (Cu), arsenic (As), and zinc (Zn), in surface sediments collected from two coastal sites on Grand Bahama Island: Dover Sound (DS) and East End (EE). Metal concentrations were determined using inductively coupled plasma–mass spectrometry (ICP-MS). Mean concentrations exceeding sediment quality References values at Dover Sound were observed for Cd (25.64 ± 25.64 mg $kg^{-1}$), Sb (44.92 ± 9.62 mg $kg^{-1}$), and Cu (195.33 ± 67.51 mg $kg^{-1}$), while at East End exceedances were recorded for Cd (442.58 ± 137.06 mg $kg^{-1}$) and Sb (56.62 ± 8.31 mg $kg^{-1}$). The pollution load index (PLI) indicated that sediments at both sites were not polluted overall (PLI < 1). In contrast, the ecological risk index (RI) revealed high ecological risk (RI > 600) at most sampling locations, with the exception of sites D2, D3, and D4, largely driven by elevated Cd and Sb concentrations. Contamination factor analysis showed moderate contamination by Cu (1 ≤ CF < 3) and very high contamination by Cd and Sb (CF > 6), while geo-accumulation index values further suggest anthropogenic enrichment of Cd and Sb (Igeo > 1). Human health risk assessment indicates that As and Cd may pose both non-carcinogenic and carcinogenic risks to adults and children. These results demonstrate that localized metal enrichment in coastal sediments can generate disproportionate ecological and human health risks in small island environments, underscoring the need for continued monitoring of Cd, Sb, Cu, and As to support environmental management and resilience.

The authors acknowledge the generous support of the Wilson Foundation for research on Hurricane Dorian– related impacts on coastal sediments, groundwater, and soils in The Bahamas.

# A seminal paper, 25 years on: enrichment factors cited rather than understood

**M. Filella**[1*]

[1] *Department F.-A. Forel, University of Geneva, Geneva, Switzerland)*

*montserrat.filella@unige.ch

Determining whether soils, sediments, or waters are contaminated is a recurring challenge in environmental sciences. A widespread approach is to compare measured concentrations with so-called "natural" background values, often operationalised through pollution indices such as enrichment factors. However, the conceptual weaknesses of these approaches have been clearly identified for decades. In particular, a seminal paper published 25 years ago (Reimann and Caritat, 2000) demonstrated why enrichment factors cannot be used in a straightforward or universal manner, given the heterogeneity of the Earth's crust, natural element fractionation, analytical variability, and the influence of biogeochemical processes.

Despite being widely cited, this work is rarely cited correctly. In many cases, the original cautions and conditions attached to the use of enrichment factors are ignored or misunderstood, and the citation serves primarily as a formal justification for their routine application. As a result, enrichment factors have become a methodological reflex, frequently applied "blindly" and often in combination with several other indices, with little reflection on their scientific meaning or limitations.

This contribution revisits the arguments developed in the original study and examines how they have been subsequently interpreted—or misinterpreted—in the literature. Rather than re-demonstrating the technical limitations of enrichment factors, which are already well established, we focus on how and why a method that was explicitly criticised has nonetheless become standard practice. We argue that this trend reflects a broader issue in environmental research: the progressive loss of conceptual understanding behind commonly used tools, and the transformation of critical References into ritual citations.

By highlighting this disconnect between citation frequency and methodological understanding, we aim to stimulate discussion on good scientific practice, the responsible use of indices in contamination studies, and how the soil science community can better preserve and transmit the conceptual meaning of its analytical tools.

*E-mail wangchengchen88@126.com

**ABSTRACT**

Unintentional ingestion of arsenic (As) from contaminated mining and smelting soil poses significant health risks, particularly to liver function. While As-induced hepatotoxicity is documented, the mechanisms linking oral exposure to liver damage remain poorly understood. In this study, we characterized As bioaccessibility through in vitro Solubility Bioaccessibility Research Consortium assays and determined its relative bioavailability using the mouse model. Following 10-day oral exposure, bioaccessibility assays revealed significant variation in As availability. Bioavailable arsenic accumulated in liver tissue, leading to iron overload and oxidative stress. Integrative transcriptomic and metabolomic analyses revealed ferroptosis as the primary mechanism of As-induced programmed cell death in hepatocytes. We discovered that oral As exposure triggers a cascade leading to ferroptosis: disruption of iron homeostasis, impairment of glutathione metabolism, and excessive lipid peroxide production. Mechanistically, As exposure decreased cysteine and glutathione levels while promoting iron accumulation, creating preferred conditions for ferroptotic cell death. These changes were accompanied by altered expression of key iron regulatory genes and disrupted antioxidant pathways, affecting glutathione-dependent defense systems. Our findings establish ferroptosis as critical in As-induced hepatotoxicity and provide insights for risk assessment and therapeutic development. This work advances our understanding of As toxicity mechanisms and offers potential targets for intervention strategies.

# Particle and mass characteristics influence in vitro and in vivo lead bioavailability from multiple sources

**Xiaoping Li [1*], and Weixi Zhang [1]**

*[1] Department of Environmental Science, School of Geography and Tourism, Shaanxi Normal University, Xi'an, Shaanxi, 710062, PR China*

**ABSTRACT**

Whilst lead (Pb) exposure poses significant risks to human health, understanding its bioavailability (BA) from multiple sources remains challenging. Current human health risk assessments (HHRA) use 250 µm as the upper limit for ingestible particles. In order to achieve a more precise definition for suitable particle sizes, we studied two common lead ores, cerussite and galena, and sieved them into two size fractions: ≤50 µm and 50-250 µm. We then created mixed mineral systems using varying mass ratios (0%, 25%, 50%, 75%, 100%) of these compounds. We used a mouse model to measure the relative bioavailability (RBA) of lead in single and mixed mineral systems in five key tissues: blood, brain, liver, kidney, femur and tibia (bones), after 15 days of oral exposure. Our findings showed that the Pb-RBA across the combined endpoints was 33.1% (95% CI: 27.8%-50.9%) for the ≤50 µm fraction, which was 1.5 times higher than the 50-250 µm fraction (21.5%, 95%CI:18.4%-34.2%). We also assessed in vitro bioaccessibility (IVBA) using four different assays. The SBRC method proved to be the most accurate predictor of lead RBA. The study also presents a new method to estimate the RBA/IVBA of lead mixtures considering both size and mass. We hypothesized and verified that the Pb-RBA of compounds from multiple composite sources is closely related to the Pb-RBA of the single phases they contain and their fraction. The accuracy of this model predictions can reach 79.63%, and the R2 value is 0.64.

## ABSTRACT

Since the beginning of 21st century, soil heavy metal pollution has become increasingly prominent in China, with over-standard rate of polluted farmland sites reaching 19.4%. This poses a grave threat to food security and public health. The green remediation and safe utilization of polluted farmland is not only an urgent environmental challenge to be addressed in China, but also a long-standing research hotspot in the global academic community.

Heavy metal pollution in China's farmland features a wide distribution and high spatial heterogeneity, with slightly, moderately, and heavily polluted plots often coexisting in the same region. This makes it impossible for a single technology to address the issue systematically. Through over 20 years of joint research efforts, this study has broken through a series of key green remediation technologies for heavy metal-polluted farmland, overcome the challenges of low remediation efficiency, short durability, and high costs, and established replicable and promotable safe utilization modes.

1) to address the issues of slightly polluted farmland, which is characterized by large area, wide distribution, and high risk of crop heavy metal content exceeding standards, we originally proposed the concept of "Phytoexclusion" and developed iron-silicon-based soil amendments with multiple barrier functions. When applied in paddy fields, a fourfold barrier system is formed both inside and outside rice plants, including reduced soil metal bioavailability, increased metal absorption at the root surface (via enhanced iron plaque formation), downregulated expression of key genes (*OsNRAMP5*, *OsHMA2*, *OsLCT1*, etc.) involved in root uptake, xylem translocation, and phloem redistribution of heavy metals; and intraplant metal precipitation. Through the application of this iron-silicon-based soil amendment, the average cadmium content in rice grains decreased by 45.4%, arsenic content by 22.5%, and 100% of the rice grains met the national heavy metal standards.

2) to address the moderately polluted farmland where a single barrier technology fails to ensure crops meet safety standards, we identified a batch of heavy metal hyperaccumulator plant resources, and pioneered a high-efficiency heavy metal removal technology centered on "phytoextraction" in China. Based on the interfacial activation effect of phosphorus on arsenic, a phosphorus-based mobilization agent was developed, improving soil arsenic removal efficiency by 39.6%~50.0%. Leveraging the high affinity between cadmium and hydroxyl/amino groups, a chitosan-based carbon mobilization agent was formulated, increasing soil cadmium removal efficiency by 56.1%~116%, thus achieving the goal of reducing heavy metal content in farmland soils.

3) to address the heavily polluted farmland that requires strict regulation, we screened a batch of tolerant cash crops such as *Jatropha curcas*, *Boehmeria nivea* (ramie), and *Sorghum bicolor* (sweet sorghum), developed an alternative cropping - "Phytostabilization" technology based on iron-silicon regulation, and formulated standards including the '*Technical Specifications for Sweet Sorghum Cultivation in Heavy Metal-Contaminated Soils*'. This provides standardized alternative cropping strategies for heavily polluted farmland.

Based on the aforementioned research, this study has innovatively established a "*Phytoexclusion – Phytoextraction - Phytostabilization*" remediation technology system. Listed as key technologies for farmland remediation promotion by the Ministry of Agriculture and Rural Affairs (MARA) and the Ministry of Science and Technology (MOST) of China, this system has been implemented in standardized engineering applications across 23 provinces nationwide, covering a total area of nearly 400,000 hectares. It has continuously provided technical support for the remediation of heavy metal-polluted farmland soils in China.

*lijj393@mail.sysu.edu.cn

**ABSTRACT**

In studies of heavy metal contamination in rice, traditional frameworks have largely focused on the uptake and toxicity of soluble metal ions, while the colloidal forms widely present under flooded paddy conditions have received far less attention. Trivalent chromium (Cr(III)), in particular, is commonly regarded as a low-toxicity, easily precipitated species and is often underestimated in risk assessments. However, we found that under typical paddy redox conditions, Cr(III) readily forms colloids that exhibit markedly higher mobility and interfacial reactivity than the presumed precipitated form, thereby potentially increasing its entry into the food chain.

This study compared the uptake, translocation, and subcellular distribution of soluble versus colloidal Cr in rice. The results show that inorganic Cr readily transforms into colloids in aqueous environments; these colloids strongly adsorb to root surfaces and act as surface "reservoirs," substantially enhancing Cr accumulation in both roots and shoots. In contrast, strongly chelated soluble Cr remains relatively stable in solution, posing lower exposure to root surfaces and showing markedly reduced uptake and translocation compared with colloidal Cr. Building on this, we further investigated the cellular uptake pathways of Cr colloids of different sizes. Smaller colloids were more prone to enter cells through active uptake processes, whereas larger or more strongly adsorbing colloids were predominantly retained in the cell wall and root-surface microenvironments.

Under realistic agricultural conditions, the colloidal forms of heavy metals should not be overlooked; their formation, stability, and interactions at biological interfaces directly influence plant uptake and ultimately food safety. This work provides a mechanistic perspective essential for recognizing the risks associated with colloidal heavy metals and for guiding contamination management in paddy systems.

## ABSTRACT

Forests mediate the mercury (Hg) biogeochemical cycling between the atmosphere and terrestrial ecosystems, while there remain substantial knowledge gaps regarding the cycling processes. Here, we determined the mass flow and isotopic compositions/fractionations associated with Hg cycling in the air-water-plant-soil compartments in an evergreen broadleaf forest site in Southwestern China to reveal mechanisms underlying the cycling of Hg. It is found that that annual Hg mass flow is -26.8±12.7 μg $m^{-2}$ $year^{-1}$ for air-foliage $Hg^0$ flux, 6.7±20.5 μg $m^{-2}$ $year^{-1}$ for air-soil $Hg^0$ flux, 9.1±1.2 μg $m^{-2}$ $year^{-1}$ for bulk Hg deposition, 31.8± 10.6 μg $m^{-2}$ $year^{-1}$ for throughfall Hg deposition, 0.3± 0.1 μg $m^{-2}$ $year^{-1}$ for stemflow Hg deposition, and 1.8±0.4 μg $m^{-2}$ $year^{-1}$ for Hg runoff. Mass balance analysis using the flux data shows a 50.4±44.2 μg $m^{-2}$ $year^{-1}$ net atmospheric Hg sink. Interestingly, we observed the $\delta^{202}$Hg shift of 0 to -3.1‰ between air and foliage as leaf age increases, and so for the $\Delta^{199}$Hg shift of 0 to -0.15‰. The observed isotopic composition of foliage Hg and isotopic shift support re-emission of $Hg^0$ occurring after reductive loss from foliage. The $\delta^{202}$Hg shift cause by Hg evasion from soil in summer ranges -0.92‰ to -0.23‰ with a $\Delta^{199}$Hg shift from -0.25‰ to -0.10‰; while in winter only $\delta^{202}$Hg shift is observed with range of -0.28‰ to 0.41‰. Given the isotopic compositions found in soil pore gas ($\delta^{202}$Hg=-0.94±0.32‰, $\Delta^{199}$Hg=-0.49±0.07‰ and $\Delta^{200}$Hg=-0.03±0.04‰) and ambient air ($\delta^{202}$Hg=0.26±0.20‰, $\Delta^{199}$Hg=-0.16±0.06‰ and $\Delta^{200}$Hg=-0.05±0.04‰), legacy Hg re-emission is largely caused by dark reduction processes in deep soil in summer, and by photo-reduction processes in surface soil in winter. Moreover, the distinctly negative $\Delta^{199}$Hg (range of -0.40‰ in Oi to -0.47‰ in Oa) and ~0 $\Delta^{200}$Hg in organic soils indicate atmospheric $Hg^0$ deposition is the dominant source of Hg in soil. Finally, we observed positive $\Delta^{199}$Hg (0.57±0.32‰) and $\Delta^{200}$Hg (0.22±0.06‰) in bulk precipitation, however, the $\Delta^{199}$Hg and $\Delta^{200}$Hg in throughfall (-0.34±0.20‰ and 0.06±0.05‰), stemflow (-0.41±0.20‰ and -0.04±0.08‰) and runoff (-0.40±0.08‰ and -0.02±0.04‰) exhibit distinctly negative values. This suggests a significant atmospheric $Hg^0$ source contribution in throughfall (60±13%), stemflow (96±25%) and runoff (89±23%). Results from mass balance modeling show that atmospheric $Hg^0$ deposition accounts for ~75% of total atmospheric Hg deposition, ~2 times greater than values by the estimate from air-foliage/soil flux. Overall, this study highlights the governing role of atmospheric $Hg^0$ deposition and re-emission processes in Hg cycling of forest ecosystems. Knowledge gaps in mercury (Hg) biomagnification in forest birds, especially in the most species-rich tropical and subtropical forests, limit our understanding of the ecological risks of Hg deposition to forest birds. This study aimed to quantify Hg bioaccumulation and transfer in the food chains of forest birds in a subtropical montane forest using a bird diet recorded by video and stable Hg isotope signals of biological and environmental samples. Results show that inorganic mercury (IHg) does not biomagnify along food chains, whereas methylmercury (MeHg) has trophic magnification factors of 7.4−8.1 for the basal resource− invertebrate−bird food chain. The video observations and MeHg mass balance model suggest that Niltava (Niltava sundara) nestlings ingest 78% of their MeHg from forest floor invertebrates, while Flycatcher (Eumyias thalassinus) nestlings ingest 59% from emergent aquatic invertebrates (which fly onto the canopy) and 40% from canopy invertebrates. The diet of Niltava nestlings contains 40% more MeHg than that of Flycatcher nestlings, resulting in a 60% higher MeHg concentration in their feather. Hg isotopic model shows that atmospheric $Hg^0$ is the main Hg source in the forest bird food chains and contributes >68% in most organisms. However, three categories of canopy invertebrates receive ~ 50% Hg from atmospheric $Hg^{2+}$. Overall, we highlight the ecological risk of MeHg exposure for understory insectivorous birds caused by atmospheric $Hg^0$ deposition and methylation on the forest floor.

# Dietary strategies to reduce bioavailability and toxicity of lead, cadmium, and arsenic following oral exposure: Mechanisms and health implications

**Hong-Bo Li** [1*]

[1] *State Key Laboratory of Water Pollution Control and Green Resource Recycling, School of Environment, Nanjing*

* hongboli@nju.edu.cn

**ABSTRACT**

Currently, the health of the world population faces severe challenges due to exposure to multi-media, multi-pathway, and multi-heavy-metal compound pollution. Traditional heavy metal health prevention strategies have primarily focused on pollution source management. There is an urgent need to reduce intestinal absorption efficiency of heavy metals after ingestion, i.e., bioavailability. In-depth research on the factors influencing heavy metal bioavailability in the human body and its mechanisms of action, as well as the development of technologies to reduce heavy metal bioavailability, can provide innovative scientific solutions for the prevention and control of human heavy metal exposure. In recent years, the speaker has systematically conducted research on dietary regulation mechanisms to mitigate health risks from heavy metal exposure, with a particular focus on nutritional element antagonism and gut microbiota optimization. Firstly, the regulatory effects of calcium and iron supplementation on the expression of intestinal calcium, phosphorus, and iron absorption channels were revealed. A new understanding was established regarding the simultaneous reduction of lead, cadmium, and arsenic intestinal absorption through calcium supplementation. The optimal calcium and iron supplements for protective effects were identified. Additionally, new mechanisms were uncovered, showing how gut microbiota influences the absorption of nutritional elements, participates in the metabolic transformation of heavy metals within the gut, and regulates intestinal barrier functions to control heavy metal bioavailability. Furthermore, differences in cadmium bioavailability between rice and wheat, as well as between indica rice and japonica rice, were revealed. Based on Cd bioavailability differences, a novel dietary structure adjustment technique was established to reduce the risks of cadmium and arsenic exposure. Our research provides a comprehensive foundation for developing innovative approaches to mitigate heavy metal exposure risks through dietary and biological interventions, which are important to protect human health from toxic metal exposure in active manner.

# Agricultural Water Reuse: Effects on Soil and Ecosystem Health

**Benny Chefetz**

*Agricultural Research Organization – Volcani Institute*

*Hebrew University of Jerusalem*

*Rishon LeZion 7505101, Israel*

**ABSTRACT**

The use of reclaimed wastewater for agricultural irrigation is essential for water security in arid regions, yet it presents a challenge by introducing pollutants of emerging concern, specifically pharmaceuticals and personal care products (PPCPs), into the agro-environment. This study leverages Israel, which recycles approximately 90% of its wastewater for agricultural irrigation, as a Living Lab to investigate the fate of PPCPs across the water-soil-plant continuum and their potential for food chain transfer.

Analysis revealed widespread contamination: Reclaimed irrigation water and soils irrigated with this type of water contained tens of different PPCPs. Number of PPCPs and their concentrations strongly correlated with wastewater treatment type and source. Critically, PPCPs were detected in all tested crops (sampled across the country). Leafy greens exhibited the highest number of pollutants of emerging concern at the highest concentrations reaching up to >2000 ng/g. Carbamazepine and venlafaxine (psychoactive pharmaceuticals) exhibited the highest detection frequencies in the fresh produce. The accumulation factor of PPCPs in plant leaves was observed to decrease with increasing soil organic matter content.

The findings of this study, aligning with our publications in this subject, are of importance to human health, providing essential, real-world data that directly addresses the public health risk associated with consuming food irrigated with recycled wastewater. By demonstrating that xenobiotics like Carbamazepine—a compound known for its persistence and recalcitrance to conventional treatment— are successfully taken up by food crops and subsequently excreted in human urine following consumption of the produce, this research provides the necessary "proof of concept" to guide risk assessments. This concrete evidence is vital for the development of unified, health-protective regulations and advanced treatment strategies required to ensure the long-term safety and sustainability of water reuse for food production globally.

**ABSTRACT**

Soil salinization, driven by geogenic and anthropogenic factors, affects over 830 million hectares globally, severely compromising agricultural productivity, food security, and ecosystem stability. Salinity impedes plant growth via hyperosmotic stress, $Na^+/Cl^-$-induced ionic toxicity, and oxidative damage, particularly in arid, semi-arid, and coastal zones where irrigation and evaporation intensify salt accumulation. Conventional remediation methods (e.g., gypsum amendment, leaching) are often costly, energy-intensive, and ecologically unsustainable. In contrast, biosaline agriculture harnesses salt-tolerant halophytes for phytodesalination, a scalable, eco-friendly strategy that rehabilitates degraded soils while enabling resource-efficient production of food, fodder, bioenergy, and phytochemicals. This ABSTRACT focuses on the genus *Pennisetum* (Poaceae), including *P. glaucum* (pearl millet) and *P. giganteum* (Giant Juncao), as model dual-purpose systems. Though halophytes constitute <1% of terrestrial flora, they deploy sophisticated adaptations: osmotic adjustment via proline and glycine betaine, ion compartmentalization by *SOS1* and *NHX* transporters, and salt excretion through specialized glands. *Pennisetum* species thrive on marginal saline soils, improve soil structure, and yield high biomass for fodder, bioenergy, and biorefineries, while producing bioactive compounds with nutraceutical potential. Their $C_4$ photosynthetic efficiency, rapid growth, and genetic plasticity make them ideal for climate-resilient agriculture. We advocate a multidisciplinary framework integrating agronomy, soil science, and biotechnology to accelerate halophyte domestication, support farmer-centered policies, and apply genomic tools to enhance salinity resilience. This approach can convert saline lands into productive agroecosystems, advancing UN Sustainable Development Goals (SDG 2, 13, 15). Ultimately, redefining salinity from a constraint to a resource heralds a transformative, nature-based paradigm for 21st-century sustainable agriculture.

**ABSTRACT**

Arbuscular mycorrhiza fungi (AMF) enhance phosphorus uptake in As-hyperaccumulator *Pteris vittata*, but how hyphospheric P acquisition influences As accumulation remains unclear. We investigated the underlying mechanisms by measuring *P. vittata* growth, AMF colonization, As/P uptake, fatty acid metabolisms, and P transporter expressions. *P. vittata* was grown for 3 months in soil containing 100 mg/kg As with/without AMF, and 50 mg/kg P was applied to the rhizosphere or hyphosphere using a three-compartment rhizobox. Compared to rhizospheric P+AMF treatment, hyphospheric P+AMF increased *P. vittata* biomass by 24%, driven by its 22% greater AMF colonization. The increased colonization resulted from 1.4-fold greater fatty acid content to supply AMF with essential carbon, consistent with 2-fold greater expression of fatty acid synthesis (*PvFatM*) and lipid transport (*PvSTR*) genes. Hyphospheric P also activated two complementary P-transport pathways via upregulating expressions of plant *PvPht1;6* and AFM *RiPho84* and *RiPT7* by 1.8−2.2 fold for mycorrhizal uptake, and plant *PvPht1;3* by 2.5-fold for root uptake. Together, these processes elevated the frond As content in *P. vittata* by 29% to 9119 mg/kg. Our findings reveal that AMF-facilitated P uptake drives As hyperaccumulation through coordinated mycorrhizal and root uptake pathways, providing a mechanistic basis for optimizing phytoremediation in contaminated soil.

## ABSTRACT

Sparingly-soluble phosphate rock (PR), a raw material for P-fertilizer production, can be effectively utilized by the As-hyperaccumulator *Pteris vittata* but not terrestrial plants in most cases. In this study, we investigated the associated mechanisms by measuring organic acid exudation and acid phosphatase in the rhizosphere, and nutrient uptake and gene expression related to the As metabolism in *P. vittata.* The plants were grown in a soil containing 200 mg $kg^{-1}$ As and/or 1.5% PR for 30 days. Compared to the As treatment, the *P. vittata* biomass was increased by 33% to 4.6 g $plant^{-1}$ in the As+PR treatment, corresponding to 27% decrease in its frond oxidative stress as measured by malondialdehyde. Due to the PR-enhanced dissolved organic carbon (DOC) production in the rhizosphere, the Ca, P, and As contents in *P. vittata* fronds were increased by 17% to 9.7 g $kg^{-1}$, 29% to 5.0 g $kg^{-1}$, and 57% to 1045 mg $kg^{-1}$ in the As+PR treatment, thereby supporting its better growth. Besides, PR-induced rhizosphere pH increase from 5.0 to 6.9 promoted greater P uptake by *P. vittata* probably via upregulating low-affinity P transporters *PvPTB1;1/1;2* by 3.7−4.1 folds. Consequently, 29% lower available-P induced the 3.3-fold upregulation of high-affinity P transporter *PvPht1;3* in the As+PR treatment, which was probably responsible for the 58% decrease in available-As content in the rhizosphere. Consistent with the enhanced As translocation and sequestration, arsenite antiporters *PvACR3/3;3* were upregulated by 1.8−4.4 folds in the As+PR than As treatment. In short, sparingly-soluble PR enhanced the Ca, P, and As availability in *P. vittata* rhizosphere and improved their uptake via upregulating genes related to As metabolism, suggesting its potential application for improving phytoremediation in As-contaminated soils.

## ABSTRACT

The extensive use of chromium (Cr) in leather tanning creates a potential dermal exposure risk to consumers from toxic chromate (CrVI) in finished leather products. Here, we combined a large-scale market survey and permeability-based health risk assessment. First, we analyzed 470 commercial genuine leather products from 7 countries using a calibrated portable X-ray fluorescence spectrometer (pXRF). Measurements revealed exceptionally high total Cr, with 93% of samples exceeding 10,000 mg $kg^{-1}$, highest being 60,200 mg $kg^{-1}$. A positive correlation was found between product price and total Cr content ($R^2$=0.65), indicating higher levels in luxury full-grain leathers. To assess the bioavailable risk, we quantified bioaccessible Cr in artificial sweat extracts using pXRF (474–4,460 mg $kg^{-1}$), achieving excellent agreement with ICP-OES data ($R^2$=0.992). Critically, this bioaccessible Cr pool showed a strong correlation ($R^2$=0.77) with CrVI content determined by ICP-MS ranged from 0.33 to 141 mg $kg^{-1}$, with 86% of samples exceeding the European Union limit of 3 mg CrVI $kg^{-1}$. Specifically, color-based analyses suggest that brighter-colored leathers exhibited higher bioaccessible Cr and CrVI contents. Moreover, 5 leather samples with the highest bioaccessible Cr were further assessed for Cr permeation through mouse skin by Franz diffusion cells, indicating a positive correlation between permeable Cr and CrVI concentration in simulated sweat solution, which were utilized to refine exposure for human health risk assessment. Long-term dermal exposure to Cr in leather products may pose both permeable-Cr induced non-carcinogenic and permeable-CrVI induced carcinogenic risk for adults and children. This study demonstrates that pXRF can be transformed into a validated tool for rapid, risk-based screening, providing a method to monitor and mitigate Cr exposure from the global leather consumer market, highlighting bright-colored luxury leather products may pose carcinogenic risk via dermal contact, emphasizing the need for increased attention to potential Cr exposure from leather products.

**Keywords**

Portable X-ray fluorescence spectrometer; full-grain leather by Cr tanning; Cr bioaccessibility and speciation; Franz diffusion cell with mouse skin; permeable-chromate induced carcinogenic risk.

**ABSTRACT**

The increasing frequency of extreme climate events threatens agricultural production and food security, especially in tropical regions. Climate adaptation management solutions that enhance soil health are key strategies to ensure production stability and improve the resilience of agricultural systems. Understanding how soil processes interact to support ecosystem functioning is essential for elucidating the pathways through which management influences yield. Here we reveal how sustainable management practices that increase agroecosystem diversification influence the functional networks that underpin soil health, resilience and stabilize yields in a region highly exposed to climate variability. Thirteen farmer-led experiments under contrasting management were assessed through topsoil (0–10 cm) sampling. Twelve chemical, physical, and biological soil health indicators were integrated through Exploratory Factor Analysis to derive latent soil function constructs. A Structural Equation Modeling framework quantified how diversification influences crop yield and crop instability through soil-health-mediated pathways. The soil indicators explained 79% of soil health variance, while crop yield was explained at 64% by the model. Soil health emerged as the primary mediator linking diversification to crop yield, acting through direct effects and four indirect pathways: (i) complex pore networks formed by diverse root systems provided physical support for plant growth and enhanced carbon dynamics and storage; (ii) improved physical structure promoted greater soil water storage; (iii) nutrient balance and microbial functioning enhanced the biochemical regulation of soil processes; and (iv) diversification directly increased soil water retention, jointly sustaining higher yields. Maintaining soil cover in diversified systems created a protective buffer against degradation driven by extreme climatic events. Crucially, healthier soils reduced crop instability by improving water retention and buffering crops against climatic fluctuations. Crop instability exerted strong negative effects on yield, demonstrating that resilience is strongly shaped by soil health mediated responses. Integrated diversification strategies led to yields up to 2.5 times higher than the state average, emphasizing that soil health is a critical mechanism through which diversified tropical agroecosystems achieve greater stability and predictability under climate stress. Strengthening soil multifunctionality through diversified management offers a solution that integrates both adaptation and mitigation, contributing to climate resilience and long-term food security in vulnerable tropical agricultural regions.

**ABSTRACT**

In light of rapid urbanisation globally, urban expansion is creating pressure on soil ecosystem services, threatening their ecological functions. The soil microbial community is essential for sustaining soil health and ecosystems, yet its distribution patterns and driving mechanisms within highly heterogeneous, fragmented urban environments remain unclear. This study focuses on five types of urban parks in Ningbo (Zhejiang, China). The research aims to (1) test the applicability of the classical species-area relationship (SAR) to soil microbial communities in urban parks; (2) elucidate how soil environmental factors mediate the relationship between park area and microbial community; (3) identify the key socio-economic and climatic factors that interact with natural variables to indirectly shape microbial community; (4) examine the habitat heterogeneity hypothesis as a potential mechanistic explanation for the observed SAR; and (5) clarify the synergistic regulatory mechanisms of natural and anthropogenic factors on the multifunctionality and service sustainability of urban park soils. By the application of environmental DNA (eDNA) technology, we construct a drivers-functions-management analytical framework in this study. The findings are expected to provide empirical scientific support for ecology-based urban soil conservation and resilience management.

**KEY WORDS:** Urban Parks, Soil Microbial Diversity, Environmental DNA, Species-area Relationship, Multi-dimensional Drivers

# Health risk assessment of dietary cadmium exposure based on cadmium bioavailability in food: opportunities and challenges

**Di Zhao**[1*]

[1] *College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing, China*

*dizhao@njau.edu.cn

**ABSTRACT**

Long-term exposure to cadmium (Cd) through contaminated food can lead to multiple adverse health effects. Although previous studies have addressed global food Cd concentrations and dietary Cd exposures across different populations, there are increasing concerns regarding the adequacy of current food Cd safety standards to protect populations from adverse health effects. Moreover, food Cd relative bioavailability (Cd-RBA) has been shown to improve the accuracy of health risk assessment, however, factors influencing food Cd-RBA have not been systematically discussed, hindering its application in risk assessment. This review aims to provide an overview of Cd contents in food, discuss concerns regarding international food Cd concentration standards, explore factors influencing food Cd bioavailability, and highlight the opportunities and challenges in refining differences between dietary Cd intakes and body burdens. Our findings suggest that current safety standards may be insufficient to protect human health, as they primarily focus on kidney damage as the protective endpoint and fail to account for global and regional variations in food consumption patterns and temporal changes in dietary habits over time. Factors such as crop cultivars and food compositions greatly influence food Cd-RBA. To improve the accuracy of Cd health risk assessment, future studies should incorporate food Cd-RBA, sociodemographic characteristics, nutritional status, and incidental Cd exposure. This review highlights new insights into food Cd safety standards and Cd bioavailability, identifies critical knowledge gaps, and offers recommendations for refining health risk assessments. This information is essential in informing future bioavailability investigations, health risk assessment, and safety standard development.

# How Does Vegetation Cover Alter Mercury Accumulation and Mobility in Soils of Guizhou?

**Namu Moduzuo[1*], Aoyu Wang[1], Liping Yang[1], Jicheng Xia[1,2]**

*[1]Education, College of Resources and Environmental Engineering, Guizhou University, Guiyang 550025, China*

*[2] Urban karst critical zone & climate-environmental change observation and research station of Guizhou Province, Guiyang 550081, China*

[*] gs.mydznuo24@gzu.edu.cn

**ABSTRACT**

Mercury (Hg) is a global pollutant. As the core area of the southwest karst region in China, Guizhou faces prominent soil Hg pollution risks due to the combined effects of high Hg geological background and anthropogenic activities. Since 1990, the forest coverage rate in Guizhou has increased significantly from 14.8% to 63.3%. Changes in vegetation cover may regulate the adsorption, migration, and speciation transformation processes of soil Hg. Taking a typical karst area in Guizhou as the research object, this study systematically revealed the impact of vegetation cover change on soil Hg fractionation and migration by integrating field sampling data of 470 topsoil samples, remote sensing NDVI data, climate factors, and land use information, Correlation analysis, principal component analysis (PCA), and structural equation modeling (SEM) were used to systematically reveal the effects of vegetation cover change on soil Hg speciation differentiation and migration.. The results showed that the total soil Hg (THg) content in the study area presented a distribution characteristic of cropland > rice paddy> forestland > grassland, while the proportion of Dissolved Hg (DHg) was the highest in forestland (0.133 ng $g^{-1}$). Significant differences in Hg distribution patterns were observed between karst and non-karst areas. Vegetation significantly enhanced soil Hg retention through litter accumulation and root adsorption. This study clarified the driving mechanism of vegetation cover on soil Hg fractionation and migration, identified the key points of Hg pollution prevention and control for different vegetation types, provided a new perspective for in-depth understanding of the soil Hg cycling process under special geological backgrounds, and offered scientific basis for regional Hg pollution risk management and ecological restoration.

# Calcium in Soil Health: Beyond pH Management to Mitigating Phosphorus Overuse and Enhancing Carbon Stabilization

**Xiaoming Zou and Yan Ma**

*Jiangsu Academy of Agricultural Sciences, Institute of Agricultural Resources and Environment, and Key Laboratory of Coastal Saline-Alkali Soil Improvement and Utilization, Ministry of Agriculture and Rural Affairs, Nanjing 210014, China*

xzou@jaas.ac.cn

**ABSTRACT**

Calcium (Ca) is a fundamental regulator of soil health, yet its management in agriculture remains narrowly focused on pH correction, overlooking critical ecological and physiological consequences. This synthesis argues for an optimal, rather than maximal, Ca strategy in agroecosystems based on three interconnected lines of evidence. First, while Ca is essential for soil structure and plant function, excessive Ca can induce stomatal closure and disrupt plant water relations, impairing photosynthesis and resilience under stress. Second, we present a paradigm-shifting perspective on global phosphorus (P) overuse: historical and ongoing misapplication of P fertilizers—particularly in the form of calcium phosphates (e.g., SSP, TSP)—and routine liming have inadvertently driven a hidden over-application of P to meet perceived crop needs of Ca. This has exacerbated soil P accumulation, eutrophication risks, and inefficient use of finite P reserves. Third, Ca plays a vital but underutilized role in soil organic carbon (SOC) stabilization through the formation of Ca-organic complexes, aggregation, and protection of organic matter against microbial decomposition. Re-framing Ca management toward optimal levels could thus simultaneously reduce P pollution, enhance C sequestration, and support plant physiological health. We call for integrated soil–plant Ca diagnostics, Ca-aware P fertilizer recommendations, and a precise nutrient management strategy that leverages Ca's dual role in nutrient stewardship and climate-smart soil systems to achieve sustainable development goals on food security, water quality, and climate action.

# Biochar laced with elemental sulfur restores microbial function in aridland soils

**Bashair Al-Maghatasi[1], Daniel Blackburn[1*], Buthaina Al-Siyabi[1], Said Al Ismaily[1]**

*[1] Department of Soils, Water and Agricultural Engineering, Sultan Qaboos University, PO Box 34, Al Khoud 123, Muscat, Sultanate of Oman*

*danielblac@squ.edu.om

**ABSTRACT**

Degraded arid soils often exhibit low microbial activity and impaired nutrient cycling, limiting their capacity to sustain ecosystem functions. This study evaluated the individual and combined effects of biochar (B), and elemental sulfur (S) on soil microbial abundance, enzyme activities, functional gene profiles, taxonomic diversity, and functional diversity related to carbon (C), nitrogen (N), and sulfur (S) cycling. After two months of amendment application, microbial enumeration, enzyme assays, qPCR, high-throughput sequencing (16S rRNA and ITS), functional annotation (FAPROTAX), and multivariate analyses were integrated to assess soil biological responses. Biochar treatments significantly increased bacterial, fungal, and actinomycete abundance, reflecting improved habitat structure, organic substrate availability, and nutrient supply. Biochar reduced the microbial metabolic quotient ($qCO_2$), indicating enhanced microbial carbon use efficiency, whereas sulfur increased $qCO_2$, likely due to shifts toward sulfur-oxidizing communities and altered carbon availability. Sulfur inhibited urease activity when applied alone or with other amendments, consistent with its acidifying and urease-inhibitory role. The combined S+B treatment produced the highest urease activity and balanced enhancement of multiple enzymes, indicating synergistic effects on soil biochemical functioning. qPCR analyses revealed that biochar strongly upregulated carbon degradation genes (e.g., alkane and aromatic hydrocarbon monooxygenases), while suppressing some nitrogen fixation genes. Compost combined with biochar enhanced both C- and N-cycle genes, confirming improved nutrient availability and microbial stimulation. Sulfur addition promoted genes associated with nitrification, denitrification, and sulfur transformation, highlighting its role in driving redox-sensitive pathways. Sulfur promoted functional redundancy within C–N–S cycling but lowered diversity indices due to dominance of specialized guilds. Overall, the combined application of biochar and sulfur most effectively enhanced microbial abundance, functional breadth, and coupled C–N–S cycling. These findings demonstrate that co-amendment strategies optimize soil biological function and resilience in degraded arid soils, supporting sustainable soil management and nutrient cycling. Keywords: biochar; sulfur; amendment; Aridland

# Variation in Arsenic Accumulation and Remediation Potential among Different Genotypes of Pteris vittata

**Yue Cao[1*], Mengyang Xu[1], Wumei Xu[2] and Dan Sun[1]**

[1] *School of Environment Science and Engineering, Sun Yat-sen University, Guangzhou, China*

[2] *School of Energy and Environment Science, Yunnan Normal University, Kunming, China*

* caoy85@mail.sysu.edu.cn

**ABSTRACT**

Arsenic (As), a widespread toxic metalloid, poses a serious threat to food safety and human health through soil contamination. Phytoremediation, especially using hyperaccumulators, offers an environmentally friendly and cost effective approach for As-contaminated soil. Pteris vittata is the first discovered As hyperaccumulator, exhibiting strong As tolerance and accumulation capacity. It is widely distributed worldwide, and adaptation to different environments has led to diverse populations. Previous studies show significant differences in morphology, genetic makeup, and As accumulation among different populations of P. vittata.

To clarify the differences in As accumulation among genotypes and to identify optimal materials for remediation, this study collected large scale samples from 53 sites across China and introduced three foreign genotypes as an outgroup for calibration. Phylogenetic trees were constructed using chloroplast genome sequences. Morphological traits such as plant height, frond number, leaf shape index, and pinna density were measured. Under greenhouse conditions, spore germination, uniform cultivation, and As treatment experiments were conducted to compare biomass, shoot As concentration, and total As accumulation among populations. Finally, four ecotypes (JS NJ2, GZ ZY, US F3, GX GL1) showing outstanding performance in long term low As soil culture were selected for a two year field remediation evaluation in As-contaminated farmland.

Results showed that based on chloroplast genome evolution analysis, Chinese P. vittata genotypes formed three distinct clusters, indicating differentiated populations. Morphological traits varied significantly among regional types. Under greenhouse conditions, biomass, shoot As concentration, and total As accumulation differed by up to 15.9-, 3.6-, and 23.6 fold, respectively, among genotypes. Analysis of element correlations and expression of key As accumulation genes suggested that the differences in As accumulation may be related to As uptake mediated by Pht1 genes. Five genotypes with high per plant As accumulation and one commonly used remediation genotype were tested in As-contaminated soil. Significant differences in As accumulation capacity were observed, with the ecotype JS-NJ2 performing best, showing a 2-fold improvement compared to the currently used remediation genotype. JS-NJ2 is thus proposed as a suitable material for As-contaminated soil remediation.

This study systematically compared differences in morphology, phylogeny, and As accumulation traits among P. vittata genotypes, revealed potential molecular mechanisms underlying As accumulation, and identified superior ecotypes for field remediation. The findings provide both theoretical support and practical materials for enhancing the efficiency of phytoremediation in As-contaminated soils.

**ABSTRACT**

There are approximately 4.3Mha of olive trees (*Olea europaea* L.) in the EU, with most of this area located in Spain (50%), Italy (27%) and Greece (16%). Conventional tillage, fertilization and phytosanitary practices are the most widespread management systems in many of these olive-growing regions. The intensification of cultivation is widely recognized as one of the most significant human induced alterations to the global environment. Concerned by these issues, the European Commission has initiated agro-ecological policies promoting environmental-friendly practices. In this context, the interest is being focused on crop production systems, such as organic and integrated agriculture, that optimize yields while preserving soil quality and protecting the environment.

The aim of this study was to evaluate the effect of different olive farming management systems (conventional, integrated and organic) on soil microbial community structure and functional diversity. To obtain a wider perspective of soil health under the different farming systems, these soils were compared them with those from natural ecosystems (Mediterranean forest-shrubland).

The study was conducted at three different locations representative of mountainous olive orchards of South-Eastern Spain. Microbial functional diversity was assessed using MicroResp™ system, a whole-soil method based on community level physiological profiles (CLPP) obtained by testing the utilizations of different carbon sources. In addition, microbial community structure was evaluated analyzing soil ester linked fatty acid profiles (ELFA).

Substrate utilization profiles did not show significant differences among different management systems when analyzed overall. However, these differences were pronounced when management systems were compared within individual study areas.

Significant differences in microbial community structure (ELFA) were observed among different study areas. In contrast, differences in soil microbial communities among agricultural management systems were less pronounced. Nevertheless, a gradual shift in microbial composition was observed from conventional agricultural systems to ecosystems with natural vegetation. This shift was associated with a decrease in fungi markers and monosaturated fatty acids and an increase of fatty acids with hydroxyl group.

Both microbial approaches, particularly ELFA analysis, proved to be good indicators of soil health and were sufficiently sensitive to detect changes in soil quality resulting from olive management systems when compared with natural vegetation ecosystems. However, although different olive management systems (organic, integrated and conventional) showed significant differences in terms of soil microbial community structure (ELFA), they did not differ markedly in terms of functionality (CLPP), suggesting certain functional redundancy of soil microbial communities of these agro-ecosystems.

# Seeing is believing: Exploring metal interactions in rice paddies using chemical imaging tools

**Dong-Xing Guan[1]*, Chao Zhang[1], Jia-Lu Gao[1], and Lena Q. Ma[1]**

[1] *State Key Laboratory of Soil Pollution Control and Safety, College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, 310058, China*

*dxguan@zju.edu.cn

**ABSTRACT**

Understanding the interactions between cadmium (Cd), manganese (Mn), and selenium (Se) is crucial for managing their bioavailability in rice paddies. This study integrates findings from multiple field and rhizotron experiments, employing a suite of *in situ* chemical imaging tools, including diffusive gradients in thin-films (DGT), planar optodes (PO), and soil zymography, to visualize and quantify these dynamics. High-resolution DGT imaging revealed spatially heterogeneous, inversely correlated fluxes of labile Cd and Mn in the rhizosphere. The application of Mn oxides ($MnO_2$ and $Mn_2O_3$) significantly reduced Cd bioavailability (by up to 28.9%) and uptake in rice. This remediation effect was mechanistically explained by the DGT-induced fluxes in soils (DIFS) model, which showed that Mn addition prolonged the soil solid-phase response time ($T_c$) and slowed the Cd desorption rate ($k_{-1}$). In naturally enriched soils, DGT measurements further identified a critical labile Se:Cd molar ratio; values below 0.7 indicated Cd risk, whereas ratios increasing from 0.7 to 20 progressively lowered grain Cd concentration. The integrated chemical imaging platform consistently outperformed traditional extractions in predicting grain metal uptake. This work demonstrates that direct visualization via chemical imaging, coupled with kinetic modeling, provides unparalleled insight into metal interactions. It offers a powerful approach for developing targeted strategies to mitigate Cd contamination and leverage beneficial Se and Mn interactions for safer rice production in contaminated or geogenically enriched paddies.

## ABSTRACT

Nonferrous metal smelting is one of the predominant sources of heavy metal accumulation in the environment. China is the world's largest producer and consumer of several highly toxic heavy metals. Over the past three decades, the production of Pb, Cd, and Zn in China has undergone three major phases: a rapid growth phase characterized by weak pollution control, a slowdown phase, and a rejuvenation phase. The shutdown of many small-scale smelters between 2005 and 2012 substantially reduced heavy metal emissions from smelting activities; however, large amounts of legacy heavy metals accumulated in soils, dust, and sediments at smelting sites still require proper management. Measures such as relocating residents from contaminated areas to clean areas and converting polluted farmland to forest are among the most effective approaches for reducing human exposure to heavy metals. There is also evidence that heavy metal concentrations in local ground dust have steadily declined over the past decade. Another important source of Cd pollution is Cd battery manufacturing, which has caused severe Cd accumulation in soils and wheat grains in Xinxiang, China.

Soil is the primary sink for heavy metals emitted from industrial activities. After contaminated farmland is no longer used for crop cultivation, the transfer of heavy metals to humans through crops is greatly reduced; however, the migration of pre-existing heavy metals in soil to higher trophic levels of the food chain still occurs, a process that remains insufficiently studied. In this study, the transfer of soil heavy metals was investigated in both a soil–native plant–woodlouse system and a soil–free-range chicken system.

In the soil–plant–woodlouse system near a long-term nonferrous metal smelter, paired soil samples (total Cd: 1.15–34.5 mg/kg; total Pb: 36.7–1090 mg/kg), native plants (Humulus scandens, Digitaria sanguinalis and Setaria viridis), and woodlice (Armadillidium vulgare) were collected and analyzed to assess heavy metal transfer. The native plants exhibited higher bioconcentration factors (BCFs) for soil Cd, Cu, and Zn than for Mn, Ni, and Pb, although all BCF values were <1.0. Mean concentrations of Cd, Cu, Mn, Ni, Pb, and Zn in woodlice were 20.5, 697, 169, 5.41, 472, and 424 mg/kg, respectively. The BCFs of woodlice indicated much greater accumulation of Cu, Cd, and Zn than of other metals, suggesting an elevated health risk for woodlouse predators. Mean woodlouse BCFs for plant Cd, Cu, and Zn were 11.2, 52.6, and 10.6, respectively. For samples collected at increasing distances from the smelter, a declining trend in woodlouse Cd concentrations was observed, whereas no such trend was evident for Pb. In addition, the bioaccumulation factors of Cd and Pb in woodlice from plants and soil exhibited a nonlinear decrease with increasing heavy metal concentrations in soil or plants.

In the soil–free-range chicken system, samples of free-range chicken organs (liver, kidney, heart, intestine, and gizzard) were collected from areas affected by nonferrous metal smelting, Cd battery production, and from areas free of heavy metal contamination. The results showed that free-range chickens raised near the nonferrous metal smelter and in the Cd battery production area contained substantially elevated Cd concentrations in their organs. In the Cd battery production area, mean Cd concentrations followed the order: liver (8.33) > gizzard (4.66) > kidney (1.80) > intestine (1.45) > heart (0.390 mg/kg, dw). In the nonferrous metal smelting area, the sequence was liver (5.11) > intestine (2.23) > gizzard (1.75) > kidney (0.650) > heart (0.123 mg/kg). In contrast, Cd concentrations in market chicken samples were all <0.1 mg/kg, ranging from 0.0102 to 0.0877 mg/kg. In areas free from heavy metal contamination, organ Cd concentrations of free-range chickens ranked as intestine (0.130) > gizzard (0.0900) > liver (0.0763) > kidney (0.0235) > heart (0.0151 mg/kg). In the nonferrous metal smelting area, Pb concentrations in free-range chicken organs followed the order: intestine (1.73) > liver (1.29) > gizzard (0.849) > kidney (0.743) > heart (0.300 mg/kg).

Comparisons among different chicken samples indicate that: (i) in nonferrous metal smelting areas and Cd battery production areas, there is a significantly increased risk of Cd exposure to consumers through the consumption of free-range chicken organs, and free-range chicken farming should be prohibited in such contaminated areas; (ii) in nonferrous metal smelting areas, similar risks also exist for Pb exposure; and (iii) compared with Chinese food quality standards, market chickens and free-range chickens from non-polluted areas contain Pb and Cd at safe levels.

Overall, these results highlight the persistent risks posed by legacy heavy metals in contaminated soils. Strict control of land use and careful consideration of heavy metal transfer from soil to the food chain are essential in polluted areas.

## ABSTRACT

Microbial communities are pivotal to soil and environmental health, ecological functions and agricultural productivity. However, microbial community responses to soil cadmium (Cd) contamination remain unclear. Therefore, we comprehensively analyzed bacterial and fungal diversity, composition and community stability in both topsoil (0–20 cm) and subsoil (20–40 cm) from a long-term wastewater-irrigated farmland on the North China Plain, under low (mean Cd = 0.53 mg/kg), medium (1.23 mg/kg), and high (2.64 mg/kg) Cd levels. Results showed that topsoil fungal Hill-α diversity decreased significantly with rising Cd levels. Differentially abundant operational taxonomic units (OTUs) across Cd levels were mainly affiliated with bacterial Phyla Acidobacteriota, Actinobacteriota, Bacteroidota and Chloroflexi, and fungal Phyla Ascomycota, Basidiomycota, Chytridiomycota and Mortierellomycota, respectively. Only 1%–10% of OTUs exhibited monotonic changes in relative abundance with increasing Cd contents. Cd levels significantly altered microbial community structures (β-diversity), explaining 34.1%–63.7% of bacterial and 55.2%–70.9% of fungal compositional variation in topsoil, and 12.0% (bacteria) and 18.5% (fungi) in subsoil. Based on LefSe analysis (LDA score ≥2) and abundance monotonicity, 45 bacterial and 21 fungal Cd-indicating biomarkers were identified, belonging to bacterial Orders Burkholderiales, Gemmatimonadales, Thermomicrobiales, and fungal Families Mortierellaceae and unclassified, respectively.

Co-occurrence network analysis revealed that Cd exposure increased average degrees but reduced modularities of microbial networks (except for topsoil fungi), indicating enhanced interspecific interactions but weakened community stabilities, with subsoil bacterial communities being the most vulnerable. Bacteria-fungi linkage densities at the phylum level increased with Cd levels, confirming strengthened cross-kingdom interactions under Cd stress. A polarization effect was observed: network nodes shifted from uniform multi-module distribution to aggregation into fewer modules as Cd levels increased, suggesting microorganisms tended to form fewer but more robust assemblages under Cd stress. Distinctively, modularity of the topsoil fungal network increased with Cd levels, reflecting strong resistance to environmental disturbances.

In conclusion, compared to bacteria, topsoil fungi were able to maintain community stability and ecological functions via compositional regulation under Cd stress. Our study highlights the vulnerability of subsoil bacterial communities and the potential application of topsoil fungal microbiota in the bioremediation of Cd-contaminated soils.

*stu_lisw@ujn.edu.cn

**ABSTRACT**

Prediction and controlling hexavalent chromium (Cr(VI)) contamination in agricultural soils are crucial for crop safety and sustainable production. Here, eight agricultural soils spiked with 20-300 mg $kg^{-1}$ Cr(VI) were aging for 180 d to develop an aging model to predict Cr(VI) transformation. Then sulfidated nanoscale zero-valent iron (S-nZVI) was tested to immobilize residual Cr(VI) in two contrasting soils by evaluating Cr speciation, leachability and wheat phytotoxicity. Results showed that higher pollution level accelerated early-stage reduction kinetics, but also increased the bioavailable Cr(VI) fraction and reduced the overall reduction efficiency, which was more pronounced in alkaline soils. This highlights scenarios where natural attenuation is unlikely to eliminate Cr(VI) rapidly. Kinetic modeling indicated a predominantly chemisorption-associated reduction process, while diffusion-limited mechanisms became increasingly important at higher loadings, providing a mechanistic framework for scaling transformations across concentration gradients. A multiple linear regression model incorporating pollution level, aging time, pH, and organic matter significantly improved the prediction of Cr(VI) reduction ($R^2$= 0.74). Guided by these high-risk scenarios, sulfidated nanoscale zero-valent iron (S-nZVI) was evaluated to immobilize Cr(VI) in two contrasting soils with comparable Cr(VI) concentration. At an optimal S/Fe molar ratio of 0.1, S-nZVI achieved dose-dependent immobilization (>93% reduction at 10 g $kg^{-1}$ within 28 days), shifted Cr from labile to more stable fractions, and significantly reduced leachable and plant-available pools, being consistent with Fe(III)–Cr(III) co-precipitation as confirmed by XRD, SEM-EDS, and XPS analyses. Wheat growth assays further revealed a soil-specific safe-dosing window: moderate S-nZVI amendments alleviated Cr phytotoxicity, whereas excessive application induced Fe-related stress and inhibited growth. Our study provide a model to predict Cr(VI) redox transformation and highlight soil-specific management of Cr(VI) when employing engineer material as amendment.

# PFAS in Agro-Food Systems: Risk Management Strategies

**Jay Gan[1,2*], Qingyang Shi[2], Rebecca Yates[2], Jingjing Zhang[2], and Zhaoyang Liu[2]**

[1] *College of Agriculture & Biotechnology, Zhejiang University, Hangzhou, China*

[2] *Department of Environmental Sciences, University of California, Riverside, CA, USA*

*Email: jgan@ucr.edu

**ABSTRACT**

Per- and polyfluorinated substances (PFAS) encompasses thousands of compounds with diverse structures. Their extremely low safety thresholds make them an urgent concern in agricultural-food systems. PFAS may enter agricultural fields from point sources such as industrial activities, and non-point sources from the use of biosolids for fertilization, and wastewater and other contaminated water sources for irrigation. Due to the large numbers of PFAS, a wide range of scenarios in the source and nature of PFAS contamination, and the vast area and complexity of agro-food systems, it is a formidable task to manage potential PFAS risks in agro-food systems. A first-step strategy is to prioritize the types of PFAS, crop species and agronomic practices that may present the greatest risk for PFAS contamination of food produce. This may be achieved by understanding PFAS uptake, translocation and accumulation as a function of PFAS structures as well as plant species. Existing knowledge from other contaminants, including pesticides, may be leveraged and incorporated into data-driven models to predict and identify a short list of "high risk" scenarios. Resources can then be focused on developing management practices to ensure minimal transfer of PFAS into food produce for these high-risk scenarios. For the majority of scenarios, however, PFAS likely pose only a low to moderate risk in the context of food contamination. For the moderate risk scenarios, risk avoidance may be a practical yet effective strategy to ensuring safety. An example is the use of biosolids in agricultural fields. Some PFAS are likely enriched in biosolids, especially when there are contributions of industry sources to the waste stream. In such cases, biosolids may be isolated to applications after harvest or before planting, and uses on non-food crops such as cotton and trees, feed crops, or fruiting plants that have biological barriers to deter contaminant translocation to edible organs. Such risk-avoidance strategies are low-cost and easily implementable and can be particularly practical for addressing PFAS concerns in agro-food systems.

## ABSTRACT

Agricultural runoff often contributes to phosphorus losses in dissolved and sediment-bound forms, impacting water quality. No-till and cover cropping practices are effective strategies that crop managers can implement to reduce erosion and nutrient loss. The overall aims of this long term study were to characterize and evaluate the effects of fertilizer (placement and source) and cover crop management on P speciation in source soil and surface runoff sediments. In 2014, a field-scale experiment was established in a no-till, corn (Zea mays L.)-soybean (Glycine max L.) cropping system with two cover crop treatments (with and without a winter crop; cereal rye (Secale cereale L.)) and three P fertilizer management treatments (2014- 2020, no P, fall broadcast diammonium phosphate, and spring subsurface injected ammonium polyphosphate and 2020-2023 no P, drawdown, and build and maintenance via subsurface injected APP). Phosphorus fractionation in source soil collected in the fall of 2019-2022 and sediment samples collected throughout 2020-2023 were analyzed using a modified sequential P extraction method to evaluate the cumulative effects of imposing the treatment factors over the first five years (2014-2019) and annually after 2020. The direct P speciation was performed using X-ray absorption near edge structure spectroscopy. Findings showed that P management and cover cropping significantly influenced P fractions and speciation in both soils and sediments. Further, sediments collected later in the study (after 2020) showed a greater effect of cover crop management on additional sediment P fractions. Runoff sediments were generally enriched in P relative to the source soils, likely due to increased organic matter and stimulated root and microbial activity, which affected P stabilization through sorption, precipitation, and occlusion within aggregates. These results demonstrate that integrated P fertilizer and cover crop management influence P speciation and mobilization in soils and sediments, providing insight for nutrient management and erosion mitigation in long-term no-till systems. Developing P fertilizer and cropping system management options, with an understanding of soil P transformations, helps maintain environmental sustainability.

# Recruitment of copiotrophic and autotrophic bacteria by hyperaccumulators enhances nutrient cycling to reclaim degraded soils at abandoned rare earth elements mining sites

**Yong-He Han[1,*], Xi-Wen Cui[1], Hong Zhang[1], Yong Zhang, Zhibiao Chen[2]**

[1] *Fujian Key Laboratory of Pollution Control and Resource Reuse, College of Environmental and Resource Sciences, Fujian Normal University, Fuzhou, China*

[2] *Key Laboratory for Humid Subtropical Eco-Geographical Processes of the Ministry of Education, Fujian Normal University, Fuzhou, China*

*yhhan@fjnu.edu.cn

**ABSTRACT**

Hyperaccumulators harbor potentials for remediating rare earth elements (REEs)-contaminated soils. However, how they thrive in low-nutrient abandoned REEs mining sites is poorly understood. Three ferns (REEs-hyperaccumulators *Dicranopteris pedata* and *Blechnum orientale*, and non-hyperaccumulator *Pteris vittata*) along with their rhizosphere soils were collected to answer this question by comparing differences in soil nutrient levels, soil and plant REEs concentrations, and bacterial diversity, composition, and functions. Results observed lower soil pH (4.67–4.95 vs. 7.96), total carbon (TC) (0.35–0.62 vs. 2.84 g $kg^{-1}$), total nitrogen (TN) (20–23 vs. 133 mg $kg^{-1}$), and total phosphorus (TP) (81–91 vs. 133 mg $kg^{-1}$) at sites Dp and Bo than site Pv. Hyperaccumulators efficiently extracted soil REEs and translocated them to fronds (up to 6897–7759 mg $kg^{-1}$). Bacterial α diversity in three soils did not significantly vary. In contrast, bacterial composition at sites Dp and Bo was dominant by higher abundances of copiotrophic bacteria (18 % vs. 12 %, p_Actinomycetota; 3.3–8.3 % vs. 1.9 %, p_Bacteroidota; 8.3–14 % vs. 6.9 %, c_Gammaproteobacteria) and autotrophic bacteria (18 % vs. 13 %, p_Chloroflexota; 13 % vs. 8.6 %, p_Cyanobacteriota) when compared to site Pv. These bacteria likely acted as nutrient cyclers that promoted the growth of hyperaccumulators, based on functional predictions from DiTing analyses. This study provides new insights into nutrient recovery in abandoned REEs mining sites, offering strategies to reclaim degraded soils using phyto-microbial technology.

*yhhan@fjnu.edu.cn

**ABSTRACT**

Rare earth elements (REEs) are crucial for green technologies, but their mining can severely degrade soil. While bacterial succession, often involving photoautotrophic and copiotrophic taxa, aids the colonization of REEs-hyperaccumulators in nutrient-poor soils, its applicability across plant ecotypes and light-limited conditions (e.g., winter) remains unclear. We compared two ferns (*Dicranopteris pedata* and *Blechnum orientale*) from core (DpM/BoM) and surrounding (DpS/BoS) areas, analyzing their REEs accumulation and rhizobacterial regulation of soil carbon (C) and nitrogen (N) cycling. Despite lower soil total REEs (5.28–9.37 times lower) and nutrients (TC ≤ 0.67 g $kg^{-1}$; TN ≤ 23.33 mg $kg^{-1}$), core ecotypes accumulated more REEs (e.g., 2765.03 vs. 131.67 mg $kg^{-1}$ Ce in *D. pedata*; 1486.22 vs. 660.90 mg $kg^{-1}$ La in *B. orientale*). The *r*/*K* life-strategy framework (copiotrophs vs. oligotrophs) did not fully explain microbial diversity and functions, as key taxa exhibited metabolic flexibility (e.g., chemoautotrophy). Core soils hosted copiotroph- and chemoautotroph-dominated microbiomes (p_Pseudomonadota, p_Actinomycetota, and p_Bacteroidota), linked to C/N cycling, whereas surrounding soils favored oligotrophs (p_Chloroflexota and p_Acidobacteriota). Both ferns enriched c_Alphaproteobacteria (especially g_*Bradyrhizobium*) and p_Actinomycetota (especially g_*Acidothermus*) for C/N fixation, these keystone taxa serve as potential biomarkers for monitoring soil nutrient recovery in REEs mining areas. Our findings indicate that microbial functional traits, beyond taxonomy, drive nutrient cycling in soils and REEs hyperaccumulation in plants, refining and expanding the *r*/*K* framework and suggesting seasonally tailored plant-microbe partnerships could optimize C/N cycling and enhance REEs phytoremediation in degraded soils.

*yhhan@fjnu.edu.cn

**ABSTRACT**

Rare earth elements (REEs; scandium (Sc), yttrium (Y), and the 15 lanthanides—lanthanum (La), cerium (Ce), praseodymium (Pr), neodymium (Nd), promethium (Pm), samarium (Sm), europium (Eu), gadolinium (Gd), terbium (Tb), dysprosium (Dy), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb), and lutetium (Lu)—are indispensable to modern technologies and emerging low-carbon systems. With rising demand and supply constraints, improving resource efficiency has driven interest in secondary REE sources beyond conventional mining. Industrial REE production typically relies on beneficiation followed by chemically intensive hydrometallurgy, including roasting/activation, strong-acid leaching (e.g., HCl, $H_2SO_4$, $HNO_3$), and downstream separation/purification. However, such flowsheets are often optimized for primary ores and can be less efficient for complex residual solids. Mine tailings can retain a non-trivial fraction of REEs after processing, making them a potentially valuable secondary resource for targeted recovery. Here, we investigate element-resolved REE bioleaching from REE-bearing tailings mediated by the heterotrophic bacterium *Komagataeibacter xylinus*, focusing on dissolution selectivity and cyclic stability. The tailings were wet and acidic and showed pronounced REE heterogeneity with relatively higher Nd, Dy, Er, Yb, and Y. Sequential fractionation concepts were used to interpret intrinsic mobility, where oxide-bound and residual associations generally indicate stronger mineral binding and lower immediate leachability. The tailings REEs were predominantly hosted in refractory Fe–Mn oxide–bound and residual fractions. Bioleaching was evaluated by comparing HR and HBR. Relative to HR, HBR substantially increased dissolved REEs dominated by Y, Nd, and Yb, with HREEs generally exceeding LREEs. Initial leaching efficiencies reached ~40%, while a three-cycle operation sustained release and increased cumulative efficiencies to ~80–92% for multiple elements while maintaining HREE enrichment. These results support K. xylinus–mediated bioleaching as a promising route for tailings valorization and secondary REE recovery.

# Effects of different nitrogen fertilizer types on the remediation efficiency of Pteris vittata in arsenic-contaminated soil

**Xiao-min Wang[1], Hong Zhang[1], Yong Zhang[1], Yong-He Han[1,*]**

[1] *Fujian Key Laboratory of Pollution Control and Resource Reuse, College of Environmental and Resource Sciences, Fujian Normal University, Fuzhou, China*

*yhhan@fjnu.edu.cn

**ABSTRACT**

In the phytoremediation of arsenic (As)-contaminated soil, *Pteris vittata* has garnered significant attention due to its hyperaccumulation capabilities. However, the efficiency of remediation is greatly influenced by nutrient supply, with the type of nitrogen(N) fertilizer being a key regulatory factor. This study conducted a pot experiment to investigate the effects of three common N fertilizers—potassium nitrate, urea, and ammonium dihydrogen phosphate—along with a no-fertilizer control (CK) on the growth, As uptake, and soil physicochemical properties of *Pteris vittata*. The results indicated that fertilization significantly enhanced both biomass and As accumulation in *Pteris vittata*. Urea treatment exhibited the greatest efficacy in promoting biomass growth and As absorption, achieving the highest remediation efficiency. While potassium nitrate treatment had a relatively minor impact on soil pH, it still significantly enhanced remediation efficiency. Although ammonium dihydrogen phosphate effectively mobilized soil As, it posed a risk of phosphorus(P) accumulation and led to a notable decrease in soil pH. Overall, urea is recommended as the preferred N fertilizer for improving the remediation efficiency of *Pteris vittata*, although long-term application should be approached with caution due to potential soil acidification and P pollution risks. This study provides a theoretical foundation for the scientific selection of N fertilizers in the remediation of As-contaminated soil.

# Multi-Pathway Synergy Drives Rapid Soil Fertility and Crop Yield Improvement in Newly Reclaimed Cropland: The Role of Integrated Soil Improvement

**Yanfang Chen, Xinzhe Lu, Kaifeng Fu, Guohui Zhan, Tingqun Li, Ruosong Zhou, Jianjun Cheng , Rui Sun, Linwei Xu, Feng Hu, Xiaochun Ji**

Zhejiang Institute of Geosciences, Hangzhou, Zhejiang Province, China

## ABSTRACT

Newly reclaimed cropland commonly faces issues such as poor soil structure, low fertility, and insufficient biological activity, which constrain crop production. However, the comprehensive effects of different soil improvement measures on various aspects of soil health and their relationship with crop growth remain unclear. To address this, a field experiment was conducted with the following treatments: chemical fertilizer alone (NPK), bio-organic fertilizer (MF), two integrated improvement measures (MCN and MCN_2), and a blank control (CK). Both the bio-organic fertilizer and the two integrated measures were amended with an equivalent amount of organic matter. The integrated measures comprised an organic material source combined with modified biochar, minerals, and microbial inoculants. The study aimed to investigate the effects of these different treatments on soil physical, chemical, and biological properties as well as wheat growth, and to identify key soil factors driving yield improvement. Measurements at wheat maturity showed that, compared to the NPK treatment, the MCN treatment was most effective in improving soil structure (bulk density reduced by 0.14 g/cm³), alleviating acidification (pH increased by 0.87 units), enhancing fertility (soil organic matter increased by 4.43 g/kg, the ratio of available phosphorus to total phosphorus increased by 3.5%, and calcium content increased by 0.07%), and boosting microbial richness (Observed, Chao1, and Shannon indices increased by 28.6%, 28.3%, and 7.3%, respectively) and activity (activities of β-glucosidase, leucine aminopeptidase, and β-N-acetylglucosaminidase increased by 106.1%, 29.7%, and 60.0%, respectively). LEfSe analysis revealed that the integrated treatments enriched nitrogen-fixing bacteria (e.g., *Mesorhizobium*), organic matter-decomposing bacteria (e.g., *Fibrobacteraceae*, *Pseudohongiellaceae*), and beneficial *Bacillus* strains (e.g., *Blastocatellaceae*). Furthermore, the MCN treatment significantly increased wheat plant height, stem diameter, and yield, resulting in yield increases of 294.3% and 16.5% compared to the NPK and MF treatments, respectively. Correlation analysis indicated that grain yield was significantly correlated ($p < 0.05$) with soil organic matter, total nitrogen, total phosphorus, available phosphorus, calcium, manganese, the Shannon index, and bacterial phyla including *Pseudomonadota*, *Verrucomicrobiota*, and *Actinomycetota*. Yield also showed positive correlations with soil pH and the activities of sucrase, β-glucosidase, leucine aminopeptidase, and β-N-acetylglucosaminidase. Partial least squares path modeling identified the core pathway as "Improvement measures → Enhanced soil fertility (increased organic matter and mineral elements) → Microbial regulation → Yield promotion." In conclusion, the integrated measure combining organic materials with modified biochar, minerals, and microbial inoculants can rapidly improve soil health and crop yield in newly reclaimed cropland through synergistic multi-pathway effects, representing an effective strategy for achieving rapid maturation and ensuring high, stable yields in such soils.

# Qualidade e saúde do solo: bases para a transição agroecológica em agroecossistemas

**Leonir Terezinha Uhde[1*], Maria Cristina Martins Ribeiro de Souza [2], e Gustavo Henrique Filippin[3]**

*1* e 3UNIJUI – Universidade Regional do Noroeste do Estado do Rio Grande do Sul, Núcleo de Suporte aos Cursos das Agrárias, Ijuí, Rio Grande do Sul, Brasil

*2* Instituto Federal do Ceará (IFCE), Sobral, Ceará, Brasil

* uhde@unijui.edu.br

**ABSTRACT**

A qualidade e a saúde do solo são componentes essenciais para a sustentabilidade dos agroecossistemas e para o fortalecimento da transição agroecológica, pois expressam a capacidade do solo em sustentar a produtividade biológica, manter a qualidade ambiental e promover a saúde das plantas, dos animais e das populações humanas. Na abordagem agroecológica, o solo é compreendido como um sistema vivo e dinâmico, cuja avaliação deve integrar atributos químicos, físicos e biológicos. Nesse contexto, sistemas de semeadura direta de longa duração, especialmente em Latossolos Vermelhos Distroférricos, contribuem para a conservação da estrutura, o acúmulo de matéria orgânica e o estímulo à atividade microbiana. O objetivo foi avaliar a qualidade e a saúde do solo em sistema de cultivo aveia preta/soja, utilizando análises químicas e físicas do solo e a Cromatografia Circular de Pfeiffer (CCF). O estudo foi realizado em uma Unidade de Produção Agrícola no município de Ijuí, Rio Grande do Sul (RS) - Brasil. As amostras de solo foram coletadas nas camadas de profundidades de 0–10, 10–20 e 20–40 cm.

Os resultados indicaram boas condições químicas do solo, com acidez controlada e teores adequados de bases trocáveis, além de clara estratificação de fósforo, potássio e matéria orgânica, característica do manejo em semeadura direta. A densidade do solo e a porosidade total revelaram estrutura estável na camada superficial (0–10 cm), compactação moderada na camada de 10–20 cm e leve recuperação estrutural em 20–40 cm. A umidade volumétrica aumentou em profundidade, refletindo maior retenção de água e redução do espaço aéreo, que se manteve adequado às trocas gasosas e à atividade biológica.

A cromatografia circular indicou elevada atividade biológica e boa organização estrutural na camada superficial, redução da atividade na camada intermediária e menor dinamismo biológico na camada mais profunda. Conclui-se que o sistema de manejo adotado favorece a sustentabilidade e a qualidade do solo, contribuindo para a produtividade agrícola e a transição agroecológica.

## ABSTRACT

Phytate enhances arsenic metabolism in As-hyperaccumulator *Pteris vittata*, but the underlying mechanisms remain unclear. Using *P. multifida* and *P. ensiformis* as comparisons, we investigated the plant growth, As/P uptake, and phytate synthesis, sequestration, and exudation in *P. vittata* under 10-100 μM As exposure. The expressions of P transporters Pht1;2-1;4, phytate synthesis genes including myo-inositol 3-phosphate synthase (*MIPS*), myo-inositol monophosphatase (*IMP*), and 2-phosphoglyceric acid kinase (*2-PGK*), and phytate transporter multidrug resistance-associated protein 5 (*MRP5*) were analyzed. After 3 weeks of growth, *P. vittata* accumulated the greatest As in the fronds at 155-3098 mg $kg^{-1}$, with biomass being increased by 9.8–63%. While greater expression of PvPht1;2-1;4 helped *P. vittata* to maintain stable plant P contents at 3005-3552 mg $kg^{-1}$, PmPht1;2/1;4 and PePht1;2/1;4 expression was reduced by 10–55%. Arsenic exposure enhanced phytate accumulation in *P. vittata* by upregulating phytate synthesis genes MIPS, IMP and 2-PGK and phytate transporter gene MRP5 by 1.3-1.7 fold, increasing phytate contents by 1.1-2.1 fold to 69.2-371 mg $kg^{-1}$. Further, *P. vittata* increased phytate root exudation by 1.5-3.6 fold under As exposure, whereas *P. multifida* and *P. ensiformis* mainly exuded tartrate. In short, As-enhanced phytate metabolism in *P. vittata* is unique and contributes to its superior As-accumulation ability, showing implication for phytoremediation of As-contaminated soils.

# Soil quality in a long-term Tifton 85 pasture overseeded with forage radish and annual ryegrass

**Leonir Terezinha Uhde[1*], Éverton Deckert Prauchner[2], e Roberto Carbonera [3]**

[1,2 e 3]UNIJUI – Universidade Regional do Noroeste do Estado do Rio Grande do Sul, Núcleo de Suporte aos Cursos das Agrárias, Ijuí, Rio Grande do Sul, Brasil

* uhde@unijui.edu.br

**ABSTRACT**

This study evaluated soil quality in a long-term Tifton 85 pasture, overseeded with forage radish and naturally reseeded ryegrass. The assessment was carried out through the integration of physical, chemical, and biological indicators, including qualitative measures such as Pfeiffer Circular Chromatography. This is a qualitative and semi-quantitative method primarily used to assess soil biological quality in agroecological contexts, biodynamic agriculture, and soil health studies. The physicochemical analyses revealed a pattern typical of perennial systems, characterized by higher soil quality in the surface layer (0–10 cm), with greater organic matter contents, lower soil bulk density, and higher air-filled porosity. In contrast, deeper layers (10– 20 and 20–40 cm) showed increased compaction, reduced organic carbon, lower phosphorus availability, and decreased porosity. The chromatograms corroborated these results by indicating high biological vitality and good structural integration in the surface layer, followed by a progressive reduction in microbial activity and colloidal stability with increasing depth. The complementarity between alternative methods and conventional indicators broadened the functional understanding of the soil, demonstrating that the integrated use of qualitative and quantitative tools enhances diagnostic sensitivity, especially for detecting changes in structural and biological attributes that are not evident when assessed in isolation by traditional analyses. The study showed that the evaluated system presents good surface soil (edaphic) functionality, resulting from the continuous input of roots, plant residues, and nutrient cycling promoted by forage species. However, limitations persist in subsurface layers, such as reduced effective rooting depth, moderate compaction, and low phosphorus availability. These conditions indicate the need to adopt management practices that enhance biological activity at depth, such as the strategic use of plants with taproot systems, appropriate grazing management to reduce soil compaction, and improvements in subsurface fertility. It is concluded that the combined use of Pfeiffer Circular Chromatography and physicochemical analyses constitutes a robust and efficient approach for assessing soil quality and health in long-term forage systems, providing essential support for the implementation of more sustainable, resilient, and conservation-oriented management practices.

**ABSTRACT**

Agriculture is the backbone of Bihar's economy and a critical component of India's food production system, forming an integral part of the eastern Indo-Gangetic Plains, one of the most densely populated and climate-vulnerable agricultural regions of the world. supporting more than 70% of the population; however, the sector is increasingly threatened by climate variability, rising input costs, and uneven adoption of modern technologies. This study evaluates the interlinkages among technology adoption, economic constraints, climate resilience, policy awareness, and income stability across Bihar's four agro-climatic zones (ACZ-I, ACZ-II, ACZ-IIIa, and ACZ-IIIb). Primary data were collected from 2,000 farmers across seven districts using a structured survey framework. Composite indices including Yield Impact Score (YIS), Technology Adoption Index (TAI), Input Cost Index (ICI), Climate Resilience Index (CRI), Policy Awareness Index (PAI), and Income Stability Index (ISI) were developed to assess spatial and socio-economic disparities. Results revealed pronounced inter-zonal variability. ACZ-II emerged as the most resilient zone, with the highest TAI (5.9), CRI (6.8), and ISI (4.5), supported by improved access to credit, mechanization, climate-smart varieties, and post-harvest infrastructure. In contrast, ACZ-I and ACZ-IIIb experienced high input cost escalation (26.7–28.9%), lower technology adoption, and reduced income stability. Regression analysis identified technology adoption as the strongest positive driver of climate resilience ($\beta = +0.45$, $p < 0.01$), followed by income stability ($\beta = +0.30$, $p = 0.06$), while high input costs exerted a significant negative effect ($\beta = -0.25$, $p < 0.05$). Spatial analysis using QGIS highlighted clear hotspots of vulnerability and resilience across agro-climatic zones.

The findings underscore that climate resilience in Bihar is not solely technology-driven but depends on an integrated approach combining affordable inputs, credit access, policy outreach, and market linkages. Strengthening extension services, scaling climate-smart technologies, and improving post-harvest infrastructure are critical to enhancing resilience and ensuring sustainable agricultural development in climate-vulnerable regions.

**ABSTRACT**

Future climate change is projected to have profound impacts on global soil health, with the response and feedback mechanisms of carbon-nitrogen (C-N) cycles playing a particularly critical role. Soils serve as major sources and sinks of carbon and nitrogen in terrestrial ecosystems, yet the key processes governing C-N cycling are highly complex and remain among the most uncertain components of climate-change response mechanisms. This uncertainty substantially constrains the accuracy of future C-N dynamic predictions and undermines the reliability of soil health assessments.

To address this challenge, this study integrates observational data from multi-site climate-change manipulation experiments worldwide to construct a systematic database. Combined with process-oriented C-N cycle models, we systematically analyze the key pathways through which climate change affects soil C-N transformation, storage, and loss. Building on this, we further develop an integrated soil health indicator system encompassing physical, chemical, and biological attributes, and evaluate the multidimensional impacts of different climate-change scenarios—such as warming, precipitation variation, and elevated $CO_2$ concentrations—on soil health.

The results demonstrate that climate change, by altering the balance of C-N cycles, significantly affects soil organic matter stability, nutrient availability, and microbial functionality, thereby threatening the long-term maintenance of soil health. Finally, this study proposes climate-adaptation strategies centered on sustainable soil resource management. These strategies emphasize enhancing soil resilience to climate change through optimized agricultural practices, restoration of ecosystem functions, and increased soil organic carbon sequestration capacity. The findings provide a scientific basis for achieving global land sustainability and supporting climate mitigation and adaptation goals.

# Reinventing Soil Health in the Plastic Age: Fungal-Nano Synergies for Microplastic Remediation

**Nasir Mehmood[1*], Vishnu D. Rajput[1], Saglara Mandzhieva[1], and Tatyana Mikhailovna Minkina[1]**

[1234] *Academy of Biology and Medicine, Southern Federal University, Rostov on Don, Russia*

*E-mail: nasirm20@gmail.com

**ABSTRACT**

Microplastic contamination is now recognized as one of the most persistent and underestimated dangers to soil ecosystems with agricultural soils as significant long-term sinks. Polymer residues accumulate and affect soil structure, microbial functioning, nutrient cycling and plant performance, posing concerns to food security and human health. Traditional remediation procedures remain costly, inadequate, and detrimental to the environment, emphasizing the critical need for scalable, soil-compatible alternatives. This paper presents recent breakthroughs in fungal bioremediation combined with nano-enabled technology as a next-generation technique for mitigating soil microplastic contamination. Filamentous fungi such as *Aspergillus niger, Aspergillus terreus, Penicillium chrysogenum, Fusarium solani, Trichoderma harzianum*, and white-rot fungi like *Phanerochaete chrysosporium* and *Trametes versicolor* have a unique ability to colonize hydrophobic plastic surfaces and enzymatically depolymerise recalcitrant polymers like polyethylene, polystyrene, and polyurethane. These fungi secrete oxidative and hydrolytic enzymes, such as laccases, manganese peroxidases, esterases, and cutinases, which cause polymer oxidation, chain scission, and biofragmentation. However, fungal decomposition alone is typically limited by slow reaction kinetics, partial mineralization and environmental unpredictability in field circumstances. Recent nano-enhanced techniques provide an effective way to circumvent these restrictions. Photocatalytic nanoparticles including titanium dioxide ($TiO_2$), zinc oxide (ZnO), iron oxide ($Fe_3O_4$) and graphitic carbon nitride (g-$C_3N_4$) produce reactive oxygen species that pre-oxidize polymer chains, enhancing fungal accessibility and enzymatic efficiency. Enzyme immobilization on silica nanoparticles, magnetic $Fe_3O_4$ nanocarriers, graphene oxide and biochar-based nanocomposites improve enzyme stability, recyclability and polymer-enzyme interaction. Emerging myco-nano hybrids, such as fungal-biosynthesized metal nanoparticles and nanoparticle-decorated mycelial networks, exhibit synergistic degrading capability while minimizing ecotoxicological concerns. Advances in analytical validation such as FTIR, Raman spectroscopy, Py-GC/MS, and electron microscopy now allow for precise differentiation between real biodegradation and physical fragmentation. The remaining challenges such as nanoparticle fate, by-product toxicity, consequences on non-target soil biota and large-scale field deployment are thoroughly examined. This work outlines a forward looking remediation paradigm with global relevance by bridging soil microbiology, nanotechnology and sustainable agriculture. It establishes fungal-nano systems as a cornerstone technology for restoring soil health, informing environmental policy and advancing resilient agri-food systems as an impact that extends far beyond disciplinary boundaries.

# Digital Characterization of the Spatial Distribution of the Albic Horizon in the Northeast Black Soil Region

**Shou-Xi Lv [1*], Zhong-Xiu Sun [1], Ying-Ying Jiang [2], Si-Yi Duan [1], and Qiu-Bing Wang [1]**

[1] *College of land and environment, Shenyang Agricultural University Shenyang, Liaoning, China*

## ABSTRACT

This study aims to clarify the spatial distribution, characteristics, and multi-factor driving mechanisms of the albic horizon—a critical soil constraint layer in the Northeast Black Soil Region, which serves as China's premier grain production base. The albic horizon, characterized by high bulk density, elevated hardness, and shallow burial depth, severely restricts plant root penetration and hydrological processes, hindering sustainable agricultural development in this strategically important region. Taking the Northeast Black Soil Region as the research area, a soil profile dataset was constructed by integrating measured data from 5 field-investigated standard profiles and systematically compiled records from 776 historical survey profiles. Combined with 21 environmental covariates spanning 7 categories (including climate, topography, hydrology, and soil properties), a random forest (RF) machine learning model was applied to quantitatively analyze the spatial distribution and characteristics of the albic horizon. The results showed that the albic horizon was mainly distributed in the Sanjiang Plain (covering Jiamusi, Shuangyashan, and Jixi), the northern foothills of the Changbai Mountains (including Mudanjiang, Hegang, and Harbin), and the central low mountain-hilly terrain of Jilin (encompassing Liaoyuan, Tonghua, and Yanbian), with a total predicted area of approximately 29,100 km$^2$ (model Kappa coefficient=0.87, indicating excellent predictive accuracy). In terms of characteristics, the burial depth exhibited a distinct "deep northeast, shallow southwest" spatial gradient: deeper zones concentrated in the Sanjiang Plain interior and central Jilin hilly regions, while shallower zones occurred in the southern Wanda Mountain foothills and western Changbai Mountain foothills, with burial depths ranging from 13.44−38.29 cm. Thickness showed a "thicker central, thinner peripheral" pattern: thick layers mainly located in the eastern Songnen Plain and western Zhangguangcai Mountain foothills, while thinner layers distributed along the southern Xiao Hinggan Mountain foothills and northern Liaoning Horqin Sandy Land margins, with thickness spanning 12.98−33.36 cm. Multivariate analysis identified key environmental drivers: climate-topography interactions primarily regulated burial depth, hydrology-geomorphology-biology synergies shaped thickness spatial patterns, and soil property-climate-topography interactions dominated albic horizon occurrence and distribution. This study establishes a robust digital characterization framework for the albic horizon and accurately delineates its spatial distribution patterns alongside multi-factor driving mechanisms. The findings provide a scientific foundation for developing differentiated black soil conservation and restoration strategies, which hold profound implications for sustainable black soil resource utilization and regional food security assurance.

# EcoPond: A Nature-Based Solution to Reduce Methane Emissions from Animal Effluent and Manure Storage Systems

**Keith C Cameron[1] and Hong J Di[1*]**

*[1] Centre for Soil and Environmental Research, Lincoln University, Christchurch, New Zealand.*

**hong.di@lincoln.ac.nz*

**ABSTRACT**

Methane ($CH_4$) emissions from animal effluent ponds and manure storage systems represent a significant source of agricultural greenhouse gases (about 10-15% of methane emissions from animal production systems), contributing substantially to global climate change. Traditional manure management practices often rely on anaerobic decomposition, which generates methane ($CH_4$) as a by-product. The EcoPond technology offers an innovative, low-cost, and scalable approach to mitigating methane emissions by inhibiting methanogenesis within effluent storage systems.

EcoPond employs a targeted, environmentally benign food additive treatment, using poly-ferric sulphate (PFS) and sulphuric acid, that disrupts the activity of methane-producing microbes without negatively impacting nutrient recycling or the downstream use of effluent as a nutrient source. The technology is applied directly to effluent ponds or storage tanks, rapidly creating a microbial environment that favours alternative pathways over methanogenesis. This intervention results in a substantial reduction in methane production during storage, with field trials demonstrating reductions averaging about 96%.

Multiple on-farm studies have evaluated EcoPond across diverse climatic regions, animal production systems, and pond configurations. These trials have consistently shown significant methane suppression within days of application, sustained over several months. Importantly, the treatment does not adversely affect effluent nutrient content, allowing for continued use in soil nutrient management plans without adversely affecting nutrient availability or microbial populations. Furthermore, the treatment also significantly reduce phosphate leaching and E coli leaching by more than 90% when the treated effluent is applied back to the soil to recycle nutrients. EcoPond represents a valuable tool in integrated nutrient and greenhouse gas management, aligning with climate-smart farming practices. By reducing methane emissions at the storage stage, the technology addresses a critical gap between farm productivity and environmental stewardship. Widespread adoption of EcoPond could contribute material greenhouse gas reductions, while maintaining soil fertility and water quality outcomes.

This paper presents the underlying mode of action of EcoPond, experimental design and methodologies for emission measurement, and results from on-farm trials. The findings highlight the potential for targeted microbial management to transform manure storage from a major methane source into a more climate-resilient component of agricultural nutrient cycles.

**ABSTRACT**

The intensification of agricultural systems leads to soil degradation, posing a serious risk to sustainable food production. The use of cover crops is a strategy for climate change adaptation and mitigation, as they contribute to carbon sequestration. This study examined the effects of cover crops on carbon contents and stocks at 0-1 m depth in fruit and olive tree crops in southeastern Spain. To this end, 12 commercial farms (6 olive groves and 6 fruit orchards) were selected. For each crop type, farms with cover crops (6-19 years of implementation) were compared with farms that maintained soil bare through tillage and herbicides application. The treatments were: olive grove with cover crops (OCC), olive grove with bare soil (OBS), fruit trees with cover crops (FCC), and fruit trees with bare soil (FBS). In each plot, six profiles were opened, and soil samples were collected from each genetic horizon. The soil profiles had an average depth of 100 cm, with four horizons identified in each profile. Bulk density (BD), soil organic carbon (SOC), and total nitrogen (TN) were analyzed to calculate soil organic carbon (SOC stocks) and total nitrogen (TN stocks) stocks. The results showed an increase in stocks in the surface horizon (Ap) under cover crops in both crop types. In olive groves, OCC showed a higher SOC stock in A horizon (27.34 Mg $ha^{-1}$) compared to OBS (16.29 Mg $ha^{-1}$). In fruit trees, FCC showed a SOC stock of 29.03 Mg $ha^{-1}$ in the A horizon, significantly higher than FBS (11.54 Mg $ha^{-1}$). The TN stock in topsoil followed a similar trend, also being significantly higher in the plots with cover crops. However, when considering the complete profile, the total stocks showed different patterns. In fruit trees, FCC showed higher SOC stock (99.73 Mg $ha^{-1}$) compared to FBS (78.53 Mg $ha^{-1}$). In contrast, in olive trees, OBS had higher SOC stock (111.19 Mg $ha^{-1}$) than OCC (82.76 Mg $ha^{-1}$). The TN stock followed the same pattern than SOC stock in both crops. Therefore, the effects of cover crops were mainly observed in topsoil (Ap), with higher SOC and TN stocks than on farms with bare alleys. Thus, cover crops contributed to C sequestration and storage only at 0-20 cm depth after more than 6 years of implementation. This study also shows the importance of studying deeper horizons, as their exclusion from the analysis could lead to misleading conclusions.

**ABSTRACT**

Spatial soil/crop mapping by remote sensing products, together with proximal sampling and/or sensors, provide data important for decision-making, particularly regarding precision agriculture. However, the high cost of sensors and sampling limits their use and reduces the accuracy of spatial representation. Additionally, spatial autocorrelation affects sampling efficiency, indicating redundancy when samples close to one another are similar. When planning sensor or sampling point distribution, questions to be addressed include: (a) the minimum number of sensors/samples required, (b) the location and distribution of samples in the field that accurately represent the spatial variability, and (c) the environmental variables that should be considered in the process.

We present a model and decision support tool (DST) that represents spatial variability using stratified-based sampling by integrating multi-variable spatial-statistical analysis with machine learning. The model is based on and accounts for: (a) stratified-based sampling in which management zones (MZs) act as confining sub-regions, (b) local spatial autocorrelation, and (c) correlation between predicting and predicted (to be sampled) variables. The calculated degree of spatial correlation in each MZ determines the number of samples. The distribution of samples is based on spatial histograms and interpolating the selected samples to assess configuration errors. A web-based DST outputs maps based on optimal spatial placement of sensors or samples within a field, indicating the required number of samples and quantifying accuracy levels for configurations using fewer samples. Progress and opportunities currently available, as well as remaining issues and challenges, both theoretical and regarding the model's practical application, will be discussed.

# Pathways to resilience in dryland agricultural systems

**Zhihao Tan[1*], Daniel Rodriguez[1]**

[1] *THE University of Queensland (QAAFI, Brisbane, Australia)*

*Zhihao.tan@uq.edu.au

**ABSTRACT**

Agricultural systems are facing escalating challenges from increased climate variability, particularly due to the rising frequency and intensity of extreme weather events. Despite academic progress in defining farm resilience, current research has often focused too much on setting system boundaries, which might not translate into practical operational measures at the farm level. In this study, we used the APSFarm model to simulate the likely pathways for 3 case study farms, aiming to understand how extreme climate influences farm resilience indicators and how to bridge the gap between academic resilience theories and farm management practices.

A conceptual whole farm-level resilience framework that integrates adaptive cycles and multi-level analyses was developed. The framework focuses on six cyclical key steps: 1) defining vulnerable farm components, 2) identifying the frequency and intensity of stressors, 3) setting resilience goals, 4) quantifying farm resilience capacities and responses to stressors, 5) determining tipping points, and 6) feedback and enhancing resilience attributes. Interviews with high-performing farmers and well-known private consultants were used to learn about present farmers' coping mechanisms and to parameterise and validate the whole farm model APSFarm Next Gen. Long-term climate records were analysed to identify critical climate factors and their tipping points using Gradient Forest and Spearman correlation analyses. Future climate scenarios were used to introduce stress on the simulated case study farms, study resilience responses to stressors, and identify tipping points. Feedback meetings with the participating farmers and consultants were used to discuss opportunities to optimise agricultural practices.

# Impacts of Corn Hybrid and Fertilization Strategies on Plant Carbon Allocation and Soil Carbon Dynamics Under Variable Moisture Conditions

**Yichao Rui [1,*], Binod Joshi[1], Carson Pearl[2], Raziel Ordonez[1], and Dan Quinn[1]**

*[1] Department of Agronomy, Purdue University, West Lafayette, Indiana, USA*

**ABSTRACT**

Intensive agricultural activities deplete soil organic carbon (SOC) stocks in global croplands. A thorough understanding of how management practices impact SOC dynamics is essential for developing effective strategies to rebuild C stocks. This study investigates how corn hybrids (Bayer tall- and short-statured) and nitrogen (N) fertilizer strategies (rates and types) influence root exudation, belowground C inputs, and soil C pools (microbial biomass and total C) in different soil types and moisture conditions in a greenhouse and field studies. By analyzing C allocation between above- and belowground components, as well as root exudation and soil microbial C, we aim to determine whether belowground C inputs can be enhanced through hybrid selection and fertilization strategies. Findings reveal that short-statured corn exhibited greater belowground root biomass and root length compared to tall-statured corn, while excessive N tended to diminish these benefits. These trends were consistent with several other observations, including soil microbial biomass C responses to N fertilization, particularly in loamy soils. However, root exudate C did not show a consistent trend with increasing N rates. Overall, this study provides mechanistic insights into the 'Surplus Plant C Theory', which suggests that crop-soil-microbe interactions can be optimized through intermediate levels of N fertilization to enhance soil C accumulation. Further research is needed to validate these findings under diverse field conditions.

*[3]Department of Primary Industries and Regional Development, South Perth, WA, Australia.*

*James.O'Connor@uwa.edu.au

**ABSTRACT**

Pasture systems across the world face increasing pressures from climate variability, soil degradation, and declining productivity. Developing resilient and diversified pastures is therefore critical for sustaining agricultural output while enhancing soil health and carbon storage. In response, the University of Western Australia (UWA) and the Department of Primary Industries and Regional Development (DPIRD) have launched a three-year field program to trial and demonstrate the benefits of innovative pasture species diversification across WA's high- and low-rainfall zones with funding support from the Department of Agriculture, Fisheries and Forestry. Five demonstration sites were established to evaluate combinations of perennial and annual legumes and grasses, including *Tedera* (*Bituminaria bituminosa*), *Lucerne* (*Medicago sativa*), and cocksfoot (*Dactylis glomerata*), under contrasting environmental conditions. Each site follows a replicated experimental design with standard fertiliser, weed-control, and defoliation regimes to ensure robust assessment of pasture productivity, soil improvement, and climate resilience.

Soil sampling and laboratory analyses quantify physicochemical and biological properties, including nutrient dynamics and organic-carbon fractions, while bioinformatics tools are applied to evaluate microbial community structure and function. High-resolution imagery complements field observations to track pasture establishment, canopy cover, and temporal trends in productivity. Carbon movement and storage potential are modelled to build a systems-level understanding of diversified pasture performance under variable climates.

This initiative builds on previous UWA-DPIRD collaborations in soil restoration and carbon farming, introducing a novel combination of soil bioinformatics, and carbon modelling to evaluate pasture diversification as a climate-smart practice. By coupling on-farm demonstration with advanced analytical approaches, the project will generate evidence-based recommendations for improving soil health, enhancing carbon dynamics, and supporting producer adaptation to a variable climate. Outcomes will directly inform WA's climate-smart agriculture strategies and provide a transferable framework for sustainable pasture management across southern Australian mixed-farming systems.

**ABSTRACT**

Switching from conventional tillage operations to no-till often improves soil properties long-term, but effects on nitrous oxide ($N_2O$) emissions are less known. The objective of this study was to determine the influence of tillage practices on soil properties, $N_2O$ emissions, and corn (*Zea mays* L.) and soybean (*Glycine Max* L.) yields after 49-52 years of continuous treatment implementation in a long-term corn-soybean rotation experiment in southern Illinois, USA. The experimental design was a randomized complete block design replicated four-times with four treatments. Treatments were two tillage systems, chisel tillage (RT) and no-tillage (NT). Each tillage system received either no-fertilizer (control) or was fertilized with 196 kg N $ha^{-1}$, 24 kg P $ha^{-1}$ and 140 kg K $ha^{-1}$ during the corn years (optimum fertility). No fertilization was applied during soybean years. Nitrous oxide was measured prior to field operations (baseline sampling), after planting, and during corn and soybean growing seasons. Our results indicated that no-till resulted in similar corn grain yield at optimum fertility but higher $N_2O$-N emissions in RT-NPK during the corn year. Soybean yields were higher in NT than RT with $N_2O$-N emissions being similar over the two years. Over a four-year period, we also observed that NT resulted in a reduction in $N_2O$-N emissions and yield-scaled $N_2O$-N emissions. Therefore, we suggest NT can be implemented to provide environmental and soil benefits in corn-soybean rotations.

# Neglecting Non-Rainfall Water Contributions Results in an Overestimation of Crop Water Use Efficiency

**Anqi Wang[1], Yuchuan Fan[1*]**

[1] College of Jiyang, Zhejiang A&F University, Zhuji 311800, China
* fanyuchuan@zafu.edu.cn

**ABSTRACT**

Non-rainfall water (NRW)—including dew, fog, and vapor adsorption—constitutes a hidden yet critical component of cropland water input that is often overlooked in hydrological and agricultural assessments. Using multi-year observations from eight long-term experimental stations across China, this study quantified the magnitude, variability, and climatic controls of NRW across ten representative cropland types, including millet, soybean, spring corn, winter wheat, and peanut. Continuous measurements of meteorological variables, evapotranspiration (ET), and soil temperature were analyzed using structural equation modelling (SEM) and SHAP-based attribution to disentangle direct and indirect climatic influences on NRW formation and its contribution to the crop water balance. Results showed that NRW accounted for 3–12% of total water inputs and 5–18% of ET, with nighttime condensation being the dominant process. Relative humidity and radiative cooling were identified as the strongest positive drivers, while wind speed and vapor pressure deficit exhibited negative effects. SEM analysis revealed that temperature and humidity jointly mediated surface energy exchange, reinforcing nocturnal cooling essential for condensation. Regional differences in factor sensitivity reflected local climate regimes rather than crop-specific variations, indicating that NRW represents a stable supplementary water source under precipitation variability. When NRW was excluded from the water balance, the calculated crop water use efficiency (WUE)—defined as the ratio of net primary productivity to total water input—was systematically overestimated, particularly in semi-arid regions where NRW contributions were highest. Incorporating NRW into water accounting improves the consistency between evapotranspiration and total water input, providing a more accurate estimation of water use efficiency under variable climate conditions. These findings highlight the need to treat NRW as a routine component of the water budget, improving field-scale water-use assessment and guiding adaptive irrigation management.

# Soil Carbon Cycle and Carbon Sequestration Strategies in Saline-Alkali fields

## ABSTRACT

We researched carbon cycle processes in saline-alkali soils in the oasis agricultural ecosystem of the Tarim River Basin. Through a combination of laboratory analyses and field observations, we systematically examined soil $CO_2$ emission characteristics, identified key transport mechanisms and influencing factors, and elucidated the phenomenon of negative $CO_2$ flux observed. The results demonstrate that inorganic carbon absorption increases with decreasing temperature, rising alkalinity, and higher partial pressure of $CO_2$. Furthermore, microbial activity, soil flooding conditions, and reduced salinity collectively affect soil $CO_2$ concentration and suppress the recrystallization of calcium carbonate.

In addition, our research specifically addressed carbon cycling in agricultural ecosystems by assessing greenhouse gas emissions, soil organic carbon sequestration, and the carbon footprint under varying water and fertilizer management practices. Our findings suggest that integrating biochar amendment with reduced water and fertilizer inputs represents a viable strategy for achieving water-efficient, low-carbon, and sustainable agricultural development in saline-alkali regions.

**ABSTRACT**

Organic amendments such as straw and biochar are widely applied to enhance soil fertility, yet their distinct contributions to soil organic C (SOC) stabilization remains poorly understood. Through a 180-day laboratory incubation experiment, we quantified and compared the effects of two straw amendment strategies—direct straw incorporation and straw-derived biochar application—on SOC stabilization across different soil types, with a focus on the underlying chemical and microbial mechanisms. This study revealed that biochar-treated soils exhibited significantly lower SOC mineralization than straw-treated soils. Furthermore, biochar-straw co-application demonstrated greater efficacy in suppressing C losses relative to straw alone, with reductions of 49% in sodic solonchaks and ~25% in cambisols. This reduction was attributed to biochar's inherent resistance to microbial degradation, strong adsorption of ammonium nitrogen, and reduced dissolved organic C availability. These effects highlight biochar's dual role as both a biologically inert C pool and an active regulator of soil nutrient dynamics. Notably, biochar application promoted SOC stabilization by increasing the aromatic-to-aliphatic C ratio (quantified as relative absorbance ratio of 1630 $cm^{-1}$ to 2920 $cm^{-1}$, rA1630/rA2920), indicating enhanced aromatic C accumulation while suppressing bacterial activity and aliphatic C formation. In contrast, direct straw incorporation stimulated microbial growth, increasing microbial residue C accrual, its contribution to SOC (~13%), and the fungal-to-bacterial residue C ratio, suggesting distinct SOC stabilization via microbial residue formation. Straw amendment significantly enhanced microbial residue C accumulation by ~20% relative to controls and biochar treatments, where biochar-treated soils showed microbial residue C levels similar to controls. Notably, under straw amendment, cambisols exhibited a 1.5-fold greater microbial residue contribution to SOC than sodic solonchaks. These findings demonstrate a fundamentally different SOC stabilization mechanisms: biochar enhances chemical stabilization through aromatic C enrichment, whereas straw fosters biological stabilization through microbial residue accumulation. Moreover, the ability of biochar to mitigate nutrient-induced SOC destabilization underscores its potential for reducing soil $CO_2$ emissions and advancing sustainable soil C management.

# Short rotation coppice on degraded and fertile soils

**Vladimir Ivezić[1*], Jurica Jović[1], Vladimir Zebec[1], Dario Iljkić[1] and Filip Štenta[1]**

[1] *Faculty of Agrobiotechnical Sciences Osijek (FAZOS). University of Josip Juraj Strossmayer in Osijek. Vladimira Preloga 1, Osijek, Croatia*

*vivezic@fazos.hr

**ABSTRACT**

Our research examines the productivity and growth of short-rotation coppice (SRC) species in an alley-cropping system on soils of varying quality and under different mulching treatments at the experimental site of the Faculty of Agrobiotechnical Sciences Osijek, Croatia. In 2021, an SRC trial was established with willow (*Salix alba* L.) and poplar (*Populus* spp.). Trees were planted in four 8-m belts, each with six rows spaced 1–2 m apart, separated by 24-m alleys for machinery access. Belts were 100 m long, with 50-m sections assigned to each species. A control plantation was located on the southern edge, and a canal bordered the western side.

The study evaluated growth performance and biomass productivity of willow and poplar across four soil treatments: degraded soil, fertile soil, fertile soil with straw, and fertile soil with nylon mulch. This setup enabled analysis of how soil quality and mulching influence SRC development. Biomass sampling was conducted in 2025, while tree height was measured in 2021, 2023, and 2024.

During the four years (2021-2025), poplar consistently produced more biomass than willow across all soils. Poplar performed best on fertile soil without mulch (50,05 t/ha), though mulch with nylon (42,55 t/ha) and mulch with straw (38,90 t/ha) also supported strong growth. Willow showed its best growth on fertile soil with nylon (26,32 t/ha), likely due to improved moisture retention and reduced weed pressure. Straw mulch was the least effective for willow (2,21 t/ha), limiting water and air availability and resulting in the lowest yields. Degraded soil produced moderate but acceptable growth (willow – 11,90 t/ha; poplar – 28,63 t/ha) in comparison to the control (willow – 5,00 t/ha; poplar – 17,71 t/ha).

Height measurements from 2021–2024 supported these patterns: nylon mulch benefited willow heights, while poplar was highest on fertile soil without any mulch. Statistical analyses confirmed significant differences among treatments, emphasizing the importance of soil quality and mulch choice.

Biomass data from 2021 and 2025 further showed that soil quality determined yield. Fertile soil produced the highest biomass, with nylon mulch offering notable gains, especially for willow. Mulch treatments showed that straw-covered blocks consistently had the lowest yields, although poplar performance on straw improved by 2025. Overall, findings demonstrate that alley-cropping systems with fast-growing SRC species such as willow and poplar provide an effective approach to producing renewable raw materials. They also offer potential for rehabilitating and economically using degraded or marginal soils, contributing to more resilient and diversified land-use systems.

# Effects of combined application of biochar and manure composts on greenhouse gas emissions and forage maize yields

**Tsuyoshi Yamane**[1]*

[1] *Hokkaido Agricultural Research Center, NARO, Sapporo, Japan*

*yamane.tsuyoshi756@naro.go.jp

## ABSTRACT

To develop agricultural practices that increase the soil carbon stock, we applied biochar in combination with manure compost (MC), a conventional organic amendment, and evaluated greenhouse gas (GHG) emissions and forage maize yields. Five treatments were established: (1) no-nitrogen control (P+K only), (2) inorganic fertilizer (F) treatment, (3) biochar (B) + F (B+F) treatment, (4) MC+F treatment, and (5) B+MC+F treatment. Inorganic fertilizer was applied at 19 g N $m^{-2}$, 8 g P $m^{-2}$, and 11 g K $m^{-2}$ in all treatments except the control (no N) and the MC+F and B+MC+F treatments (no added K owing to sufficient K in MC). MC (3.58% ± 0.26% N, 35.5% ± 2.8% C on dry matter [DM] basis, mainly cattle manure) was applied at 1000 g DM $m^{-2}$ in the MC+F and B+MC+F treatments. Biochar (80.2% ± 3.9% C on DM basis, made mainly from wood, with particle size of <5 mm) was applied at 1000 g DM $m^{-2}$ in the B+F treatment, and 10% by weight (289–306 g DM $m^{-2}$) of MC in the B+MC+F treatment. Three blocks were prepared, and five treatment plots (8 m × 6 m = 48 $m^2$ per plot) were randomly arranged within each block (total of 15 plots) in an experimental field at our research center in Sapporo, Japan. The field soil is classified as Allophanic Andosols. GHGs ($N_2O$, $CH_4$, and $CO_2$) were measured at least weekly, except during the snow season, in each plot by the closed chamber method. For $CO_2$ measurement, to exclude the influence of root respiration, stainless steel plates were inserted into the soil around the chamber base to a depth of 30 cm. Forage maize (*Zea mays* L.) was grown (in 75-cm rows and an 18-cm plant spacing) in each plot. Experiments were conducted from 1 May 2023 to 24 Apr 2024 and from 1 May 2024 to 24 Apr 2025. The GHG balance (total GHG emissions as $CO_2$ equivalent minus input C from biochar, MC, and crop residues) in each treatment decreased in the order of control ≥ F > MC+F > B+MC+F > B+F in each year (Fig. 1). It was positive in the control and F treatments, slightly negative (close to 0) in the MC+F treatment, and negative in the B+MC+F and B+F treatments. The addition of biochar did not affect GHG ($N_2O$, $CH_4$, and $CO_2$) emissions. Forage maize yields did not differ significantly among treatments in 2023–24 except in the control, in which it was significantly lower. But the yield was significantly higher in the B+MC+F treatment than in the other treatments in 2024–25, and yields tended to be higher in the treatments with MC. The addition of biochar to MC increased the soil C stock and had no effect on or increased forage maize yield relative to MC alone.

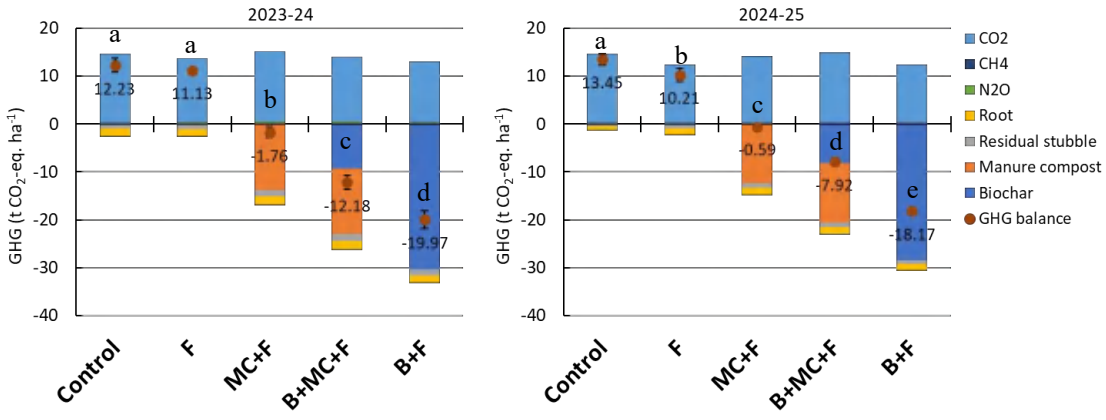

Figure 1 GHG balance in the field experiments in 2 years. Identical letters indicate that there is no significant difference among GHG balance by Tukey's HSD test ($P < 0.05$).

## ABSTRACT

Enhanced rock weathering (ERW) is a promising carbon dioxide ($CO_2$) removal strategy achieved through application of crushed silicate rock to soils. Beyond its potential for large-scale atmospheric $CO_2$ drawdown, ERW may provide agricultural co-benefits such as soil pH enhancement, replenishment of soils with essential macro and micro-nutrients, stabilization of soil organic carbon, and increased crop yields. While agriculture offers an infrastructure for ERW, the weathering rates of applied minerals and their impacts on soil and plant systems remain unclear. Among various silicate lithologies, basalt, a Ca- and Mg- rich mafic rock, is suitable for ERW due to its favorable mineralogy, high weathering rate, and widespread availability as a reasonably fine grained (<4 mm) quarry by-product. This study characterizes the physical and chemical properties of three different basalts from South Australia, Queensland, and New South Wales, Australia to evaluate their liming value in acidic agricultural soils. The study focused on the weathering rate, base cation release, and acid neutralization capacity (ANC) of basalt, which holds potential as an alternative to agricultural lime for correcting soil acidity. The particle size distribution of basalt was determined by sieving followed by laser diffraction (<75 µm fractions) analysis and, specific surface area (SSA) was measured using the $N_2$ adsorption-desorption method. Surface morphology and roughness were evaluated using scanning electron microscopy (SEM). Mineralogy and elemental compositions were determined through X-ray diffraction (XRD) and SEM with energy dispersive X-ray spectroscopy (SEM-EDS), and total elemental contents were analyzed using inductively coupled plasma-optical emission spectroscopy and mass spectrometry (ICP-OES/MS). The basalt samples yielded p80 values (i.e., 80% of particles less than this size) of 1,454-1,710 µm. Elemental analysis across all basalt samples indicated high concentrations of the essential plant macro-nutrients such as Ca (56.33-73.30 g/kg), Mg (34.78-49.77 g/kg), K (16.84-26.36 g/kg), P (0.40-5.70 g/kg) and, S (0.17-0.26 g/kg). Potentially toxic elements such as As and Cd, were present at 0.86-2.75 g/kg and 0.08-0.35 g/kg, respectively. The ANC values of basalt samples will be determined by titrations and a 90-day soil incubation experiment, comparing five treatments: T1 (<75 µm basalt), T2 (<75-250 µm basalt), T3 (<250-4000 µm basalt), T4 (pure $CaCO_3$), and T5 (agricultural lime). The findings of this study will provide valuable insights into the industrial relevance of utilizing basalt as an alternative soil amendment enhancing fertility, crop production, and atmospheric $CO_2$ removal via minimizing risks of potentially toxic element release.

[2] *Pee Dee Research and Education Center, Florence, SC 29506, United States*

*franko@g.clemson.edu

**ABSTRACT**

Organic agriculture is a prominent strategy for maintaining or enhancing sustainability; however, the impacts of common conservation management practices within these systems remain underrepresented in the scientific literature. Here, a two-year field experiment was established to assess the integrated effects of cover cropping (cereal rye and hairy vetch mixture), manure compost amendment (with and without), and tillage practices (no-till and conventional tillage) on soil biogeochemical properties, greenhouse gas emissions ($CO_2$, $CH_4$, and $N_2O$), and yields in a sandy soils under organic vegetable production (tomato-sweet corn) from 2022 to 2024. Integrating the CC mixture resulted in higher $CO_2$ emissions, likely due to increased organic C inputs from root exudates and residue returns, which, however, were not affected by the simultaneous applications of manure compost and conventional tillage. No significant treatment effects on $CH_4$ and $N_2O$ emissions or vegetable yields were observed throughout the study. Conservation tillage with fall manure application and CC mix resulted in a higher greenhouse gas index (GHGI) than fallow, which was attributed to higher GHG emissions under CC and a similar vegetable yield among all treatments. Overall, integrated conservation management practices did not result in significantly higher environmental footprints and could serve as promising options for sustainability and soil conservation.

# Can Perennials Cut Nitrous Oxide Emissions? Insights from Manitoba Cropping Systems

**Faezeh Parastesh[1], Xiaopeng Gao[1*], and Joanne Thiessen Martens [1]**

[1] *Department of Soil Science, University of Manitoba, Canada*

*Xiaopeng.gao@umanitoba.ca

**ABSTRACT**

Agriculture is a major source of greenhouse gas (GHG) emissions. Nitrous oxide ($N_2O$) is especially important because it has a strong warming effect and stays in the atmosphere for a long time. Reducing $N_2O$ from farmland is a key step toward the net-zero climate goals. As part of the Leveraging Ecosystems to transform Agriculture on the Prairies (LEAP) project, this study examines how different cropping systems and soil textures affect $N_2O$ emissions in Manitoba, Canada. The cropping systems include perennial, annual, and intermediate systems. Two main soil textures are studied: clay and sandy. These systems represent common farm practices in the region.

This is a three-year (2025-2027) field study across six sites. During the growing season, in-situ $N_2O$ fluxes are measured using static chambers. At the same time, silicon diffusive samplers collect $N_2O$ concentrations at 5, 15, 30, and 60 cm soil depths. These measurements help us understand both surface emissions and $N_2O$ movement and production below ground. The study addresses three main questions:
(1) Do perennial systems release less $N_2O$ than annual or intermediate systems?
(2) How does soil texture change $N_2O$ emissions and productions?
(3) What soil, environmental, and management factors mainly control $N_2O$ emissions?

We expect that perennial systems may lower emissions because they receive less fertilizer, disturb soil less, keep living roots year-round, and improve soil structure. Soil texture may also influence $N_2O$ production and emissions by affecting soil water, aeration, and microbial activity. The results will give new information about how farm management and soil conditions affect $N_2O$ emissions. This knowledge can support better nutrient management and help design farming systems that ensure crop production while reducing GHG emissions. Preliminary findings from the first year of field measurements will be shared in this poster.

# A Spatially-Explicit Framework for Agricultural Best Management Practices: Guidelines, Database, and Future Directions

**Yuchuan Fan***

Zhejiang A&F University, Zhuji 311800, China
* fanyuchuan@zafu.edu.cn

**ABSTRACT**

The effective implementation of Best Management Practices (BMPs) is crucial for mitigating the environmental impact of agriculture. However, the vast and often disorganized nature of existing BMP information can hinder their adoption and optimization. This initiative addresses this gap by introducing a comprehensive program to establish clear guidelines, a centralized database, and a robust conceptual framework for agricultural BMPs. A key innovation of our approach is the spatial categorization of all BMPs into four distinct categories: Edge-of-Field Practices, Airway BMPs, Surface BMPs, and Underground BMPs. This spatial taxonomy provides a systematic method for understanding, selecting, and implementing practices based on their location and primary zone of influence within the agricultural landscape. The outcomes of this initiative include: (1) a set of refined BMP guidelines tailored to this new categorization, (2) a searchable database to facilitate access to technical specifications and efficacy data, and (3) a conceptual framework that supports decision-making for farmers, planners, and policymakers. Finally, we discuss the future direction of this initiative, including the integration of precision agriculture technologies and the development of decision-support tools, aiming to enhance the scalability, effectiveness, and adoption of conservation practices for sustainable agricultural systems.

# Mechanism of soil carbon sequestration in cover cropping systems

**ABSTRACT**

Cover cropping is an effective agricultural management practice to enhance soil organic carbon (SOC) sequestration and mitigate climate change. However, the contributions of different cover crop (CC) species to specific soil carbon (C) fractions remain unclear. Here, we combined a 5-year summer CC-winter wheat field experiment and an in-situ $^{13}$C-labeled CC residue decomposition experiment on the Loess Plateau of China to clarify: (1) the responses of soil C fractions to cover cropping, and (2) the distribution and sequestration mechanisms of CC-derived C. In the field experiment, three CC treatments were established during summer fallow—soybean (*Glycine max* L., SB), sudangrass (*Sorghum sudanense* (Piper) Stapf, SG), and their mixture (SS)—with residues incorporated into the soil two weeks before winter wheat planting annually. The in-situ decomposition experiment included $^{13}$C-labeled SB residues, $^{13}$C-labeled SG residues, and a no-residue control to investigate CC residue decomposition dynamics, the distribution of CC-derived C into aggregate-protected and unprotected fractions, and associated sequestration mechanisms. Measured soil C fractions included coarse particulate organic C (cPOC), free fine particulate organic C (fPOC), intra-microaggregate fine particulate organic C (iPOC), and mineral-associated organic C (MOC), with iPOC and MOC considered protected against mineralization. Field experiment results showed that integrating CCs into the winter wheat system enhanced soil aggregation and SOC sequestration compared to no cover cropping, primarily by increasing microaggregate-protected C and MOC and thus improving C stabilization. The SS mixture was more effective than monoculture SB or SG in promoting aggregate stability and C fractions. In-situ incubation results indicated that the seasonal cumulative recovery rate of CC-derived C in SOC was higher for SB than SG. Soil C sequestration from CC residues occurred mainly as aggregate-protected C, predominantly MOC. Cover cropping directly promoted SOC sequestration primarily by increasing aggregate-protected C. SG residue incorporation sequestered C mainly via enhancing cPOC and iPOC, while SB residue increased cPOC, iPOC, and MOC. Collectively, our findings clarified the distinct C sequestration mechanisms of legume and non-legume cover cropping systems, providing scientific supports for CC adoption in climate-smart agriculture in the Loess Plateau and similar regions.

* muhammad.riaz@gcuf.edu.pk

**ABSTRACT**

Cereal-legume intercropping provides multiple benefits to agroecosystems, and thus, can promote sustainable intensification and climate-resiliency. However, such agricultural practices are little explored in dryland agroecosystems such as those existing in Pakistan. As a part of the Horizon Europe LEGUMINOSE Project, we established 14 wheat-legume intercropping living labs at farmers' fields (eight wheat-pea, five wheat-chickpea and one wheat-faba bean) across Pakistan. Thirteen living labs followed strip intercropping method whereases alternative row intercropping method was adopted at one wheat-pea intercropping lab. At the end of the growth season, crops were harvested to record biomass and grain yield data; surface soil samples were collected for analysis of soil physico-chemical and biochemical functions. We also collected economic analysis and farm-profitability data from one wheat-pea living lab. Results revealed synergistic effects of cereal-legume intercropping mainly on the biomass and yield of wheat; wheat biomass production and grain yield were higher when intercropped with legumes than solo cultivated wheat. Similar trends were observed for wheat-pea and wheat-chickpea intercropping living labs; however, under the wheat-faba bean living lab, both the yields of wheat and faba bean were lower under intercropping compared to their solo cultivations. When wheat and pea were intercropped following the alternative row method, this also did not increase biomass and grain yield of wheat and peas under intercropping. Data on land equivalent ratio (LER) also suggested cereal-legume intercropping resulted in more productivity as LER values were generally >1.00 in most cases. Economic analysis from one wheat-pea intercropping living lab showed adopting intercropping was more profitable and also resulted in better grain quality. Results from soil nutrient availability and soil organic carbon (SOC) analyses provided evidence that cereal-legume intercropping improved soil fertility and quality. These living lab studies demonstrated that cereal-legume intercropping can be an important tool to increase crop productivity and soil multifunctionality.

# Towards a low-carbon and climate-resilient Mediterranean agriculture: the integration of Conservation Agriculture and 4R Nutrient Stewardship in herbaceous and woody crops

**Jesús Sevillano-Caño[1*], Alfonso Moreno-Moraga[2], Miguel Ángel Repullo-Ruibérriz de Torres[2], Andrés Peñuela[1], Tom Vanwalleghem[1], Emilio Jesús González-Sánchez[2] and Antonio Rafael-Sánchez-Rodríguez[1]**

*[2] Department of Rural engineering, University of Córdoba, Córdoba, Spain*

*o42secaj@uco.es

**ABSTRACT**

Conservation Agriculture (CA) and 4R Nutrient Stewardship are two pillars to adapt to climate change, enabling productive, climate-resilient and low-carbon agricultural systems. CA promotes permanent soil cover, minimum soil disturbance and crop diversification, enhancing soil organic matter (SOM), water infiltration, biodiversity and reducing erosion and greenhouse gas (GHG) emissions. In combination with the 4R principles (right source, rate, time and placement of fertilizers), nutrient use efficiency can be maximized while minimizing losses of nitrogen (N) and phosphorus (P). However, evidence under real farm conditions, especially in Mediterranean environments where carbonates pose a major nutrient constraint and SOM content is commonly low, remains limited. Therefore, the aims of this study are: i) to evaluate whether localized, variable-rate applications of single P fertilizers at sowing, together with delayed or crop-specific N applications, improve nutrient use efficiency, and reduce GHG emissions; ii) to assess the role of legumes and cover crops in increasing SOM, fixing biological N, and improving water balance under Mediterranean rainfed conditions, and iii) to quantify CA impact on carbon (C) sequestration, lower $CO_2$/$N_2O$ emissions and reduced fuel use relative to conventional tillage systems. To this end, four field trials in four long-term commercial farms under CA are developed: two for annual crops (cereals, sunflower and legumes in crop rotation), and two for perennial crops (olive and citrus orchards). The experimental design in each field follows a complete randomized block design with four different treatments: i) conventional tillage and conventional fertilization, ii) CA and conventional fertilization, iii) CA and optimized fertilization (following the 4R principles), and iv) CA with strategically managed groundcovers or cover crops. In annual rotations, focus is on direct seeding and variable-rate P placement, while in olive and citrus orchards groundcovers are used to improve SOM, nutrient cycling and biological N fixation. Under this combined framework, GHG emissions ($CO_2$ and $N_2O$) together with several soil-health indicators such as enzyme activity and C sequestration are being periodically measured to generate robust, transferable data to support the transition toward a low-carbon, resource-efficient agriculture. In this sense, optimized fertilization improves nutrient use efficiency and lower GHG emissions, while cover crop mixtures enhance soil functionality even under the limited precipitation typical of Mediterranean conditions, fully aligning with European and Mediterranean sustainability targets.

## ABSTRACT

Achieving Climate-Smart Agriculture (CSA) requires Best Management Practices (BMPs) that not only ensure productivity but also enhance soil resilience and mitigation potential against climate variability. Within the framework of the Horizon Europe project AGROSUS (GAP-101084084), this study assesses the impact of agroecological (AGRO) weed management strategies versus conventional chemical control (CON) on soil health indicators across six distinct European biogeographical regions: Alpine (ALP), Atlantic (ATL), Boreal (BOR), Continental (CONT), Macaronesian (MAC), and Steppic (STP). Soil samples from long-term field trials were analyzed for physicochemical properties using multivariate statistical approaches. Results revealed that while regional pedogenesis explained over 50% of the total variance, AGRO induced significant, site-specific alterations. In CONT region, soils exhibited the highest sensitivity, with AGRO significantly improving drought adaptation indicators, increasing field capacity water content ($p < 0.05$). The BOR and STP regions demonstrated significant increases in Cation Exchange Capacity (BOR) (8.17 (AGRO) vs 6.25 $cmol^+ kg^{-1}$ (CON), $p < 0.001$) and STP (22.7 AGRO vs 18.13 $cmol^+ kg^{-1}$ (CON); and exchangeable Calcium (BOR: 1339.89 (AGRO) vs 966.09 (CON) mg $kg^{-1}$) (STP: 3940.25 (AGRO) vs 3264.91 (CON) mg $kg^{-1}$) ($p<0.001$) under agroecological management. under agroecological management. This enhancement in soil structure is directly linked to improved soil organic carbon stabilization, a key pillar of climate mitigation. Similarly, the Alpine region showed tightened nutrient cycling, marked by significantly different Nitrate levels (7.15 (AGRO) vs 9.72 (CON) mg $kg^{-1}$, $p = 0.006$). In the saline-prone Macaronesian region, sustainable practices moderate Electrical Conductivity (152.98 (AGRO) vs 232.25 $dSm^{-1}$ (CON), $p = 0.016$), suggesting a vital pathway to mitigate salinization. Conversely, the Atlantic region displayed physicochemical stability with minimal significant changes, suggesting CSA strategies here should focus on biological indicators. This data provides a robust framework for tailoring agroecological strategies within the AGROSUS project, supporting the transition towards resilient agroecosystems across Europe in alignment with the EU Farm to Fork Strategy and the European Green Deal.

# Nitrogen use for improved profitability and sustainability of rice production in central Myanmar

**Xia Liang [1*], Ian R. Willett [1], Arjun Pandey [1], Helen Suter [1], Gayathri Mekala [1], Yunrui Li [1], Baobao Pan [1], Deli Chen [1]**

## ABSTRACT

This study explores optimal N application rates for sustainable rice production in central Myanmar by integrating recent research with additional economic and environmental analyses. Results indicate limited yield responses to applied N in monsoon rice, but significant gains—from ~4 to 8 t ha_1—are achievable in dry-season irrigated rice mainly due to higher solar radiation during the dry season. For monsoon-season rice, the economically optimal N rates were found to be 82.8 kg N ha–1 with the maximum net economic benefit (NEB) at 617 US$ ha_1. For dry- season irrigated rice, higher N rates were recommended, with the economically optimal N rates at 202 kg N ha–1 and the maximum NEB at 661 US$ ha_1. However, high fertilizer N inputs to rice in Myanmar have been shown to increase native soil N extraction in rice paddies and negatively affect microbial N retention and the promotion of Nr losses. If we take the social costs of Nr losses into the cost benefit analysis, the ecological optimal N rates were found to be 66 kg N ha_1 for monsoon season rice and 48.2 kg N ha_1 for dry-season irrigated rice. The adoption of ecologically optimal N rates could avoid social pollution costs of US$55 and US$368 per hectare annually compared to the current farming practices and economically optimal N rates, with benefits that outweigh the marginal drop in net economic returns. Farmer engagement revealed a pReferences for co-developing tailored fertilizer strategies with peers, extension agents, and researchers via interactive platforms (e.g., Facebook). This participatory model may be extended to similar contexts in Cambodia and Lao PDR.

*liang.xia@unimelb.edu.au

**ABSTRACT**

Rice production in Southeast Asia is critical to local food security and rural livelihoods, providing over half of daily caloric intake and contributing more than one-third of household income. However, existing research is unevenly distributed across the region. Much of the current evidence base draws on relatively well studied countries such as Thailand, while nations like Lao PDR, Vietnam and Cambodia remain under presented in the literature. Their rice sectors are characterised by low external inputs, and large reliance on rainfed production. Although these features are often framed as limitations, they also represent a unique opportunity. Unlike China and India, where decades of intensive nutrient use have generated severe environmental impacts, these less managed systems are still a stage where sustainable intensification can be achieved without inheriting the environmental legacy of overuse.

This review synthesises current knowledge on rice production in underdeveloped regions in Southeast Asia, highlighting the environmental and socioeconomic factors shaping production. It argues that improving soil fertility through site-specific nutrient management, integrating organic inputs, and adopting water-saving approaches such as alternate wetting and drying can substantially enhance productivity while maintaining low environmental pressure. Coupling these agronomic interventions with modelling tools (e.g. ORYZA, CERES-Rice) enables more accurate and cost-effective planning under increasing climate variability. Policy measures that reward ecosystem services and recognise the added value of green rice products can create additional income streams for smallholders, supporting both livelihood improvement and the transition towards sustainable management.

Together, these strategies illustrate a development pathway in which Southeast Asia's less-intensive rice systems can leapfrog the high-pollution trajectory experienced elsewhere, advancing productivity, nitrogen-use efficiency and long-term resilience through a greener model of rice production.

## ABSTRACT

Functional legume rotations offer a promising pathway for improving soil health while sustaining food production under climate change. Soil organic carbon (SOC) is central of this challenge[1], yet the global capacity of legume functional types (grain, forage, green manure) to enhance SOC and yield—and their future climate sensitivity—remains poorly quantified. Existing evidence shows inconsistent SOC responses and unclear yield synergies[2], limiting targeted soil-restorative cropping strategies.

Here, we compile the most comprehensive global synthesis to date, integrating 161 legume rotation systems across 610 sites with 3,865 SOC and 15,282 yield observations from 1959 to 2024. Using machine learning upscaling (random forest; $R^2$ = 0.73–0.86) and spatial prioritization, we quantify: (i) the SOC and yield impacts of legume types, (ii) global biogeographic patterns, and (iii) performance under future climates (SSP245, SSP585).

Across systems, legume rotations increased SOC and crop productivity by 4.4% and 20%, respectively. Functional type was the dominant determinant of SOC gains: Forage legumes increased SOC by 8.2%, green manure by 5.2%, whereas grain legumes showed minimal change. Carbon gains coupled with yield benefits, with green manure rotations producing the largest yield improvement (35.3%) and the strongest SOC–yield synergies. Spatial upscaling revealed marked biogeographic differentiation: Forage performed best in temperate humid regions, while green manure was most effective in C-poor tropical and subtropical croplands. Optimized global legume allocation could deliver up to 8.6% SOC sequestration and 43.5% yield increase, with balanced SOC–yield maximization achieving 7.1% and 41.3%, respectively. Future climate projections indicate that SOC–yield co-benefits will strengthen under SSP585 by 5.6–8.5% by 2100, but ~40% of croplands need optimal legume types shifts to maintain benefits. Green manure showed the highest climatic resilience, requiring substantially smaller geographic adjustments. Our findings demonstrate that functional diversification of legume rotations is a globally scalable strategy for enhancing SOC while supporting food security. By linking legume functional types to geographic context and climate adaptability, this study provides a quantitative framework to inform soil-centered climate-smart agricultural cropping worldwide.

## ABSTRACT

The increasing urgency of climate change mitigation requires a better understanding of the trade-offs between soil organic carbon (SOC) sequestration and nitrous oxide ($N_2O$) emissions. While cover crops are integral to no-till systems and enhance SOC storage, they also influence nitrogen (N) cycling, potentially increasing $N_2O$ emissions that can offset their climate benefits. This study investigated how different N sources, organic (legume and grass cover crop residues) and inorganic (ammonium sulfate), affect ammonia-oxidizing microorganisms and $N_2O$ emissions in tropical soils with contrasting pH (5.6 and 7.0) during a microcosm incubations experiment. Legume residues mineralized approximately 20 µg NH4+-N g-1 more than grass residues in acidic soil, and both residues increased soil pH by up to 1.5 units within 10 days. Nitrous oxide emissions varied significantly with N source and soil pH, exhibiting distinct temporal patterns. In acidic soil, litter decomposition produced higher $N_2O$ emissions than ammonium sulfate during the first 13 days, although cumulative emissions were 45% greater than with litter. In near-neutral pH soil, ammonium sulfate and legume residues generated up to 10.7-fold higher $N_2O$ emissions than grass residues or the control. Emission factors showed that ammonium sulfate contributed a greater proportion of added N to $N_2O$ emissions, particularly in acidic soil (0.48% of total N), whereas grass and legume residues emitted 0.13% of their total N, corresponding to 0.54 and 0.44% of mineralized N, respectively. In near-neutral soil, EFs decreased to 0.32% for ammonium sulfate and to 0.05 and 0.11% of total N (0.21 and 0.54% of mineralized N) for grass and legume residues. The abundance of ammonia-oxidizing bacteria increased under all N amendments relative to the control, especially in acidic soils with organic inputs, whereas ammonia-oxidizing archaea were most responsive to organic inputs in near-neutral soils. Cover crop management play an important role in regulating soil N dynamics and activity of ammonia-oxidizers by modifying soil pH and ammonium availability, thereby influencing $N_2O$ emissions and partially offsetting the climate benefits of SOC sequestration.

## ABSTRACT

Although the effects of planting density, nitrogen fertilizer application, and supplemental irrigation on crop growth are well-studied, their underlying mechanisms, particularly source-sink relationships, in yield formation and water/nitrogen use efficiency improvements remain unclear. This study investigated how these three factors affect source-sink characteristics in maize, aiming to identify key factors for improving yield and resource use efficiency. The goal is to support a green theoretical system for crop that achieves high yield, high efficiency, and synergy. For this purpose, a three-year field experiment was conducted during the maize growing seasons from 2023 to 2025, with treatments combining different planting densities, nitrogen application rates, and supplemental irrigation volumes. Source and sink indicators were measured throughout the growth period, and their relationships were quantified. Results showed that leaf area index (LAI) increased with planting density and irrigation under the same nitrogen level. Higher nitrogen application led to higher and longer-lasting relative chlorophyll content (SPAD) peaks. Biomass under medium and high nitrogen treatments was significantly greater than that under the low nitrogen treatment. Split nitrogen application enhanced maize yield. However, yield gains from higher density diminished beyond the D2 level. Total source supply and source supply rate increased with planting density under the same nitrogen input. Under the different cultivation practices, sufficient source supply was accompanied by a concurrent increase in sink storage capacity. The source-sink ratio was >1 in most treatments, indicating ample source for sink development. Compared to one-time basal fertilization, integrated water-fertilizer topdressing significantly increased partial factor productivity of nitrogen ($PFP_N$) and nitrogen use efficiency (NUE), by up to 209.49%. Source serves as the key link connecting planting management and resource use efficiency. Planting density was the main driver of source improvement. Optimal density and precise water-nitrogen synchronize source and sink, enhancing both yield and water/nitrogen use efficiency. This study provides new insights into source-sink regulation under density-nitrogen-irrigation interaction and provides a physiological pathway for high-yield, high-efficiency maize cultivation.

## ABSTRACT

Emerging soil organic matter (SOM) continuum models describe SOM as a spectrum linking particulate, dissolved, and mineral-associated organic matter. At the scale of soil aggregates, dissolved organic matter (DOM) serves as a dynamic and mobile link within the SOM continuum, yet the agronomic factors regulating aggregate-scale DOM remain poorly understood. We used soil aggregates from a long-term integrated crop-livestock experiment in Southern Manitoba, Canada (est. 2007) with an RCBD split-split plot design: two cropping systems (annual vs annual-perennial), four manure treatments (no manure, liquid pig, solid pig, solid dairy), and two soil management strategies (regenerative: no-till with cover crops; vs conventional tillage). Bulk soil aggregates (< 8 mm) were wet sieved into macroaggregates (250-2000 µm), microaggregates (53-250 µm), and silt+clay (< 53 µm). Macro- and microaggregates were water-extracted to obtain aggregate-derived DOM and further fractionated to isolate associated particulate (POM) and mineral-associated (MAOM) fractions. DOM was characterized using UV-Vis indices and fluorescence EEM-PARAFAC components. We used PERMANOVA ($\alpha = 0.05$) to test treatment effects, NMDS to visualize DOM gradients, and envfit to link those gradients to POM and MAOM mass fractions and C: N ratios. Manure form was the dominant driver of DOM composition, whereas crop rotation and soil management had negligible effects. NMDS revealed an aggregate-DOM continuum in which DOM shifted from more plant-like, aromatic signatures toward more N-rich, microbially processed components, and these gradients closely tracked underlying POM and MAOM quantity and stoichiometry. Solid manures, especially solid pig, most strongly diversified this DOM continuum by enhancing both plant-derived and microbially processed fluorescence components within aggregates. Preliminary $\delta^{13}C$–$\delta^{15}N$ biplots for macroaggregate-associated cPOM and free MAOM show that solid pig treatment occupies the most $^{15}N$-enriched region of C–N space, indicating efficient transfer and incorporation of manure-derived N into both particulate and mineral-associated pools.

# Soil Organic Carbon Buffers Wheat Yield Against Warming by Regulating Phenological Sensitivity

## ABSTRACT

**Background:** Global warming threatens crop production primarily by accelerating crop development, shortening phenological phases, and reducing the time available for biomass and yield formation. Soil Organic Carbon (SOC), a key regulator of soil physical and biological functions, has been proposed to mitigate warming impacts through its effects on soil water-holding capacity and thermal dynamics. However, the quantitative capacity of SOC to buffer yield loss under warming, and whether its effects are mediated by modifying crop phenological responses to temperature, remain poorly quantified.

**Methods:** To address these gaps, we performed a meta-analysis of 9 field experiments with controlled temperature treatments from 13 site-years across China (growing-season temperatures ranging from 5.4 ℃ to 17.3 ℃, $n$ = 34). We quantified the interactive effects of SOC and temperature on wheat yield, and tested the hypothesis that SOC buffers yield against warming by altering crop phenological sensitivity to temperature.

**Results:** The study revealed a significant positive interaction between SOC and temperature on wheat yield. While elevated temperatures generally reduced yields, higher SOC levels significantly mitigated this loss. A critical SOC threshold of 16.3 g $kg^{-1}$ was identified, above which warming-induced yield loss was largely eliminated. Importantly, we found a strong negative correlation ($R=-0.776$, $P<0.01$) between SOC content and the developmental sensitivity of the vegetative stage to temperature. This indicates that SOC acts as a phenological stabilizer. High SOC soils effectively alleviated the negative effects of warming on crop's physiological development, slowing down the temperature-induced acceleration of development and extending the vegetative growth period, which benefit high yield.

**Conclusion:** Our findings advance understanding of soil-climate-crop interactions by identifying a novel mechanism: SOC buffers wheat yield against warming primarily through phenological stabilization. The critical threshold (16.3 g $kg^{-1}$) provides a practical target for SOC management in Chinese wheat fields to enhance climate resilience. Enhancing SOC sequestration therefor offers a synergistic pathway for climate smart agriculture by offsetting greenhouse gas emissions while reducing the harmful effects of high temperature on crop development.

# Decadal biochar legacy alters soil physicochemical properties but not microbial C turnover

**Mingming Zong[1*], Lars Elsgaard[1], and Zhi Liang[1]**

[1] *Department of Agroecology, Aarhus University, Tjele 8830, Denmark*

*E-mail address: zongmmkm@163.com

**ABSTRACT**

Biochar is increasingly applied as a land-based carbon (C) sequestration option with agronomic co-benefits. However, the long-lasting effects of biochar in soil ecosystems remain poorly documented. In particular, it is unclear whether a single application leaves durable and decadal legacies, e.g., for microbial soil C cycling, and whether these effects depend on soil texture, and biochar application dose or biochar types. Here, we studied a semi-field lysimeter facility in Denmark where biochar was applied to investigate (i) effects of soil texture and biochar application dose with three soils (coarse sand, sandy clay, clay) that received a single straw biochar application in 2015 at doses of 0, 0.5, 1 and 2% (w/w), and (ii) effects of biochar type with a sandy clay soil that received a single application in 2015 of straw biochar, manure biochar and a 1:1 mix thereof, all at 1% (w/w). All treatments had biochar mixed into the top 0-20 cm of the soil and were established in four replicates. A decade later in 2025, we measured topsoil physicochemical properties and tested C turnover using $^{14}$C-labelled ryegrass root material and $^{14}$C-labelled vanillin in mesocosms to resolve potential changes in mineralization of organic C compounds with varying chemical recalcitrance and potential priming of native SOC. Across soil types, the single biochar application had decadal legacy effects in terms of increased soil C in an expected dose-dependent manner. Beyond total C, biochar raised water-holding capacity and decreased bulk density in a dose- and texture-dependent way. Effects on soil pH after 10 years were minor, as opposed to marked increases seen in the first year after biochar application. Basal respiration (measured as cumulative $CO_2$ evolution during 21 weeks) in each of the three soils showed no significant response to straw biochar across application doses (0.5, 1 and 2% w/w) whereas the mixture of straw and manure biochar (1% w/w) showed significantly higher $CO_2$ evolution than the other treatments (mix > control ≈ manure > straw). The substrate-induced respiration assays with added root materials or vanillin showed no significant differences in net respiratory response across the tested application doses or biochar types. Across all three soil textures, the priming effects induced by root addition remained similar regardless of biochar application dose throughout the incubation period. In the sandy clay with 1% biochar, biochar application regardless of the type lowered root-induced positive priming after incubation for 3 months. However, with extended incubation, such effect disappeared. In summary, our results show that biochar leaves long-lasting effects on soil physicochemical properties, while legacy effects on microbial turnover of C are relatively minor.

## ABSTRACT

Under mulched drip irrigation in arid regions, soil water and salinity within the wetted root zone exhibit pronounced periodic transport driven by irrigation events. Crop water and salt stress is not only directly related to the magnitude of soil water content and salinity, but is also strongly coupled with the spatial distribution of the water-salt-root system and the dynamic physiological responses of crops to stress throughout the growing season. However, existing water-saving and salinity-control strategies primarily focus on soil water and salinity levels within the root zone-particularly in surface layers-while neglecting the synergistic effects of multiple interacting factors. As a result, irrigation regulation remains highly empirical, with limited precision, suboptimal water use efficiency, and an inability to formulate effective water-salt management strategies targeting specific yield objectives. To address these limitations, this study systematically integrates crop physiological responses to water and salt stress into an improved root water uptake model coupled with a soil water-salt transport model, substantially enhancing the simulation accuracy of soil water and salinity dynamics. Model parameters were calibrated and validated using field-measured soil water content and salinity data. The results indicate that the simulated soil water content achieved coefficients of determination ($R^2$) ranging from 0.65 to 0.73, with mean relative errors (MRE) of 0.05~0.08 $cm^3/cm^3$ and normalized root mean square errors (NRMSE) of 12.51%~25.36%. For soil salinity, $R^2$ values ranged from 0.65 to 0.73, with MRE of 0.57~0.98 g/kg and NRMSE of 17.28%~28.47%. These results demonstrate that the proposed model can reliably reproduce soil water and salt transport processes under mulched drip irrigation conditions. Using the validated model, soil water and salt transport dynamics were simulated under different combinations of irrigation quotas and irrigation water salinity. The results reveal that both irrigation quota and water salinity significantly affect the soil salinity change rate (RS), with irrigation quota exerting a more pronounced regulatory effect. Under the same salinity level, RS in the 0~40 cm soil layer decreased with increasing irrigation quota, whereas RS in the 40~80 cm layer exhibited a unimodal pattern, initially increasing and then decreasing. Higher irrigation water salinity increased the peak RS in the 0~40 cm layer; however, as irrigation quota increased, the RS increment induced by high salinity was progressively attenuated, indicating that larger irrigation quotas can effectively alleviate surface salt accumulation caused by saline irrigation. In contrast, RS in deeper soil layers (60~80 cm) responded weakly to irrigation water salinity, with only limited increases even under high salinity conditions, suggesting that salinity-induced accumulation in deep soil is substantially less pronounced than in upper and middle layers. Overall, this study provides critical scientific evidence for precision root-zone water-salt management and irrigation strategy optimization in mulched drip irrigation systems in arid regions.

**ABSTRACT**

Agriculture is a primary nonpoint source of nutrient pollution, particularly phosphorus and nitrogen, leading to eutrophication and water-quality degradation in downstream ecosystems. While best management practices (BMPs) are widely promoted to reduce these loadings, their concurrent impacts on nutrient export and direct nitrous oxide ($N_2O$) emissions remain insufficiently understood, especially under cold climatic conditions.

Eleven agricultural best management practices (BMPs), including conservation tillage, fertilizer management, and cover cropping, were assessed in the cold-climate Speed River Basin (SRB) in southern Ontario using a revised Soil and Water Assessment Tool (SWATCCN2O). While BMPs successfully reduced sediment and phosphorus losses, their effects on nitrogen and nitrous oxide ($N_2O$) emissions varied, suggesting trade-offs between improving water quality and reducing greenhouse gas emissions. A multi-objective analysis identified strip tillage with banded fertilizer and red clover cover cropping after winter wheat as the most effective practices, forming an optimal BMP. The study showed that focusing on the top 20% of hydrological response units (HRUs) with the highest $N_2O$ emissions could reduce annual $N_2O$ by 16%. Increasing implementation across the remaining agricultural HRUs further reduced sediment, phosphorus, and nitrogen loadings by up to 17%, 80%, and 11.8%, respectively. These findings emphasize the need for integrated BMP strategies that deliver co-benefits for water quality and climate mitigation.

# Silvopastoral Systems as a Strategy to Increase Carbon Stocks and Improve Soil Health in Brazilian Drylands

## ABSTRACT

Integrated agricultural production systems, such as Crop–Livestock–Forest Integration (ICLF), are nature-based solutions that represent a key strategy for sustainable agricultural intensification and climate change adaptation. ICLF systems are included in the Brazilian Sectoral Plan for Mitigation and Adaptation to Climate Change (ABC+ Plan), which supports the transition toward a low-carbon agricultural economy. To expand the evidence base on ICLF systems in Brazilian drylands, this study evaluated soil carbon and nitrogen stocks, as well as chemical, physical, and biological soil attributes, following the conversion of low-productivity pastures into silvopastoral systems in the Brazilian semi-arid region. The following land uses were assessed: native vegetation, low-productivity pasture, and two silvopastoral systems arranged with single-row and quadruple-row of *Eucalyptus urograndis* integrated with *Urochloa decumbens*. Soil bulk density, as well as carbon and nitrogen contents and stocks, were determined seven years after the implementation of the integrated systems. Additionally, microbial biomass carbon (C-mic), microbial quotient, the activity of β-glucosidase and arylsulfatase enzymes, and soil fertility parameters were evaluated during the dry and rainy seasons. Furthermore, the Soil Health Index was calculated using the Soil Management Assessment Framework (SMAF) tool. The conversion of low-productivity pastures to silvopastoral systems in Brazilian semi-arid region enhanced soil carbon stocks to a depth of 100 cm, with annual increases up to 4.81 Mg $ha^{-1}$. Improvements were also observed in chemical, physical, and biological soil attributes, with microbiological responses influenced by both management practices and seasonal climatic conditions. Overall, silvopastoral systems enhanced soil health indices derived from SMAF, demonstrating that integrated agricultural systems are a viable and effective strategy for restoring degraded soils and enhancing soil health in Brazilian drylands.

# Including water-salinity stress hysteresis and compensation to empirical root water uptake models

**Xun Wu[1*] and Yanqi Xu[1]**

[1] *China College of Land Science and Technology, China Agricultural University*

* wuxun@cau.edu.cn

**ABSTRACT**

Root water uptake (RWU) is influenced not only by instantaneous soil conditions but also by two dynamic processes often neglected in models: stress hysteresis, arising from prior exposure to suboptimal water/salinity conditions, and compensation, where roots in zones with superior conditions offset uptake reductions in zones where soil is less conducive to RWU. Empirical RWU models, such as the Feddes model (FM), are widely used due to their simplicity and low data requirements, but typically neglect these dynamic effects.

Here, we extended FM by introducing a recovery coefficient to capture stress hysteresis and incorporating either a piecewise or continuous compensation function. Six models were tested: FM, single-process models - WM (hysteresis), PM (piecewise compensation), and DM (continuous compensation); and combined-process models - WM-PM and WM-DM. Using data from a greenhouse soil column experiment with winter wheat, we found that both historical stress and spatial heterogeneity in root zone water and salinity strongly influence RWU and transpiration by plants. The coupled models (WM-PM, WM-DM) outperformed FM and single-process models in simulating transpiration dynamics, improving $R^2$ by 10.1–12.9% for actual transpiration and 3.8–29.7% for relative transpiration, while reducing RMSE by 27.6–36.4% and 13.8–41.9%, respectively. The WM-DM showed the highest accuracy, attributed to its mechanistic incorporation of soil hydraulic conductivity, matric potential, and osmotic potential into the compensation function.

Numerical simulations further revealed distinct RWU distribution patterns among the models, particularly under water and salinity stress cycles. The selected WM-DM model, embedded into the one-dimensional Richards and convection-dispersion equations, successfully reproduced soil water and salinity dynamics in both the greenhouse soil column experiment and a two-year field study of a winter wheat–summer maize rotation ($R^2 \geq 0.86$, RMSE $\leq 0.0288$ cm$^3$ cm$^{-3}$ for water content, $R^2 \geq 0.66$, RMSE $\leq 0.40$ g kg$^{-1}$ for salinity). These findings highlight the value of explicitly accounting for both stress hysteresis and compensation in empirical RWU models, with implications for improved irrigation scheduling and salinity management.

# Regional variation in the potential to reach net zero emissions in global agriculture

**Gerard H. Ros[1], Wim de Vries[1]**

[1] *Wageningen University and Research, Earth Systems and Global Change Group, PO Box 47, 6700AA Wageningen, the Netherlands*

*gerard.ros@wur.nl

**ABSTRACT**

Agriculture is a major contributor to global greenhouse gas (GHG) emissions. When associated land-use change is included, such as deforestation for pasture and croplands, peatland drainage, and loss of soil organic matter, emissions account for 20–25% of the global total anthropogenic GHG emissions, placing agriculture and land use together among the largest emitting sectors after energy and industry[1].

The dominant GHGs from agriculture are carbon dioxide ($CO_2$), methane ($CH_4$) and nitrous oxide ($N_2O$). $CO_2$ fluxes arise largely from land-use change and soil management, including tillage, drainage of peatlands, and organic matter mineralization[2]. Livestock systems, especially ruminants, are the largest single source of $CH_4$, followed by flooded rice systems and manure management[3]. Croplands contribute significantly to $N_2O$ emissions through synthetic fertilizer use and manure incorporation into soils[4].

To reach climate neutrality by 2050, net zero GHG emissions are needed for all sectors. This is not feasible in agriculture since there are unavoidable losses of $N_2O$ and $CH_4$ which cannot fully be compensated by $CO_2$ sequestration but there is ample opportunity to reduce net GHG emissions by implementation of diverse, site-specific mitigation strategies. This includes: (i) enhancing soil carbon sequestration via cover crops, conservation tillage, organic amendments, and agroforestry; (ii) improving nitrogen-use efficiency through precision fertilization, inhibitors of nitrification and urease, and integrated crop–livestock systems; (iii) reducing $CH_4$ emissions through livestock dietary interventions, improved manure management, and alternate wetting and drying in rice systems; and (iv) avoiding and reversing high-emission land uses, such as peatland drainage and deforestation[5].

In this presentation we present the mitigation potential of agricultural emissions of $CO_2$, $N_2O$, and $CH_4$ at global scale, including where possible the spatial heterogeneity, as compared to current global $CO_2$, $N_2O$, and $CH_4$ emissions.

**ABSTRACT**

Global food demand is projected to increase by 70% by 2050 (Cassman and Grassini, 2020). High-input agriculture meets this demand but causes nitrogen loss, greenhouse gas emissions and soil degradation, challenging alignment with UN Sustainable Development Goals. Soil quality, reflecting physical, chemical and biological traits, enhances crop yields, nutrient use efficiency and carbon storage. However, its quantitative relationship with nitrogen application and combined effects on productivity and emissions remain unclear globally. Existing nitrogen reduction strategies focus on short-term management, neglecting long-term soil enhancement. Using national field datasets (1981-2020) from China's rice ecosystems, combined with process-based models and life cycle assessments, we assess the impact of soil quality improvements on rice production under various nitrogen application rates. The results indicate that improving soil quality can lead to an average 9% increase in rice yield and a 6% reduction in yield-scaled carbon emissions. The northeast rice-growing regions in China, characterized by the highest soil quality and sustainability, can achieve sustainability targets primarily through optimizing nitrogen application rates. In contrast, the southern rice regions require a combined approach of soil improvement and nitrogen fertilizer optimization to achieve sustainable production. This study provides strategic insights into promoting sustainable rice production through targeted soil improvements and optimized nitrogen application.

# Controlled-Release Fertilizers in BMPs for Sustainable Agriculture

**Bin Gao[1*]**

[1] *Civil & Environmental Engineering, Rensselaer Polytechnic Institute, Troy, NY 12180, USA*

*gaob2@rpi.edu

**ABSTRACT**

Controlled-release fertilizers (CRFs) become an important component of best management practices (BMPs) for sustainable agriculture. This fertilization technique can precisely supply nutrients to match crop needs, not only maximizing nutrient use efficiency but also mitigating non-point source pollution from agriculture. This presentation highlights recent advancement in CRF technologies, focusing on novel and ecofriendly coating materials for CRFs. Perspectives and future directions for integrating CRFs into BMPs to enhance the resilience and sustainability of agricultural systems are also discussed.

**ABSTRACT**

Vineyards are critical agroecosystems where intensive management often leads to soil degradation and a decline in soil organic carbon (SOC) stock. Maintaining plant cover is widely promoted as a sustainable practice to reverse this trend, yet its effectiveness varies significantly across different environments. This study aimed to quantify the impact of management, soil types and climate on SOC stocks in vineyards worldwide, and to unravel the complex interaction between these factors. Through global, meta-analysis of 188 soil profiles from 95 relevant articles we synthesized data covering 13 soil types, 9 climate classes and range of soil managements grouped into 5 categories, from bare soil to permanent plant cover. From heterogeneous reported data, SOC stocks were harmonized across five generic depth layers (0-20, 20-40, 40-60, 60-80, 80-100 cm). Statistical analyses were first performed on the entire profile to assess SOC stocks with respect to the three parameters individually. We then focused on the upper 20 cm to examine combined effects of factors (two at a time), concluding with a model incorporating all three parameters simultaneously to explain SOC stocks. Our results reveal that management practices (i.e. plant cover) are key for carbon storage, increasing SOC stocks from 40 % to 70 % when compared to conventional bare soil management. However, the efficacy of this practice is highly context dependent. The most substantial SOC stocks gains are observed when plant cover is applied to in responsive soil and under favourable climate. For instance, plant cover increases SOC stock by a factor of 3 to 4 in Cambisol under temperate climates. Conversely, the plant cover benefit is negligible in soils under hot Mediterranean climates where climatic constraints overrode the management efforts. These findings underscore that maximizing soil carbon storage in vineyards requires moving beyond broad recommendations to tailored, climate-smart strategies. The most effective approaches will be those that account for synergistic interactions between soil type and climate, ensuring that management practices are adapted to the specific context of each vineyard.

# Optimal Selection of Soil Organic Carbon Prediction Models and Their Implications for Potential Soil Erosion Estimation Using the Revised Universal Soil Loss Equation in Southern Chinese Counties

**ZOU Qian[1], HU Bifeng[*]**

(Department of Land Resource Management, School of Public Administration, Jiangxi University of Finance and Economics, Nanchang, China)

hubifeng@zju.edu.cn

**ABSTRACT**

Soil erosion poses a significant threat to the agricultural productivity and ecological stability of counties in southern China. Accurately assessing potential soil erosion and identifying its key driving factors are crucial for formulating targeted soil and water conservation strategies. Taking the counties in southern China as the research area, this study employed the Revised Universal Soil Loss Equation (RUSLE) as the core analytical framework, with specific focus on three critical factors: K (Soil Erodibility Factor), R (Rainfall Erosivity Factor), and LS (Slope Length-Slope Steepness Factor). Given that soil organic carbon (SOC) constitutes a key variable in the calculation of the K factor, this study placed primary emphasis on SOC to address two core objectives: first, investigating how K factors—derived from SOC predicted by distinct models—influence the estimation of potential soil erosion; second, determining the optimal SOC prediction model. Three models were selected for SOC prediction, namely Random Forest (RF), Ordinary Kriging (OK), and Extreme Gradient Boosting (XGBoost), while Recursive Feature Elimination (RFE) was utilized to screen key feature variables. Additionally, explainable machine learning techniques were applied to quantify the relative importance of various factors affecting the K factor; this analysis indirectly revealed which factor exerts the most significant impact on potential soil erosion. Subsequently, the SOC prediction accuracy of the three models was compared using evaluation metrics, including the coefficient of determination ($R^2$) and root mean square error (RMSE), to identify the optimal SOC prediction model. The K factor was then calculated using the SOC results generated by this optimal model, and the derived K values were validated through comparison with existing published K factor datasets. Finally, the optimal K factor, in combination with precomputed R and LS factors, was integrated into the RUSLE model to estimate potential soil erosion in the study area. On this basis, the loss of soil organic carbon induced by soil erosion was further quantified. This study not only clarifies the performance of different SOC prediction models in supporting K factor calculation and soil erosion assessment but also identifies the dominant factors regulating soil erodibility and potential soil erosion. The findings provide a scientific basis for optimizing soil and water conservation strategies and safeguarding soil carbon pools in southern Chinese counties.

**ABSTRACT**

The spatial distribution and turnover of soil organic carbon (SOC), a critical component of the global carbon cycle, remain highly uncertain. To address the limitations of conventional models, we used SOILcarb, a whole-profile (0–100 cm) SOC simulation framework for China. A key innovation of SOILcarb is its explicit representation of SOC dynamics using measurable carbon fractions—namely, particulate organic carbon (POC) and mineral-associated organic carbon (MAOC)—instead of traditional, empirically defined conceptual pools. This physically-grounded approach improves model interpretability and transferability. SOILcarb extends simulation from typical topsoil depths to the full 100 cm profile, capturing the distinct surface and subsurface processes that govern long-term carbon stabilization. We parameterized and validated the model using a comprehensive nationwide dataset of SOC, POC, and MAOC observations to 100 cm, alongside crucial soil and environmental data. The results show that SOILcarb successfully reproduces the observed spatial patterns and vertical dynamics of SOC across China. This framework advances our understanding of China's soil carbon storage and provides a robust tool for predicting its response to environmental change.

**ABSTRACT**

Agricultural terraces are among the most widespread human–made landforms. They profoundly reshape soil landscapes and influence the carbon cycle, yet the extent and drivers of their impact remain highly uncertain. By integrating field observations from 14 well-drained terrace landforms across a climatic–geochemical gradient with a data synthesis, we show that changes in soil organic carbon (SOC) stocks after terracing are governed by two coupled C turnover–geomorphic processes: replacement of lost topsoil C at eroding positions and stabilization of buried SOC at depositional positions. Climate strongly modulates these processes by shaping soil geochemistry and plant productivity, which in turn control SOC replacement and stabilization within terraces. Thus, terracing effects on SOC stocks shift from consistently positive in humid regions to mixed (positive and negative) outcomes in dry regions. This study establishes a framework for elucidating SOC dynamics in well-drained terrace systems and provides a scientific basis for targeted management strategies to enhance C sequestration in agricultural terraces globally.

## ABSTRACT

The impact of climate change on soil organic carbon (SOC) remains uncertain, particularly in dryland agroecosystems where soils are inherently low in organic matter. Over recent decades, SOC has been repeatedly highlighted as a key parameter for maintaining soil functions and mitigating climate change through the sequestration of atmospheric carbon. In dryland croplands, SOC accumulation is also critical for maintaining crop productivity due to its influence on soil structure and, consequently, on soil water conservation. Under these conditions, certain management practices have been identified for their positive effect on SOC build-up. However, the behaviour of these practices under changing climate conditions is still poorly understood. In this context, the general aim of this study was to assess the effects of climate change on SOC dynamics in dryland croplands. To achieve this, the Daycent ecosystem model was first parameterized and validated using data from a long-term tillage and fertilization experiment conducted under rainfed Mediterranean conditions. Subsequently, eleven climate models and four CMIP6: SSP1-2.6; SS2-4.5; SSP3-7.0; and SSP5-8.5 were used to run the Daycent model under four management scenarios: conventional tillage and mineral N fertilization (CT-Nmin); no-tillage and mineral N fertilization (NT-Nmin); conventional tillage and organic fertilization (CT-Norg); and no-tillage and organic fertilization (NT-Norg). The Daycent model was run for 85 years (2015-2100 period) to estimate SOC and crop yield changes under each combination of management, climate scenario and climate model, both with and without the effect of rising atmospheric $CO_2$ concentration. In total, 440 simulations were performed.

The Daycent model predicted a marked effect of both management and climate scenarios on SOC changes. A large degree of heterogeneity was observed among the trends, depending on the climate model used. Despite this variability, the model predicted that most scenario-model combinations resulted in a carbon (C) sink situation, with SOC increasing over the 85-year period. Simulations without atmospheric $CO_2$ increase showed a lower sink C capacity compared with those that included rising $CO_2$ concentrations. In particular, the CT-min management scenario, when simulated without atmospheric $CO_2$ increase, showed SOC losses in several scenario-model combinations, acting as a C source. Across most scenario-model combinations, management scenarios with organic fertilisation presented the highest C sink potential.

This modelling study contributed to improving our understanding of the effects of climate change on SOC dynamics in Mediterranean dryland conditions. The results demonstrated that, under warmer and drier conditions, the selection of appropriate management strategies will be essential to maximize soil C sequestration capacity in these systems.

**ABSTRACT**

Soils are central to the global carbon (C) cycle and represent a critical component of natural climate solutions, which rely on quantitative spatial predictions of soil organic carbon (SOC) fractions (particulate organic carbon, POC, and mineral-associated organic carbon, MAOC) across scales. However, our understanding on the drivers of SOC fractions across diverse pedoclimatic zones is not well understood. Here, we show that the drivers of SOC fractions are divergent across pedoclimatic zones at a global scale. We used machine learning with a synthesized global dataset of SOC fractions (11,522 soil samples) to show that, globally, the climate, soil properties (e.g., nitrogen and pH) and elevation are dominant drivers. Nevertheless, we found that such general assessments overlook pedoclimatic zone-specific drivers that influence the distribution of SOC fractions. This oversight can lead to misinterpretations that hinder our understanding of soil C processes and dynamics. Climate exerts its influence through interactions with edaphic factors, topography, and vegetation, however, in certain pedoclimatic zones, its role may be negligible. These results highlight the need for regional assessments of soil C dynamics and more local parameterization of biogeochemical models. Our analysis propounds the development of science-informed and adaptive soil C management under a changing climate.

**ABSTRACT**

Sandy Coastal Plain Ultisols of the southeastern USA are characterized by critically low soil organic carbon (SOC) and rapid turnover of organic inputs. Using stable isotope probing techniques in strip-till cotton-corn systems, we quantified the allocation and distribution of organic C and N derived from cereal rye (Secale cereale L.), hairy vetch (*Vicia Villosa Roth*), and their mixtures across the soil profile. Pulse labeling revealed contrasting root-C allocation: at the mature stage, rye transferred more newly assimilated $^{13}C$ to 15-30 cm (0.85% of $^{13}C$-$CO_2$) than to 0-15 cm (0.14%), whereas vetch contributed more to 0-15 cm soils (1.17%) than to 15-30 cm (0.41%). Surprisingly, the rye-vetch mixture transferred 1.13% of the $^{13}C$ to 0-15 cm depth but none below 15 cm, demonstrating non-complementary effects on subsoil C allocation. The following field residue ($^{13}C$/$^{15}N$-enriched) decomposition study demonstrated that vetch induced negative priming of native SOC, whereas rye and the rye-vetch mixture did not. At the end of the study, regardless of the cover crops, the topsoil (0-5 cm) retained more residue-derived C, with less found at the depths below (5-20 cm). In contrast, comparable cover crop-derived N was also observed at depths of 5-10 cm and 10-20 cm, reflecting higher mobility of mineralized N. These observations indicated that the cover crop species and mixtures introduced distinctive organic C and N to the soils, either as living plants or as dead residues. Long-term reliance on surface residue retention in conservation tillage systems may lead to C stratification, but less so for N, resulting in C-N decoupling in sandy soils at different depths. Strategic species selection and mixtures are therefore critical for restoring SOC in these vulnerable agroecosystems.

## ABSTRACT

Enhanced rock weathering (ERW) using silicate minerals such as basalt has emerged as a promising strategy for removing atmospheric carbon dioxide ($CO_2$) while improving soil health and crop productivity. However, the efficiency of $CO_2$ capture through basalt weathering in agricultural soils can depend on several factors, including nitrogen fertiliser inputs that influence soil acidity and nutrient dynamics. This ongoing field study investigates the $CO_2$ capture potential of crushed basalt applied at varying rates under different nitrogen fertiliser applications in an acidic soil ($pH_{CaCl2}$ = 4.94) in South Australia, using wheat (*Triticum aestivum*) as the test crop. The trial consists of 24 plots with three basalt application rates (B1 = 0 t $ha^{-1}$, B2 = 20 t $ha^{-1}$, and B3 = 40 t $ha^{-1}$) and two urea rates (50 and 100 kg $ha^{-1}$), each replicated four times. Basalt sourced from the Moree Quarry in Victoria (p80 = 1,690 µm; i.e., 80% particles less than this size) was surface-applied before seeding. Wheat cultivar "Calibre" was cultivated following standard local practices, with diammonium phosphate applied at sowing and urea broadcast at the three-leaf stage. Soil porewater was collected using macro-rhizon samplers to measure pH, electrical conductivity (EC), alkalinity, and cation concentrations. Soil samples were taken at 0–5, 5–10, 10–20, and 20–40 cm depths at the beginning and end of the growing season to analyse pH, EC, exchangeable cations, organic and inorganic carbon contents, and available nitrogen. Soil enzymatic activities were assayed to understand the biological responses to basalt and nitrogen applications. Crop yield and nutrient uptake were measured at harvest. Porewater pH values 3 months after sowing for B1, B2, and B3 were 6.15, 6.21, and 6.80, while EC values were 703, 980, and 759 µS/cm. Porewater alkalinity was 30.25, 37.16, and 47.1 mg/L $CaCO_3$ for B1, B2, and B3, respectively. The porewater pH and alkalinity increased in basalt-amended plots after 3 months of sowing but the differences were not significant ($p > 0.05$). The mean soil pH value for B1, B2, and B3 at harvest was 4.94, 5.23, and 5.32, respectively, showing a significant variation compared to the control ($p < 0.05$). Soil EC values showed no significant change. Overall, basalt addition enhanced soil pH, indicating early signs of basalt weathering and potential $CO_2$ capture. This paper will present the results of this field ERW study in detail. The findings will provide insight into the interactions between nitrogen fertilisation, soil acidity, and basalt dissolution, contributing to a better understanding of ERW as a carbon sequestration strategy in agricultural systems.

**ABSTRACT**

More extreme climate conditions are threatening global food production. Soil organic carbon (SOC), as a key modulator of soil functionality, may play a critical role in enhancing crop yield against climate extremes. Here, we use a national dataset of 7,331 site-year measurements of maize and wheat yield and SOC content under different fertilizer management practices across China during 1978–2014 to investigate the role of SOC in regulating crop yield responses to climate extremes including heatwaves, cold, droughts and heavy rainfall. The results indicate that SOC along with fertilizer management practices and climatic anomalies explain more than 90% of the variances in detrended yields (i.e., yield deviations from the long-term trend) of both crops. SOC emerged as the most important predictor, alone contributing ~30% to the explained variance for the two crops. Climate extremes quantified by extreme climatic anomalies (i.e., standardized temperature or precipitation anomalies during the crops 'growing season separately with absolute values larger than 1.5, 2.0 and 2.5) led to significant crop yield losses, ranged from $0.79^{0.91}_{0.67}$ t ha$^{-1}$ (mean with 95% confidence interval) to $1.07^{1.19}_{0.94}$ t ha$^{-1}$ and from $0.46^{0.52}_{0.40}$ t ha$^{-1}$ to $0.88^{1.14}_{0.62}$ t ha$^{-1}$ per one standardized anomaly increase in extreme climatic anomalies, with threshold as 1.5, across the four types of extremes, for maize and wheat, respectively. Improving SOC levels with critical values were expected to promote yield gains by 0.6 t ha$^{-1}$ under extremes per 1% increase in SOC content for both maize and wheat, the positive SOC impacts thresholds of where yield changed from loss to gain were respectively 15 g kg$^{-1}$ for maize and 7 g kg$^{-1}$ for wheat with a sliding window of SOC content range as 5 g kg$^{-1}$, and the optimum SOC levels corresponding to no more yield gains with higher SOC accrual were around 21 g kg$^{-1}$ and 9 g kg$^{-1}$ for maize and wheat, respectively. The magnitude of the SOC buffer effects is extremes type- and thresholds-dependent for specific crop. Each 1% increase in SOC content resulted in substantial maize yield gains, ranged from $0.54^{1.07}_{0.01}$ t ha$^{-1}$ to $0.85^{1.35}_{0.34}$ t ha$^{-1}$, under extremes 'thresholds "z >1.5", across the four types of extremes. SOC buffers wheat production against heatwaves and droughts, respectively with yield gains of $1.31^{1.80}_{0.82}$ t ha$^{-1}$ and $1.29^{2.10}_{0.48}$ t ha$^{-1}$ per 1% increase in SOC content, under thresholds scenario "z > 1.5". These positive benefits strengthen under more extreme climatic scenarios (i.e., "z > 2.0" and "z > 2.5"), and can be amplified by adopting improved fertilizer management practices, particularly with the combined application of organic and inorganic fertilizer. Our findings reveal that sufficient SOC sequestration enhance the resilience of crops to climate extremes, highlighting the multiple benefits of improving SOC levels towards critical values for maintaining crop production in a more extreme climate.

A simple structure (Question-Data-Methods) diagram for the research.

# Mapping soil organic carbon across China using ensemble modelling at 30 m spatial resolution

**ABSTRACT**

Soil organic carbon (SOC) plays a crucial role in food security and climate change mitigation, yet high-resolution spatial mapping of SOC remains challenging over large and heterogeneous areas. This study aims to generate the first national-scale SOC maps of China at 30-m spatial resolution using an ensemble modelling approach. Multi-source soil profile data were integrated with high-resolution environmental covariates representing topography, climate, vegetation, and human activities. Ensemble modelling was applied to predict SOC content and quantify associated uncertainty across multiple soil depths. The resulting maps provide a spatially explicit baseline for assessing soil carbon stocks, supporting climate-smart land management, and informing policies related to carbon neutrality and sustainable agriculture in China.

## ABSTRACT

As global efforts to mitigate climate change intensify, scalable and sustainable carbon dioxide removal (CDR) strategies are essential to meet the 2 °C target set by the Paris Agreement[1]. Traditional soil-based CDR approaches have focused on topsoil (0–0.3 m), where a significant portion of soil organic carbon (SOC) is stored[2]. However, over 60% of global SOC resides in deeper soils (>0.3 m), which remain largely underutilized in most CDR frameworks. Perennial energy crops, such as Miscanthus, switchgrass, and woody species like poplar, willow, and Eucalyptus, present a promising, low-input solution for tapping into this largely overlooked deep soil carbon pool. These crops, with their deep and long-lived root systems, can enhance SOC accrual through root biomass and rhizodeposition, which may play a crucial role in removing atmospheric $CO_2$.

Here, we conduct the first global synthesis of perennial energy crops-driven SOC accrual across soil depths, integrating 1,161 paired field observations from 28 countries (1980–2025). We show that perennial energy crops increase global SOC by 15.4%, with deep soils (>0.3 m) contributing 59% of the total gains. Specifically, deep soils exhibit a 21.2% increase in SOC, significantly outperforming topsoil, which sees a 14.6% increase. Scaling these results to all potentially adaptable non-forest lands reveal that perennial energy crops could remove up to 408.8 Pg $CO_2$ from the atmosphere—approximately 1.7 times the global fossil $CO_2$ emissions from 2018–2024. Even when excluding croplands to safeguard food security, this approach could still offset >60% of emissions.

Our findings demonstrate that deep soil carbon accrual under perennial energy crops offers a substantial, cost-effective CDR strategy with co-benefits for land restoration and energy production. This approach is particularly impactful in regions with abundant marginal lands, including Oceania, and Africa. Integrating deep soil dynamics into national carbon budgets and international CDR frameworks could substantially enhance the realism and effectiveness of global climate change mitigation strategies, aligning with pathways to limit warming to 2°C.

## ABSTRACT

Metropolitan authorities overseeing mixed urban, peri-urban, and agricultural areas play a central role in shaping territorial trajectories through planning and incentive-based policies. To implement effective climate strategies, they need a clear understanding of how land-use patterns and management practices across agricultural, natural, and urban spaces may evolve and affect soil organic carbon (SOC) and tree biomass carbon. In line with climate commitments such as the European Green Deal and local climate–energy action plans, they must design strategies that combine emission reductions with enhanced SOC sequestration. Yet land-use change and management practices can either increase SOC or generate losses and $CO_2$ emissions, depending on the chosen trajectory. Existing tools quantify SOC dynamics under agricultural practices or estimate carbon stock changes from land-use conversion, but few approaches jointly consider SOC fluxes, land-use change, and management evolution across mixed urban–rural territories. Interactions between urban expansion and the loss of agricultural or natural soils—and their consequences for SOC—are rarely integrated into a single spatially explicit framework. Such integrated scenarios are essential for assessing the contribution of soils to carbon-neutrality strategies.

This study evaluates SOC and biomass carbon fluxes under four land-use and management scenarios co-developed with stakeholders from the Rennes Metropolitan Area (north-western France). The 705 km² territory includes 510 km² of agricultural and natural land and 195 km² of urban areas. The first scenario extends current trends with ongoing urban expansion and unchanged farming practices. The second introduces moderate improvements in agricultural management and reduced soil conversion. The third represents a transformative shift with major increases in permanent grasslands, boosting SOC storage. The fourth, maximalist scenario converts all agricultural land to forest to estimate the upper bound of carbon sequestration. These scenarios were assessed relative to the current situation to simulate changes in soil and tree-biomass carbon stocks by 2050. Models of varying complexity were used to address uncertainties associated with long-term projections.

Results indicate that all scenarios increase soil organic carbon and biomass stocks. However, even when accounting for model uncertainty, the first two scenarios remain insufficient to offset projected greenhouse gas emissions by 2050. The most ambitious trajectories also show that urban green spaces alone cannot deliver carbon neutrality. Rural soils remain the main SOC sink but also constitute a significant emission source, particularly from grazing systems, highlighting the need for ambitious soil management strategies and cross-territorial compensation mechanisms.

## ABSTRACT

Preserving and enhancing soil organic carbon (SOC) requires assessment frameworks that move beyond bulk carbon stocks to capture stabilization mechanisms, biological accessibility, and land-use legacies. However, scalable approaches that integrate these dimensions across heterogeneous landscapes remain limited, constraining soil carbon forecasting and sustainable land management.

We conducted a large-scale soil survey across forest–agriculture mosaics in Atlantic Canada to advance SOC assessment at regional scales. Soils were sampled across a gradient of land-use intensity, spanning wetlands, mature and young forests, perennial pastures, forage-based rotations, and annual cropping systems. At each site, SOC stocks were quantified alongside physically fractionated organic matter pools (labile particulate, intermediate, and mineral-associated fractions), oxidizable carbon (POX-C), microbial DNA analyses, enzyme activities, soil fauna, and key physical and chemical properties. Land-use history over the previous decade was derived from national land-cover inventories and incorporated into spatial analyses.

Total SOC stocks declined systematically with increasing land-use intensity, but losses were dominated by reductions in biologically accessible and intermediate SOC pools (Fig. 1), while mineral-associated carbon showed greater persistence. Biological indicators closely tracked intermediate SOC fractions, highlighting their sensitivity to management and disturbance. Machine-learning models integrating land-use history, terrain attributes, and soil properties substantially improved SOC prediction compared to static land-use classifications alone, revealing strong legacy effects of past management on current SOC status.

Our results demonstrate that integrating SOC fractionation, biological indicators, and land-use history enhances the detection of early SOC degradation and improves regional SOC assessment. This approach provides a scalable pathway to advance SOC science, support sustainable land management, and inform climate-relevant soil carbon monitoring and policy decisions.

**ABSTRACT**

Microbial-derived carbon (MDC) is a major contributor to persistent soil organic carbon (SOC), yet its estimation methodology, global stocks, spatial heterogeneity, and warming responses remain poorly constrained. Here, we combined 429 soils spanning China (Hailun to Haikou) with global datasets of amino sugars and microbial trait information, and integrated amino sugar biomarkers, $^{13}C$ NMR, high-throughput sequencing, and aerobic/anaerobic temperature-gradient incubations with machine learning and geospatial modelling to address these gaps. To reduce methodological uncertainty, we recalibrated the amino sugar-based conversion factors using expanded pure-strain evidence and community-structure constraints. We proposed the following factors: 31.3 for muramic acid to bacterial-derived C, 10.8 for glucosamine to fungal-derived C, and 1.63 for the bacterial glucosamine-to-muramic acid molar ratio. These updates lowered parameter-related relative errors by 71% while retaining a simple, transferable formula. Applying this framework, we estimated global MDC stocks of 758 Pg in the 0-1 m soil layer (~40% of total SOC), with 65% stored in boreal regions. Using an ensemble machine learning, we mapped MDC stock dynamics across 93.4% of global land from 1981-2018. We detected a mean decline of 6.7 Pg MDC per 1°C warming in predictable areas, with the strongest losses in the tropics. Projections under Shared Socioeconomic Pathways suggest an additional 6-37 Pg reduction by 2100, depending on the selected pathway. Finally, we showed its implications for the carbon cycle: (i) MDC preferentially associates with minerals, contributing on average 54.0% of mineral-associated organic carbon and exhibiting longer turnover than plant-derived C; (ii) the anaerobic incubations indicated that MDC regulated the SOC decomposability and affected the temperature sensitivity of wetland $CH_4$ and $CO_2$ emissions. Together, these results provided a harmonized MDC quantification method and climate-responsive, confidence-aware estimates that can improve carbon-cycle prediction and inform soil management under warming.

## ABSTRACT

Soil respiration is the largest terrestrial source of $CO_2$ to the atmosphere and a major determinant of carbon-climate feedbacks. Yet which and how vertical gradients in soil physicochemical and biological conditions regulate respiration magnitude and its sensitivity to warming remains unclear. We conducted a five-year in situ incubation with intact 1-meter-deep soil cores along an elevational climate gradient, applying a core-inversion treatment which places soil layers of the same depth-origin into different depths while maintaining overall soil structure integrity. Soil respiration was consistently lower in inverted than in non-inverted cores during the five-year incubation with an average reduction of 24%, demonstrating the importance of depth-associated microenvironmental gradients in shaping soil respiration. However, the climate responsiveness of respiration was independent of the inversion treatment, demonstrating the dominant role of intrinsic carbon substrate properties, which was proved by significant decline in the temperature sensitivity of soil respiration with the proceeding of the incubation. Vertical distribution of substrate chemistry and lability emerged as the key gradients regulating respiration. The findings provide direct, in-situ evidence of environmental constraining of soil respiration, highlighting the importance of explicitly accounting for vertical soil heterogeneity to accurately project carbon-climate feedbacks under climate change.

**ABSTRACT**

Quantifying greenhouse gas (GHG) emissions to reduce the impacts of climate change has become a global priority. The carbon footprint, quantified through Life Cycle Assessment (LCA), represents the $CO_2$-equivalent emissions associated with the production of a good or service. In agricultural systems, $CO_2$-equivalent emissions are primarily driven by the use of synthetic fertilisers, particularly nitrogen-based inputs**,** due to both upstream production and field emissions. Nitrogen recommendations are defined based on management practices, soil type, and soil characteristics, particularly chemical properties such as soil organic matter (SOM) content. Fertile soils generally require lower fertiliser inputs and, consequently, present a lower carbon footprint. Tobacco cultivation requires nitrogen inputs to promote leaf development. In this context, the aim of this study was to assess whether management practices, soil texture, soil organic matter content, and regions influence the carbon footprint of tobacco cultivation. The study was conducted in southern Brazil that accounts for approximately 95% of Brazilian tobacco production. A total of 77,132 smallholder farmers data, who delivered their production to British American Tobacco (BAT), between 2020 and 2025, were included in the study. All agricultural inputs were inventoried for the production of 1 kg of cured tobacco. $CO_2$ and $N_2O$ emissions to air were calculated using IPCC (2019) equations, while $NO_x$ emissions were estimated following Nemecek et al. (2016). The carbon footprint was quantified using SimaPro 9.6.0.1. To analyse the factors associated with the carbon footprint, a multiple correlation analysis was performed using R software. Soil type, SOM content, and producing region were significantly correlated with the carbon footprint. Tobacco-producing regions with higher SOM levels required lower nitrogen inputs from synthetic fertilisers, thereby reducing field emissions, particularly $CO_2$ and $N_2O$. The influence of soil type was primarily associated with textural differences, as soils with coarser textures generally exhibit lower aggregation capacity and nutrient retention. Under such conditions, the adoption of cover crops and residue management practices becomes essential to enhance SOM accumulation and improve fertiliser use efficiency. Overall, the results indicate that maintaining soil organic matter plays a central role in mitigating the carbon footprint of tobacco cultivation. Sustainable soil and crop management practices should therefore be encouraged to reduce GHG emissions and support climate change mitigation in agricultural systems.

## ABSTRACT

Climate warming, particularly during winter, poses a significant threat to soil organic carbon stability. Integrating global observational data with a decade-long field experiment, we identified a critical negative correlation between winter soil temperature and crop biomass carbon. Our mechanistic investigation revealed that this decline is primarily driven by the warming-induced disruption of mineral protection, which accelerates soil organic matter (SOM) degradation and depletes essential micronutrients (Fig. 1). To counteract these adverse mechanisms and advance sustainable land management, we investigated a bio-based intervention in cold-region Mollisols by inoculating nitrogen-fixing cyanobacteria to partially replace synthetic nitrogen fertilizer. Our results demonstrate that cyanobacterial inoculation not only alleviates plant nitrogen limitation but also stimulates root development and activates mycorrhizal fungi. Crucially, this microbial regulation enhances the secretion of glomalin-related soil protein, which promotes soil macro-aggregation and stabilizes microbial necromass, particularly fungal residues. Consequently, this strategy successfully offsets SOM losses, improving nitrogen use efficiency and increasing crop yield by 7.6%. This study bridges the gap between understanding the biogeochemical drivers of carbon loss and implementing effective, microbe-mediated strategies for agricultural resilience.

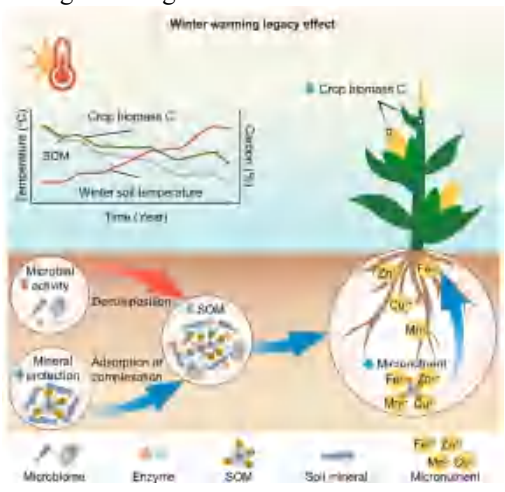

**Fig. 1** Schematic of the legacy effect of winter warming on crop biomass C. The red arrow signifies an intensified process, while the blue arrow denotes a weakened process. The Orange upwards arrow within a variable represents an increase, and the green downwards arrow indicates a decrease. Crop biomass C encompasses both straw C and grain C contents.

**ABSTRACT**

Soil degradation is a major global concern, with land-use conversion central to current debates. A recognized outcome is reduced soil productivity, often linked to agricultural intensification following shifts from native grassland or forest to cropland or pastures. Soil organic carbon (SOC) is a key indicator of soil health and an important potential sink for greenhouse gases (GHG). Thus, management alternatives that increase SOC promote sustainability while mitigating GHG emissions. In Latin America and the Caribbean (LAC) local data on SOC stocks due to land use and management changes is scarce. This cooperation between Argentina, Chile, Colombia, Costa Rica and Uruguay aims to design land use and management strategies for key LAC production systems with high carbon sequestration potential, reducing knowledge gaps, strengthening capacities and generating References SOC data to improve GHG inventories. Soil sampling campaigns following harmonized protocols were conducted in 2023-2024 at contrasting long-term land use and management paired sites, with samples collected at 0–10, 10–30, and 30–60 cm. Soils were analyzed for organic carbon (C), nitrogen (N), stable isotopes ($^{13}C/^{12}C$ and $^{15}N/^{14}N$), and for developing a NIRS calibration library for SOC and organic N quantification. A database integrating 25 long-term experiments and 240 farms (including 29 land use changes) is under development. This extensive database allows updating References values and emission factors in IPCC SOC tables (from Tier 1 to Tier 2, or even Tier 3) for key cropland, grassland and forestland systems. Using this updated tool, one major opportunity for soil carbon sequestration will be evaluated for each participating country, performing an economic assessment and GHG balance analyses, based on international methodologies (IPCC guidelines, Monte-Carlo simulation and Life Cycle Assessment, respectively). The project has strengthened local capacities to quantify, monitor and report changes in SOC stocks, as well as associated economic and GHG metrics relevant for LAC countries beyond this cooperation.

This innovative and ambitious initiative provides a foundation for policymakers to promote sustainable strategies that enhance SOC stocks through robust local evidence, generating benefits for farmers by improving soil health and productivity while contributing to global climate-change mitigation.

**ABSTRACT**

Food security is one of the defining challenges of our century, yet sustaining agricultural production is becoming increasingly precarious under accelerating climate change. Building soil organic carbon (SOC) stocks is known to improve yields; however, whether SOC can buffer agriculture against fluctuations in crop productivity remains uncertain. Evidence to date has been restricted to small-scale in situ trials, leaving its stabilizing role at larger spatial and temporal scales unexplored.

Here, we firstly quantified the relationships between SOC and stability of crop productivity across China's croplands from 2001 to 2020 using a combination of Generalized Additive Mixed Models (GAMMs) and XGBoost models with SHAP explanation framework. Vegetation indices (NIRv), Solar-Induced Chlorophyll Fluorescence (SIF), and MODIS gross primary productivity (MODIS GPP) were used as proxies for crop productivity, while their detrended interannual coefficient of variation (CV) served as a measure of stability. Across model types, results across two decades consistently showed that maintaining higher SOC content in croplands, results in more stable crop productivity. We observed critical thresholds of SOC content (maize: 10.2 – 13.4 g/kg; wheat: 8.6 – 9.9 g/kg), above which high SOC content leads to more stable crop productivity. After determining the positive relationships, we investigated marginal causal effect of SOC using causal forest double machine learning models. Results indicated that increasing one unit (g/kg) of SOC can reduce the CV of crop productivity by 1.09% to 2.08% on average nationally. Specially, in regions with lower SOC levels, the marginal benefits of increasing SOC are more pronounced, particularly in areas characterized by lower soil structure and greater climate variability. In these environment-limited croplands, increasing SOC can play a more significant role in maintaining sustainable agriculture.

Our results emphasize SOC's role in building resilient food systems. This improved understanding can refine the representation of soil carbon in earth system models and highlight the importance of soil carbon sequestration in croplands under climate change.

**ABSTRACT**

The preservation and enhancement of soil organic carbon (SOC) in grasslands are essential for maintaining soil health, supporting ecosystem services, and contributing to climate change mitigation. This study applies the RothC model to investigate SOC dynamics in MRV4SOC grassland demosite in Wallonia, Belgium, with the objective of producing an assessment of SOC stock changes at landscale scale, consisting of approximately 34,000 fields. Model simulations based on in-situ measurements on this ICOS station are compared with the simulations using remote sensing (RS) inputs. This comparison enables assessing the sensitivity of SOC stock modelling to input replacement. RS data, agricultural census datasets, and existing soil maps are used to derive key boundary conditions for both the demosite and landscape scale, with a particular emphasis on estimating carbon inputs from grassland biomass production and livestock excreta. RS inputs extracted from raster maps were calculated as mean pixel values per field to run the model at the field level across the landscape. At the demosite scale, the sensitivity of the RothC model to the replacement of measured data with RS boundary conditions showed that the largest variation in delta SOC stocks compared to model using in-situ inputs, were driven by initial SOC stock values obtained from available maps, followed by climate data from ERA5 reanalysis products. The difference in SOC stock changes between the two model (all RS vs all in-situ inputs) was 1.3 t C $ha^{-1}$ over the four-year simulation period from 2021 to 2024, which was considered the sensitivity range associated with RS data. At the landscape scale, the mean predicted SOC change across grassland fields was 2.1 t C $ha^{-1}$. When accounting for the sensitivity range, results indicated that more than 80 % of grasslands at landscape scale are predicted to have an increase in SOC stock over the past four years. This increase was particularly observed in fields with lower initial SOC stock. This pattern is consistent with trends observed in some long-term experimental sites in Wallonia, where changes in carbon inputs from biomass and therefore changes in SOC stocks reflects the effects of agricultural management activities. By integrating site-level observations from the demosite with spatial modeling, the study highlights the spatial variability of SOC responses to carbon inputs and environmental conditions. Overall, this work represents a step toward generating spatially continuous maps of SOC stock change in grasslands, providing a scalable framework to support carbon sequestration strategies.

**ABSTRACT**

Soil organic carbon (SOC) is a key indicator of soil health and is vital for many soil functions and associated ecosystem services. However, abundant literature shows SOC to be highly vulnerable to climate change or changes in land use. There is urgent need to understand the vulnerability of these soils to changes in climate or in land use, and the impact these changes will have on SOC. This understanding is not only important for maintaining or increasing soil health but is essential to understand how any potential change will impact atmospheric carbon dioxide concentrations.

The partition of total SOC into pools of different mean residence time has been used to understand the vulnerability of SOC to loss or the potential to further increase SOC, and can allow better understanding of how management, land use, or climate effects may impact stocks of SOC. The way these different forms of SOC reside in the soil has also been shown to be important, and recent work has demonstrated that the relationship between SOC fractions and mineral surface area (MSA). In this study, we investigate how the combination of spatial predictions of SOC fractions and MSA could be a useful tool to assess the vulnerability of SOC.

As those methods are cost and time intensive, the use of spectroscopy was investigated to predict the data in a more time and cost-effective way. SOC fractions and MSA were modelled from mid-infrared spectroscopy (MIR) based on a set of 302 soil samples, representative of New Zealand's agricultural land. Cross-validation results showed that most models fitted for the properties of interest in this study were very satisfactory, with CCC and R^2≥0.9, and limited bias.

Predictions for these properties were generated for the NZ Soil Spectra Library (NZ-SSL), which is a large collection of soil spectra recorded from soils all around NZ. The NZ-SSL has a total of 55,081 MIR spectra, corresponding to 11,570 individual soil samples. Those spectral estimates were used as input for the digital soil mapping (DSM) of those properties at the national scale, onto a grid of 1 km resolution, and drawing on empirical relationships between those properties and a range of environmental covariates. The results show that the performance of the DSM models fitted in this project is limited, with CCC values around 0.5, and $R^2$ values around 0.3. This level of performance, however, matches that obtained by authors mapping SOC fractions in other countries. The resulting spatial layers obtained via DSM for total SOC, SOC fractions, and MSA were then combined into a series of SOC sequestration indicators. In the last part of this study, we investigate the pertinence and geography of those indicators.

**ABSTRACT**

The significance of soil organic carbon (SOC) in promoting sustainable agricultural practices and enhancing ecosystem resilience is well-established, yet the complexity of its dynamics necessitates further investigation. The proposed research focuses on two critical aspects. The first aspect investigates the causal mechanisms linking farmland infrastructure and crop diversity to stable agricultural production and carbon sequestration. Specifically, the role of infrastructural elements—such as land layout and field access pathways—in enhancing farmland resilience to climatic stressors, including drought, extreme heat, and flooding, will be analyzed. This investigation combines empirical data and case studies to elucidate the supporting effects of these infrastructures on agricultural systems. The second aspect addresses the impact of diversified cropping patterns—specifically intercropping and crop rotation—on yield responses, water use efficiency, and the modulation of soil carbon stocks under conditions of climate-induced stress. The findings will provide insights into the regulatory mechanisms that underpin these relationships, illustrating how diversified agricultural practices can facilitate SOC enhancement while productivity.

Engagement at this conference will facilitate the exchange of knowledge among researchers, practitioners, and policymakers, fostering interdisciplinary collaboration in the realm of SOC science. The outcomes of this research are anticipated to inform the development of strategies that promote sustainable land management, ultimately contributing to the enhancement of soil health, agricultural productivity, and climate resilience. This ABSTRACT is submitted with the objective of stimulating academic discussion and advancing the collective understanding soil organic carbon dynamics and their implications for sustainable land management. Thank you for considering this contribution.

**ABSTRACT**

Soils can be either a source or sink of atmospheric $CO_2$ depending on how soil organic carbon (SOC) responds to climate warming and changes in plant productivity. While warming typically accelerates SOC decomposition, the effect of plant productivity changes remains unclear. Here we use a space-for-change substitution approach to analyse a global dataset of SOC measurements down to 1 metre. We find that warming-induced SOC reduction in the 0–0.3 m topsoil is gradually offset by increasing plant productivity, but exacerbated in the 0.3–1 m subsoil until plant productivity increase crosses a threshold of 30%. Consequently, entirely offsetting warming-induced SOC reduction in the top metre of soil requires an unrealistically high increase in plant productivity, albeit with substantial variance across ecosystems. Soil carbon-to-nitrogen ratio is the dominant predictor of the variance in SOC response, as this ratio determines whether nitrogen released during carbon loss meets the requirement for additional plant growth or whether additional nitrogen must be mined from soil organic matter. Such mining accelerates SOC losses, particularly in the subsoil, where the soil carbon-to-nitrogen ratio is lower than in topsoils. We conclude that globally, increased plant productivity may exacerbate SOC losses under climate warming, particularly in the subsoil.

# Vegetation restoration of degraded meadows by non-dominant species decreased cumulative $CO_2$ emissions and temperature sensitivity of soil respiration rates

**Bangliang Deng**[1] *

[1] *School of Soil and Water Conservation, Jiangxi University of Water Resources and Electric Power, Nanchang, China*

**ABSTRACT**

Alpine meadow degradations are common across the world. Degradation and restoration of meadow soils that have large carbon (C) and nitrogen (N) pools will cause substantial changes in soil C and N compositions as well as soil respiration that emits carbon dioxide ($CO_2$) to atmosphere. Vegetation restoration using multiple species with different origins may impose divergent effects on soil C and N status and hence respiration rates (*Rs*) due to their differences in functional characteristics. To understand the effects of meadow degradation and vegetation restorations by historically non-dominant species on $CO_2$ emissions, we measured *Rs* in meadow soils experiencing degradation or restoration using originally dominant or non-dominant species. Soil respiration rates and soil C and N variables were measured over twelve months *in situ* from randomly selected plots with five treatments: seriously degraded meadows (bare land), restored meadows using historically non-dominant (*Carex chinensis* or *Fimbristylis dichotoma*) or dominant species (*Miscanthus floridulus*), and non-degraded meadow (with original *M. floridulus*). Meadow degradation and vegetation restoration significantly impacted soil C and N variables and cumulative $CO_2$ emissions. Microbial biomass C and N, as well as dissolved organic C and nitrate N were most distinct among meadow plots of different treatments. Degradation to bare land decreased multiple C and N variables compared with non-degraded meadows. Restorations using historically non-dominant species consistently decreased temperature sensitivity of *Rs*. Contributions of C and N variables depended on the species used for restoration. Effects of meadow ecosystem degradation and restoration are important for C and N cycling. Due to the distinct effects imposed by restoration species on soil respiration, both functional group and species identity should be considered in future management and restorations of degraded meadows in terms of their profound impact on global C cycling and mitigation of climate change.

**ABSTRACT**

The Rothamsted Carbon (RothC) model is a widely used process-based model for estimating soil organic carbon (SOC) dynamics, offering simple input requirements and strong performance in croplands. However, it does not explicitly represent reductions in decomposition rates under saturated soil conditions, limiting its applicability to paddy systems characterized by irrigation-induced flooding-drainage cycles. To address this, a paddy coefficient developed in Japan (Shirato & Yokozawa, 2005) has been commonly applied in SOC estimation in the RothC model. Nevertheless, this approach relies on fixed seasonal values (0.2 in summer and 0.6 in winter), which introduces uncertainty by failing to capture the gradual and continuous soil moisture dynamics associated with irrigation management in paddy soils. In this study, we structurally refined the decomposition rate modifier for moisture (b) in the RothC model to improve SOC estimation in paddy soils. First, a soil hydrological model (HYDRUS) was integrated to simulate temporal variations in soil water content based on climate, soil, crop, and irrigation input data. The simulated soil water content was used to calculate the b modifier. Second, the b modifier was reformulated so that it decreases linearly as soil moisture approaches saturation, allowing a continuous representation of decomposition rate reduction under dynamic soil water conditions. The refined RothC model was validated using long-term data (9-54 years) from four experimental sites in South Korea and was further extended to assess SOC stocks in paddy soils at the national scale. The refined RothC model showed a modest overall improvement in predictive performance ($R^2$ = 0.97, RMSE = 4.18 ton C $ha^{-1}$), particularly under high organic inputs such as manure application. This improvement reflects a more realistic representation of SOC decomposition responses to soil moisture dynamics and rewetting effects occurring under irrigation-driven flooding-drainage cycles. By directly linking HYDRUS-based soil moisture simulations to the RothC model, this study demonstrates that structural refinement accounting for paddy soil moisture dynamics can enhance the reliability of SOC estimation. This process-based framework improves SOC assessment and forecasting under irrigated paddy management, with implications for sustainable land management and national greenhouse gas inventories.

**ABSTRACT**

Carbon neutrality is considered as the key strategy for climate mitigation. Cities which are responsible for a major part of anthropogenic C emissions invest in development of urban green infrastructures (UGI) to compensate these emissions by C sequestration in biomass. The role of urban soils in UGI C balance remains overlooked resulting in uncertainty in the estimated capacity of UGI to accumulate and store C. In fact, urban soils can be considered a social-ecological phenomena since direct and indirect anthropogenic drivers have the main impact on soil functionality and ecosystem services including C sequestration.

The research integrates several case studies, where direct and indirect anthropogenic effects distinguished spatio-temporal patterns in C stocks in and $CO_2$ emission from urban soils in different bioclimatic regions and at different scales. The first case study focused on the effects of urban mesoclimatic anomalies and soil construction practices in six cities in Central European Russia. Cities are different in climatic conditions (from subarctic to semiarid), size and history. In all cities, urban heat island (UHI) effect accelerated $CO_2$ emissions from urban soils with the most remarkable consequences in Moscow city center, where implementation of peat-sand mixtures coincided with the strongest UHI, $CO_2$ emissions increased up to 30-40% compared to the References cites. The second case study compared environmental and social drivers of spatial variability in soil C stocks in two Dutch cities: Amsterdam and Wageningen. The study in Amsterdam is based on the dataset collected by municipal services, processed based on the distinguished spatial predictors and verified based on the field survey. The study in Wageningen included several scales. First, a random stratified soil survey (n=56) was done for the whole city to capture the effect of parent materials, land cover and land-use history. Afterwards, effect of the social factor was studied by expert interviews with the owners of the green areas (key plots, n=10), where detailed soil survey was done. Finally, the effects of UGI maintenance practices were studied for the case of university campus. Land-cover and land-use history distinguished spatial patterns in soil C at the city level, whereas at the local scale social factors dominated.

## ABSTRACT

Understanding the distribution of soil organic carbon (SOC) at different depths and its environmental regulation mechanisms is crucial for managing soil health and enhancing carbon sequestration potential. However, comprehensive field data quantifying the nonlinear responses of SOC to environmental drivers in specific regions are scarce. This study analyzed SOC content from 120 cropland soil profiles (0–100 cm) to investigate the horizontal and vertical patterns of SOC, using the western Songnen Plain as a representative case. A threshold model was then applied to quantify the nonlinear relationships between SOC content and key environmental factors. Results showed that SOC content decreased sharply with depth, from 13.38 ± 8.18 g·kg$^{-1}$ (0–20 cm) to 4.37 ± 2.81 g·kg$^{-1}$ (80–100 cm), with the surface layer storing approximately three times more SOC. The primary factors influencing SOC content variation were clay content (Clay), mean annual temperature (MAT), carbon input (CI), bulk density (BD) and pH. Notably, abrupt SOC changes were triggered when these factors crossed specific thresholds, including Clay at 1.38 g·kg$^{-1}$ (in 0–20 cm), MAT at 4.7 ℃ and CI at 3.2 t C ha$^{-1}$ (in 0–40 cm), BD at 1.55 g·cm$^{-3}$ (in 40–100 cm), and pH at 7.5 and 8.9 (in 40–100 cm). This study provides an updated assessment of SOC content in the western Songnen Plain and confirms that SOC content undergoes abrupt changes at specific environmental thresholds. These findings provide theoretical support for optimizing soil management strategies in croplands of the Northeast Black Soil Region.

**Keywords:** Cropland; Deep soil organic carbon; Northeast China; Soil profile; Threshold diagnosis

**Fig. 1** The study area and soil sample points

**Fig.2** Data collection and processing: (a) representative Soil Profile Sapling Points and excavating whole-soil-profiles in the order of the occurrence layer; (b) Sketch map of distribution by standardization

**Fig. 3** Spatial distribution of SOC content in the study area at (a) 0–20cm, (b) 20–40cm, (c) 40–60cm, (d) 60–80, and (e) 80–100 cm, respectively.

**Fig. 4** SHAP values and MAS values represent feature importance of all variables in RF across various soil layers. SHAP values illustrate both the magnitude and direction of feature effects on the model output. Colors represent the feature values (orange indicates high values, blue indicates low values). SHAP values are provided for each horizontal position of each point; If the feature value is positively correlated with the SHAP value, the variable is considered to influence the SOC content.

**Fig. 5** Dependency plots of SHAP main-effect values against the environmental variables (MAT, pH, BD, Clay, and CI) at the following soil depths: 0–20 cm (blue point, a–c), 20–40cm (green point, d–f), 40–60cm (purple point, g–i), 60–80cm (brown point, j–l), 80–100cm (gray point, m–o). Red letters along the black dashed line denote the environmental thresholds where changes in the SOC content gradient occur.

# Assessing pedotransfer functions for bulk density to improve predictions of soil carbon stocks in Retisols (Moscow region, boreal zone)

**Olga I. Manakova[1*], Joulia L. Meshalkina [1], Alexey S. Sorokin[1]**

*[1]Soil Science Faculty, Moscow State University, Moscow, 119991 Russia*

*E-mail: oliamanakova98@gmail.com

**ABSTRACT**

Soil bulk density (BD) is rarely measured in soil studies due to the high cost and labour intensity involved. However, data on soil density is necessary for assessing nutrient stocks and flows in the soil. Pedotransfer functions (PTFs) can be used to estimate BD indirectly based on more readily available data.

Research objectives: (1) Identify the soil properties that are most strongly correlated with BD,(2) Evaluate the accuracy of literature-based PTFs for predicting BD in the study area, (3) Analyse the natural variation of BD across land use types and compare it with the variation introduced by PTF estimations.

The study was conducted at the Chashnikovo Training and Experimental Soil Ecology Center of Moscow State University. Retisols (WRB, 2022) represent the soil cover. Samples were collected from six key plots, which represent different natural and anthropogenic landscapes. Three soil profiles were excavated per plot. Soil samples were taken in duplicate at 10 cm intervals using 100 $cm^3$ steel cores to determine bulk density (BD) and analysed for moisture content (W), particle size distribution according to the USDA classification and organic carbon (OC) content. The total number of samples was 90.

The strongest correlations with BD were found for sampling depth and soil organic carbon content. Thirty out of the 48 PTFs tested achieved an $R^2$ greater than 0.75. Based on the performance indices of mean error (ME) and root mean square error (RMSE), five PTFs were identified as the most accurate for the studied Retisols. Functions F3 and F8 (Abdelbaki, 2018), which use OC as a predictor, and functions F23 and F34, which use OM, showed RMSE values between 0.09 and 0.12 $g*cm^{-3}$. The highest accuracy ($R^2$ = 0.81, ME = 0.73) was achieved by function F24, which incorporated five predictors: OC, W, clay, depth and silt content.

Analysis of BD variation revealed that natural BD variation across different land uses often exceeded the PTF prediction range. Consequently, PTFs may significantly over- or underestimate BD and frequently fail to capture the full scope of natural variability.

**ABSTRACT**

Soils are central to the global carbon (C) cycle, supporting climate change mitigation and essential ecosystem services. While research often focuses on topsoil (<30 cm), subsoils store a substantial share of total C due to their larger volume and lower vulnerability to disturbance. Yet, subsoil C dynamics remain poorly understood, limiting their integration into models and policy. Many soil organic carbon (SOC) models focus on only the topsoil as a single uniform layer, but differences in soil properties, microbial activity, and the sources and pathways of C inputs at greater depths mean that multi-layer and whole-profile approaches are needed. Land use and management strongly influence soil organic carbon by shaping plant traits such as root depth, architecture, and the presence of nitrogen-fixing species. These traits vary markedly between native vegetation, agricultural pastures, and crop systems. Cropping practices, such as fertilisation, tillage, stubble retention, and rotations, alter C input quantity, quality, and depth distribution. For example, fertilisation boosts biomass, increasing above- and below-ground inputs, while deep-rooted crops like canola enhance subsoil C.

Despite widespread use of process-based SOC models at the surface, scalable frameworks for predicting SOC throughout entire soil profiles remain limited. This study applies RothPC-1, a layered extension of RothC, to estimate SOC stocks to depth using readily available data. RothPC uses five conceptual C pools with distinct decomposition rates to simulate SOC dynamics. We applied the model at 164 sites in New South Wales, Australia, across five land uses: irrigated cropping, dryland cropping, grazing modified pasture, grazing native vegetation and unmanaged native vegetation. C inputs were derived from remote-sensing evapotranspiration and NDVI and scaled by land use. The model showed strong agreement between predicted and observed profile SOC stocks ($R^2$ = 0.39–0.97; RMSE = 2.0–24.7 t C $ha^{-1}$), comparable to other depth-resolved models. Grazing native vegetation performed best, likely due to limited management impacts and more uniform soil types. Irrigated cropping performed the worst, highlighting a need to adjust the model to account for irrigation events. Scaling factors for C inputs across land uses were higher for dryland cropping, native and modified pasture grazing and compared to unmanaged native vegetation, likely due to a combination of increased animal and fertiliser inputs and differing plant physiology and species composition. Our findings demonstrate RothPC-1's capability to estimate SOC to depth using accessible datasets and underscore the importance of deeper sampling to refine parameters and improve accuracy. The framework's scalability offers opportunities for carbon farming and national SOC accounting beyond the topsoil.

# Aridity-driven soil carbon vulnerability to drought shapes future carbon–climate feedbacks

**Baoku Shi**[1*]

**ABSTRACT**

Drought frequency and intensity are increasing globally, with uncertain consequences for soil organic carbon (SOC) dynamics in grasslands and shrublands. Using the International Drought Experiment (IDE) network, we quantified how total SOC and its key fractions—particulate organic carbon (POC) and mineral-associated organic carbon (MAOC)—respond to extreme, 1-in-100-year droughts imposed for 1–5 years across 19 sites spanning broad climatic and edaphic gradients worldwide. Across all sites, drought caused no overall change in SOC, POC, or MAOC concentrations. However, responses varied strongly with aridity. In mesic ecosystems (aridity index, AI > 0.65), SOC and POC concentrations declined significantly by 7.9 ± 3.9% and 15.9 ± 6.2%, respectively, whereas MAOC remained stable. In contrast, no significant changes were detected in drylands (AI < 0.65). The sensitivity thresholds of SOC and POC to drought (AI ≈ 0.61 and 0.58, respectively) coincided with the transition between mesic and dryland systems, highlighting aridity as a primary control. Declines in POC under drought were linked to reduced plant productivity and enhanced microbial turnover, while stable MAOC indicated resilience of mineral-bound carbon. In C-rich mesic soils, drought amplified microbial decomposition and priming, leading to measurable SOC losses. Conversely, high interannual precipitation variability and low substrate availability buffered drylands against further carbon depletion. Our results provide the first globally consistent experimental evidence that aridity governs the direction and magnitude of SOC responses to drought. These findings reveal that future increases in drought frequency will disproportionately deplete labile carbon pools in mesic regions, potentially weakening their role as terrestrial carbon sinks. Incorporating differential sensitivities of POC and MAOC into Earth system models will improve predictions of soil carbon–climate feedbacks under intensifying aridity.

**ABSTRACT**

Rotational grazing (RG) with no-till has been proposed as a sustainable alternative to grazing abandonment (GA) to restore soil health and biodiversity in Mediterranean woody pastures, which are crucial for climate mitigation due to their great ecological and socioeconomic importance and the key role these systems play in carbon sequestration and sustainability (Ishaq et al., 2025). To evaluate their effects on soil carbon storage and on the soil microbiome, these two management systems were compared in a dehesa in Extremadura (Spain). RG increased pH, field capacity, and nitrate and Mg content, whereas GA accumulated more total organic carbon (14.6 vs. 10.7 g $kg^{-1}$). Total microbial biomass was 65% higher under GA, but the fungi/bacteria ratio increased under RG, suggesting improved soil structural stability. In both systems, Actinobacteriota, Proteobacteria and Chloroflexi dominated the prokaryotic community, Ascomycota and Basidiomycota dominated fungi, and TSAR and Archaeplastida supergroups prevailed amongst the protistan community. In GA, however, a higher relative abundance of beneficial prokaryotic and fungal taxa (such as *Bacillus*, *Sphingomonas, Streptomyces, Mortierella*, etc.) was found than in RG. In regards of protists, consumer groups such as Cercozoa and Ciliophora presented a high prevalence in both systems, indicating stability despite compositional shifts. Venn diagrams revealed 3121 prokaryotic ASVs exclusive to RG and 2836 to GA, while for fungi 581 ASVs were exclusive to RG and 795 to GA, confirming a strong compositional turnover. Alpha diversity differed across groups. Fungal richness and Shannon index were significantly higher in GA ($p < 0.05$), while prokaryotic and protist diversity (ASVs and Shannon indices) remained similar between treatments, confirming a selective effect of management on fungi. A redundancy analysis including soil physicochemical parameters explained 57% of prokaryotic and 21% of fungal community variance, with pH, Mg, vegetation cover and soil organic carbon as main drivers. RG was associated with nutrient availability and structural resilience, while GA correlated with vegetation cover. Overall, GA promoted microbial abundance and beneficial microorganisms, whereas RG maintained soil carbon stocks and functionality. Integrating both strategies could maximize soil carbon sequestration in Mediterranean pastures.

## ABSTRACT

Fencing off grassland soils emits massive amounts of carbon into the atmosphere. Whether grazing management in desert steppes with fragile ecosystems can mitigate this trend remains highly uncertain. Here, we examined how soil carbon mineralization, as well as its underlying mechanisms, varied with grazing intensity by sheep in a long-term (17-year) experiment in the desert steppe. Carbon mineralization decreased by 15%-55% under different grazing intensities compared to fencing controls. Soil organic carbon (SOC) maintained high levels under light grazing, whereas it decreased with increasing grazing intensity. Reductions in plant carbon and absolute microbial abundance due to grazing, coupled with changes in soil carbon quality and the environment, drove the reduction in carbon mineralization. We suggest that mechanisms of carbon mineralization can be integrated into predictive modelling efforts to better understand the impact of grazing on carbon fluxes in ecologically fragile, but globally important, arid and semi-arid grasslands.

## ABSTRACT

While grazing effects on soil organic carbon (SOC) stocks are documented, how stocking rates repartition carbon between labile and stable fractions in desert steppes remains unknown. Previous studies have focused predominantly on individual carbon pool stocks rather than on inter-component equilibrium. Here, we evaluated the results of a twenty-year controlled grazing experiment, systematically analyzing how prolonged stocking pressure alters the proportional stability of particulate organic carbon (POC) and mineral-associated organic carbon (MAOC) by disrupting the formation of POC and MAOC from plant and microbial precursors. We found that, despite maintaining stable proportions relative to total SOC, POC and MAOC sub-pools exhibited parallel declines under overgrazing. This demonstrates that SOC destabilization arises from systemic changes to carbon repartitioning rather than from isolated pool depletion. Grazing-induced shifts in plant community composition and soil structural features impaired microbial functionality and enzymatic processes, limiting the transformation of organic substrates into more stable forms of soil carbon. These findings advance desert steppe management by highlighting the importance of prioritizing component ratio stability over conventional stock-based metrics and offers actionable strategies to balance carbon sequestration.

## ABSTRACT

Under global climate change, precipitation regimes are increasingly exhibiting trends of diversification and extremization. In arid regions, precipitation acts as a key driver for the formation and stabilization of soil organic carbon (SOC), making microbial necromass and extracellular polymeric substances (EPS) central to the long-term stability of SOC. Changes in precipitation may alter the carbon allocation strategies of soil microorganisms, thereby influencing the differential environmental responses and turnover capacities of microbial necromass and EPS. However, the mechanisms underlying how long-term precipitation alterations affect the composition of soil carbon-fixing bacterial communities and their impact on the dynamics of EPS and microbial necromass, as well as the factors regulating them remain poorly understood. To address this knowledge gap, we conducted a 9-year precipitation manipulation experiment with five treatments: ambient precipitation as the control, along with 40% and 20% reductions in precipitation, and 20% and 40% increases in precipitation. Although changes in precipitation did not alter soil fungal diversity indices, they modified the composition and function of dominant fungal communities. Increased precipitation promoted overall bacterial diversity but reduced the diversity of *cbbM*-carrying bacteria. Under reduced precipitation conditions, drought-tolerant Proteobacteria dominated the *cbbM*-harboring bacterial community, resulting in an increase in their relative abundance from 8.9% to 15.6%. Under extreme drought conditions, microbial necromass and EPS contents decreased by 76.0% and 30.2%, respectively. Increased drought intensity raised the EPS accumulation coefficient (24.8–41.0%), suggesting that EPS was either more efficiently formed or accumulated as a microbial residue. Overall, long-term drought shifted microbial community structure, redirecting carbon allocation from biomass growth and necromass formation toward EPS production. This shift in microbial residue composition may represent a key mechanism for SOC sequestration under drought conditions. This study provides direct and novel evidence that EPS contributes more actively than microbial necromass to SOC in response to long-term drought.

## ABSTRACT

Plastic films play an important role in achieving food security for a growing world population by increasing crop yields by more than 30%, suppressing weeds, and improving soil water and heat conditions. Polyethylene is the primary raw material for mulch film, but biodegradable mulch film has also been widely used recently. The residual plastic film in the environment will break into fragments, ultimately forming microplastics (MPs). Microplastics in soil ecosystems disrupt soil aggregate structure, alter microbial community composition, interfere with the growth of soil flora and fauna, perturb biogeochemical cycling of essential elements, and ultimately threaten human health through environmental exposure or food chain transmission, therefore, their are defined as emerging pollutants. Microplastics in terrestrial ecosystems are C-rich substances of anthropogenic origin. As MPs age, they release dissolved organic matter (e.g., polymer fragments, additives, oligomers, monomers) into the soil environment. Therefore, elucidating the aging behavior of mulch film-derived MPs in farmland soils and their influence on SOC pools is important for accurately assessing soil carbon sinks.

Microplastics are emerging pollutants that may affect soil organic carbon (SOC) and thus influence global change. However, the aging behavior of mulch film-derived MPs exposure to farmland soils and their impact mechanisms on microbial necromass carbon (MNC) formation remain poorly understood. Polyethylene (PE) and biodegradable (Bio, polypropylene carbonate and polybutylene adipate terephthalate synthetic material (PPC+PBAT)) mulch film-derived MPs at 0.2% (w/w) dosages were mixed into farmland soils, incubated for 120 days and sampled every 30 days. On day 120, compared to MPs before incubation, the relative contents of C–H or C–C on the surfaces of PE-MPs and Bio-MPs decreased by 12.2% and 3.7%. In the first 60 days, compared to control soils (CK), the bacterial necromass carbon (BNC) content decreased by 54.0–56.0% and 23.9–44.8%, while the MNC decreased by 30.2–53.8% and 11.8–23.0% in farmland soils exposed to PE-MPs and Bio-MPs, respectively ($p<0.05$). This reduction was attributed to the rapid turnover of necromass. During 90–120 days, under PE-MPs and Bio-MPs exposure, the contents of microbial biomass carbon (MBC) (66–76% and 10–18%), dissolved organic carbon (DOC) (1.8–16.9% and 12.4–26.4%), MNC (8.2–29.2% and 14.0–16.1%), and SOC (10.7–11.0% and 6.8–8.9%) showed significantly higher levels than those in the CK treatment. The PE-MPs and Bio-MPs promoted an increase in MNC and SOC content, which was associated with MPs aging that altered available nutrients and enzyme activities and directly or indirectly promoted an increase in DOC and microbial biomass. In summary, mulch film-derived MPs affect MNC accumulation and SOC sequestration, especially conventional PE-MPs.

## ABSTRACT

The incorporation of plant-derived biomass by microorganisms into deceased microbial biomass, i.e., a "microbial carbon pump", is essential for forming a soil carbon (C) pool. Therefore, microbial communities and associated functions could shape the formation of soil organic C (SOC) composition and persistence. However, the mechanism by which microorganisms mediate the degradation of various types of biomass (such as plant or microbial) and its impact on SOC formation under different vegetation types remains unclear. Herein, we analyzed microbial communities, carbohydrate-activated enzymes (CAZymes), absolute quantification of C- degradation genes, and extracellular enzyme activities to track microbial-mediated SOC formation under three vegetation types on the Loess Plateau. Changes in vegetation type influenced microbial community structure and distributions of certain bacterial groups. Specifically, dominant bacterial taxa shifted from oligotrophic Actinobacteria to eutrophic Proteobacteria from grass to forest soil. The proportion of microbial CAZymes responsible for decomposing plant-derived components (86–89%) exceeded that of microbial-derived components (11–14%), suggesting a greater capacity for the degradation of deceased plant biomass by microorganisms. There was a reduction of 14%–17% in the absolute abundance of specific C-degradation genes for hemicellulose and cellulose in forest soil compared to grass, while an increase of 20%–32% was observed in lignin and chitin degradation. This indicated a higher decomposition potential of lignin and chitin by microorganisms in forest soil. The number of CAZymes genes involved in the degradation of bacteria-derived biomass (peptidoglycan) was higher than fungi-derived biomass (chitin and glucans) and had a close correlation with the $qCO_2$, microbial biomass C (MBC), and particulate organic C (POC). The abundance of C-degrading genes increased with the increase in the corresponding enzyme activity, indicating that enzyme activity is regulated by functional genes. In conclusion, shifts in CAZymes genes encoding for the degradation of diverse carbon sources could impact microbial metabolic activity through a microbial "carbon pump" regulation process. This mechanism could facilitate the formation of soil organic carbon and its fractions across different vegetation types.

# Drivers and Consequences of Microbial-Derived Carbon Loss in Degraded Alpine Grasslands on the Qinghai-Xizang Plateau

## ABSTRACT

Soil organic carbon (SOC) and its microbial-derived C are severely reduced in degraded alpine grasslands on the Qinghai-Xizang Plateau, a region highly sensitive to climate change. Acting as relatively stable microbial metabolic products, microbial necromass carbon (MNC), extracellular polymeric substances carbon (EPSC), and glomalin-related soil proteins (GRSP) serve as key components of the SOC pool. However, their roles in degraded alpine grassland remain poorly understood. We quantified MNC, EPSC, and total GRSP across alpine grassland representing different degradation stages (non-degradation, light degradation, moderate degradation, and heavy degradation) and assessed their contributions to SOC along with controlling factors. Our results showed that although absolute contents of MNC, EPSC, and total GRSP declined significantly with increasing degradation (0.75–27.59 mg $g^{-1}$, 1.00–3.07 mg $g^{-1}$, and 0.40–13.89 mg $g^{-1}$, respectively), the relative contributions of MNC and T-GRSP to SOC remained stable, whereas the contribution of EPSC increased. Notably, MNC contributed substantially more to SOC than EPSC and GRSP (1.80%–68.34% vs. 1.37%-22.77% and 2.90%–26.48%). The absolute loss of MNC during SOC decline was 70.6 and 1.3 times as great as that of EPSC and total GRSP, respectively. Further analysis indicated that microbial respiratory entropy affected by physicochemical properties and microbial biomass was a key driver of MNC accumulation relative to EPSC. In summary, microbial metabolites are fundamental to SOC persistence, underscoring their critical role in mitigating degradation and guiding sustainable management of alpine grassland.

## ABSTRACT

Fungal necromass carbon (FNC) is a quantitatively significant and chemically recalcitrant component of stable soil organic carbon (SOC), yet its global distribution, mechanistic controls, and deliberate manipulation in agro-ecosystems remain under-characterized. Here we integrate two complementary studies that (i) resolve the biogeochemical drivers of FNC storage across major croplands and (ii) translate this knowledge into a scalable circular-agriculture technology that actively manages FNC for concurrent C sequestration, waste valorization, and crop-quality gains.

Meta-analysis of 873 topsoil samples (0–20 cm) from 124 sites across Asia, Europe and North America showed FNC averages 25.1 ± 0.6 % of SOC (range 18–34 %). Density declined: North America 8.39 g $kg^{-1}$ (25.6 %) > Asia 5.56 g $kg^{-1}$ (25.1 %) > Europe 3.94 g $kg^{-1}$ (20.3 %). Sixty-seven percent of variance was explained by three mechanisms: (1) hyphal enmeshment promoting aggregate occlusion; (2) melanin and chitin (10–15 % of dry mass) with residence times 3.4 × bulk SOC; (3) biomass input linked directly to microbial biomass C (MBC; path coefficient 0.32, $p < 0.01$). pH, clay and total N indirectly influenced FNC via MBC ($R^2 = 0.33$). Conservation practices amplified these drivers: no/reduced tillage raised FNC efficiency by 45 % and straw return increased FNC by 26 %, supplying 36 % of SOC gain under reduced tillage.

We translated these insights into a Livestock–Crop–Mushroom (LCM) biorefinery. Cattle manure (C/N 16) and straw (C/N 65) were co-composted into lignocellulosic substrate (St), colonised by *Stropharia rugosoannulata*. Fruiting bodies yielded 1.8 kg mycoprotein $m^{-2}$; spent substrate (SMS) containing 286 mg C $g^{-1}$, 23.3 mg N $g^{-1}$, 8.7 % chitin and 2.1 % melanin was pelletised as biofertilizer (StM). In oat field trials StM boosted grain crude protein by 5.1 % ($p < 0.05$), root biomass by 6.5 % and forage yield by ~20 % versus unfertilised soil, outperforming St. Thermophilic composting plus fungal metabolism cut antibiotic resistance genes by 46 %, pathogens by 25 % and oxytetracycline residues by 68 % (3232 → 630 µg $kg^{-1}$), delivering simultaneous gains in C storage, productivity and ecological safety.

Collectively, FNC is a quantifiable, manageable reservoir connecting soil C cycling with circular agriculture. Global data identify management levers (reduced tillage, residue retention) to maximise FNC, while LCM provides a farm-scale technology to engineer fungal C inputs, close nutrient loops and upgrade wastes. In the future, research priorities could focus on three key directions: (i) select fungi with high chitin/melanin for longer C persistence; (ii) scale LCM to cereals and contrasting climates; (iii) embed FNC modules in Earth-system models. By highlighting fungi as both inherent C stocks and deployable tools, this work advances fungal-centric strategies for climate-resilient and sustainable intensification of agricultural systems.

# The influence and mechanism of the interaction between Mineral-associated Organic Carbon and soil aggregates on soil carbon sequestration

**Zijia Zuo[1], Shuangying Wang[1], Jihao Li[1], and Zhijing Xue[1*]**

[1] *School of Geography and Tourism, Shaanxi Normal University, Xi'an, China*

*E-mail 2094586761@qq.com

**ABSTRACT**

Mineral-associated Organic Carbon (MAOC) serves as a key component for maintaining long-term carbon stability in soil, with its dynamic interactions with soil aggregates profoundly influencing soil carbon sequestration. To investigate the distribution patterns of MAOC across aggregate sizes and their synergistic stabilization mechanisms, the research systematically analyzes the formation processes of soil organic carbon and soil aggregates, highlights MAOC's distribution characteristics in different aggregate sizes, examines aggregates' physical protection effects on MAOC and evaluates MAOC's feedback contributions during aggregate formation. Results revealed that the MAOC content in the 0-20 cm soil layer of Cropland（Cr） was significantly lower than that in natural grassland（NaG）. MAOC exhibited greater stability in the 20-40cm soil layer, particularly in 1-2mm and 3-5mm soil aggregate sizes. This indicates that MAOC plays a crucial role in deep soil carbon sequestration, with its stable accumulation closely linked to aggregate structure. Through a synergistic mechanism of physical isolation and chemical adsorption, both factors jointly enhance the stability of soil carbon reservoirs.By exploring the MAOC-aggregate feedback relationship, this research elucidates their crucial role in soil carbon stabilization, providing theoretical foundations for understanding soil carbon sequestration mechanisms.

# Orchard soils exhibit the highest microbial $CO_2$ fixation potential and contribution to soil organic carbon across land-use types in Qaidam Basin

**Fadan Lei**[1*]

[1] *Key Laboratory of Low-carbon Green Agriculture in Northwestern China, Ministry of Agriculture and Rural Affairs, P. R. China, College of Natural Resources and Environment, Northwest A&F University, Yangling, Shaanxi, China*

*fadan2001@163.com

**ABSTRACT**

Soil organic carbon content varies across different land-use types. Elucidating $CO_2$-fixing microorganisms and their fixation potential is pivotal for accurately evaluating and improving soil carbon sinks and enriching the theory of microbial carbon sequestration. However, the $CO_2$ fixation potential, driving factors and mechanism of soil $CO_2$-fixing microorganisms in different land-use types are still unclear. This study investigated the $CO_2$ fixation potential (CFP) and sequestration mechanism in 0-10 cm topsoil (36 soil samples) of typical grassland (GL), facility farmland (FAL), farmland (FL) and orchard (OD) in the Qaidam Basin by $^{13}CO_2$ isotope tracer incubation method (61 d), metagenomic sequencing and partial least squares method. The $^{13}CO_2$-fixing rates (26.7 mg $^{13}C$ $m^{-2}$ $d^{-1}$) in OD were 2.26, 1.24 and 1.31 times those of GL, FAL and FL, respectively ($p < 0.05$). Correspondingly, 160 unique $CO_2$-fixing species were observed in OD, mainly including *methanogenic archaeon* ISO4-H5, *Leptospira alstonii*, Candidatus *Saccharibacteria* bacterium GW2011 GWA2 46 10 and *Bacillus encimensis*, with few unique species in other soils. GL showed higher relative abundances of the Calvin (8.78%) and C4-Dicarboxylic acid (3.89%) cycles ($p < 0.05$). CFP was directly affected by metabolic pathways and soil properties, and indirectly by microbial communities ($p < 0.05$), with ammonium ion, total nitrogen, and particulate organic carbon as key determinants. In conclusion, CFP can be improved by regulating soil physical-chemical factors. Our findings clarify the structural and functional variations of $CO_2$-fixing microbial communities across land uses, offering theoretical support for exploring novel $CO_2$-fixing microbes and optimizing $CO_2$ fixation capacity.

## ABSTRACT

Soil $CO_2$-fixing microorganisms (CFMs) convert $CO_2$ into soil organic carbon (SOC) via light or chemical energy, acting as core drivers of terrestrial carbon sequestration and critical for mitigating climate change and achieving carbon neutrality. However, their community assembly rules, metabolic differentiation mechanisms and contribution thresholds to SOC accumulation under natural environmental changes remain unclear. To address these gaps, this study integrated molecular biology techniques, $^{13}CO_2$ labeling and microbial isolation to systematically explore CFMs community structure, metabolic pathways and fixation potential across precipitation gradients and vegetation types on the Chinese Loess Plateau.

CFMs communities exhibited distinct spatial heterogeneity shaped by environmental factors and geographic distance: *cbbL*-harboring CFMs (dominated by *Proteobacteria* and *Actinobacteria*) prevailed in the southern Plateau, while *cbbM*-harboring taxa (primarily *Alphaproteobacteria*) dominated the north. Precipitation and vegetation jointly drove CFMs functional differentiation: fixation potential increased with precipitation (semi-arid $^{13}$C-SOC was 3.9 times higher than arid regions), with arid soils relying on the Calvin cycle (dominant genus: *Rubrobacter*) and semi-arid soils on Reductive citrate (rTCA) cycle and 3-Hydroxypropionate bi-cycle (dominant genus: *Bradyrhizobium*). Grasslands outperformed shrublands and forests in sequestration capacity (47% and 93% higher $CO_2$-fixing gene abundance), with *Rubrobacter*, *Solirubrobacter*, *Conexibacter* and *Streptomyces* as key taxa, and relied on the Calvin cycle—contrasting with forests' rTCA-dominated fixation.

Notably, CFMs showed preferential carbon allocation to mineral-associated organic carbon ($^{13}$C-MAOC, 49.3%–70.1%), particulate organic carbon ($^{13}$C-POC, 2.5%–15.9%) and microbial biomass carbon ($^{13}$C-MBC, 1.5%–18.8%), with dissolved organic carbon ($^{13}$C-DOC) accounting for only 0.3%–1.2% of $^{13}$C-SOC. Gram-negative bacteria dominated fixation (44.6%–65.6%) with strengthening dominance over time, and fixed $CO_2$ was primarily incorporated into SOC as bacterial necromass. Precipitation and vegetation indirectly regulated fixation potential via modifying soil nutrients and CFMs communities. Nine strains were isolated from grasslands, with *Agrobacterium* sp. A4 and *Brevundimonas vesicularis* sp. A7 showing the highest $CO_2$ fixation efficiency (4.2 and 4.1 mg/L, respectively).

Overall, CFMs display diverse community and metabolic adaptations to precipitation and vegetation changes, with a fixation rate of 8.1–27.0 mg $^{13}C\ m^{-2}\ d^{-1}$ and bacterial necromass as a stable SOC component. These findings clarify the linkages between environmental factors, CFMs traits and carbon sequestration, providing a scientific basis for optimizing soil management to enhance terrestrial carbon sinks.

## ABSTRACT

Microbial $CO_2$ fixation constitutes a pivotal route for soil organic carbon (SOC) formation, particularly in low-productivity ecosystems such as biocrusts. Yet, it remains unclear how microbial $CO_2$ fixation rate and the diversity of $CO_2$-fixing taxa and genes respond to biocrust succession, limiting our ability to assess biocrusts role in global C budgets. Here, we quantified the contribution of $CO_2$-fixing microbes to SOC formation across biocrust successional stages using $^{13}CO_2$ labeling, high-throughput sequencing, and absolute quantification of $CO_2$-fixation genes. Biocrust development substantially restructured $CO_2$-fixing microbial communities, increasing their ACE diversity index by 160–200%. This diversification coincided with pronounced increases in microbial $CO_2$ fixation rates, as indicated by $\delta^{13}C$ enrichment rising by 34%, 68%, and 810% in the biocrust, 0–2 cm, and 2–10 cm soil horizons, respectively, relative to bare sand. Across soil horizons, microbial $CO_2$ fixation peaked in the biocrust (16–21 g C $m^{-2}$ $yr^{-1}$), exceeding that of the 0–2 cm and 2–10 cm horizons by 4.5–6.4 and ~15 fold, respectively. Enhanced $CO_2$ assimilation correlated more with community diversity than with gene abundance, suggesting that community-level organization, rather than individual genetic capacity, drives fixation efficiency. This community restructuring and its enhanced function were supported by improved nutrient availability during biocrust succession. Correlations between $^{13}C$-SOC, dissolved nitrogen, and leucine aminopeptidase activity point to nitrogen-mediated facilitation, while co-variation between $^{13}C$-SOC, mineral associated organic C, and clay content indicates mineral association as a key stabilization pathway. In summary, biocrust succession accelerates microbial $CO_2$ fixation and SOC buildup mainly via increased fixer diversity, with clay and nitrogen jointly governing C sequestration and stabilization processes. With their 0.35 Pg C yr-1 sequestration capacity, biocrust autotrophs represent an overlooked nature-based solution, targeted restoration can amplify dryland C storage potential while buffering against climate variability.

## ABSTRACT

Climate change and human activities threaten lakes in arid regions with shrinkage and drive soil salinization, thereby compromising regional ecological security. Land degradation and ecological restoration in contracting lake areas have garnered increasing research attention. In this study, we examined changes in soil organic carbon (SOC) content and microbial community diversity under various vegetation restoration strategies—Carex (CL), Salicornia (SL), Tamarisk (TL), reed (RL), and grass (GL)—along the lakeshore of Dalinor Lake in Inner Mongolia. Results indicated that all restoration measures enhanced SOC content and increased the proportion of the more stable mineral-associated organic carbon (MAOC), and GL restoration resulted in the highest SOC storage and stability. High-throughput sequencing revealed that the proportions of plant-derived carbon (PlantC) and microbial-derived carbon (MicroC) in soil increased markedly during vegetation succession, from 6.6% and 25.77% to 43.78% and 42.88%, respectively. Vegetation restoration also stimulated microbial activity, as reflected by elevated levels of microbial biomass carbon (MBC), fungal-derived carbon (Fungal-C), and bacterial-derived carbon (Bacterial-C), with GL restoration notably enhancing Fungal-C. Compared to bare land (BL), restored sites showed increased soil microbial α-diversity (higher Chao1 and Shannon indices), though the Simpson index remained largely unaffected. In early succession, bacterial phyla such as Balneolota and Gemmatimonadota were dominant, whereas Acidobacteriota and Actinomycetota prevailed in mid-to-late stages that crucial for ameliorating degraded saline-alkali soils and metabolizing organic compounds. Redundancy analysis (RDA) indicated that soil available phosphorus (AP), available potassium (AK), pH, and total dissolved solids (TDS) were the primary factors shaping microbial diversity and composition in early succession, while SOC content and composition became dominant in later stages. Mantel test analysis further highlighted significant influences of pH, TDS, TN, CEC, SOC, C/N ratio, microbial diversity indices, and dominant bacterial phyla on both PlantC and MicroC. Structural equation modeling (SEM) demonstrated that MicroC was predominantly driven by biodiversity and bacterial phyla, whereas the composition of SOC directly regulated PlantC accumulation. Successional vegetation communities indirectly influenced soil organic carbon partly by modifying soil physicochemical properties, microbial diversity, and community composition, ultimately governing PlantC and MicroC dynamics. Collectively, this collaborative study between Chinese and Norwegian partners provides valuable insights for future adaptive management of climate change risks and SOC sequestration strategies in arid lake systems experiencing shrinkage.

**ABSTRACT**

Soil organic matter (SOM) is essential for maintaining soil fertility and sustainable agriculture. It is commonly fractionated into particulate (POM) and mineral-associated organic matter (MAOM) fractions, which differ in stability and microbial regulation. However, the specific microbial traits that regulate these fractions across large spatial gradients remain poorly understood, constraining our ability to manage SOM effectively. Here, we combined size-based SOM fractionation and amplicon sequencing of 444 cropland soils derived mainly from loamy and silt loam substrates under dominant maize and rice cultivation in Liaoning province, northeast China with a global meta-analysis (2438 observations) to disentangle microbial controls on POM and MAOM. Microbial biomass was quantified from microbial biomass carbon and nitrogen, whereas necromass was estimated from amino sugar biomarkers, revealing that microbial biomass was positively associated with both fractions, while necromass strongly predict MAOM. Microbial diversity and network influenced SOM fractions indirectly by shaping biomass and necromass, and microbial traits collectively explained up to 24% of POM and 62% of MAOM variation. These findings were corroborated by global evidence, highlighting the generality of microbial controls across ecosystems and scales. Our study provides a mechanistic framework for integrating microbial processes into SOM management and carbon stabilization strategies at landscape scales.

*Email: kuzyakov@gwdg.de

Activation energy (Ea) of (bio)chemical reactions – the fundamental parameter, defining the reaction rates – has never been critically evaluated and generalized for processes of organic matter transformations in soil. Based on the database of Ea for a broad range of i) oxidative and hydrolytic exoenzyme activities, ii) $CO_2$ production and iii) heat release during soil incubation, as well as iv) thermal decomposition of soil organic matter (SOM), we assessed the Ea for processes of SOM transformation. After a short description of the four approaches to assess Ea of SOM transformation – all based on the Arrhenius equation – we present the Ea of chemical (79 kJ $mol^{-1}$) and microbial (67 kJ $mol^{-1}$) mineralization, microbial decomposition (40 kJ $mol^{-1}$), and exoenzyme-catalyzed depolymerization (33 kJ $mol^{-1}$) of SOM. The catalyzing effects of exoenzymes reduce the energy barrier of SOM decomposition by more than twice that of its chemical oxidation (from 79 to 33 kJ $mol^{-1}$). The Ea of exoenzymatic hydrolysis of N-, P-, and S-containing organic compounds is about 9 kJ $mol^{-1}$ lower (40-fold faster reactions) than that of other (N-, P-, and S-free) organic substances. Under real soil conditions (not in suspension as in enzyme activity analysis), where organic substrates are physically protected and exoenzymes are partly deactivated, microbial mineralization of SOM is 140-fold faster compared to its chemical oxidation. The Ea of microbial mineralization of SOM increases from biochemically labile to stable pools. This is one of the reasons for the decrease in the $CO_2$ efflux from soil during long-term incubations.

Since processes with higher Ea are more sensitive to temperature increase, global warming will stimulate faster decomposition of stable organic compounds and accelerate the C cycle much stronger than the cycling of the nutrients N, P, and S. The consequence will be a shift in the stoichiometric ratios of microbially utilized substrates. Overall, Ea is an easily measurable crucial parameter of (bio)chemical transformations of organic matter in soil, enabling the assessment of process rates and the inherent stability of SOM pools, as well as their responses to global warming.

# Microbial Intracellular Carbon Storage: A Missing Link in Global Soil Carbon Sequestration Framework

**Guanglong Tian*, Benjamin Morgan, Olawale Oladeji, and Chih-Yu Chiu**

Biosolids Utilization and Soil Science Section, Monitoring and Research Department, Metropolitan Water Reclamation District of Greater Chicago, Chicago, USA

*Presenter Email: TianG@MWRD.Org

## ABSTRACT

Exploring carbon use efficiency for soil C sequestration has been focused on microbial growth and respiration. Fungi and bacteria can divert assimilated C into intracellular storage, thus reducing unnecessary C respiration loss to $CO_2$. However, intracellular C storage (accumulation of neutral lipids) as a pathway for transforming crop residue-C into soil organic C (SOC) has been neglected. As one of the first researchers to test the hypothesis, we collected soil samples in 2025 in western Illinois, USA in an experiment with four treatments: municipal biosolids, vegetative compost, grass restoration, and chemical fertilizer. Biosolids (byproduct of microbial processing of wastewater treatment) and vegetive compost (windrow-composting and curing of grass clipping and food scraps) were applied in 2013 at 8% the top 15-cm soil weight. Corn was planted annually. Grass restoration was established by converting cropland to natural regrowth. Sample analysis was conducted using standard phospholipids fatty acid (PLFA) method involving total lipid extraction, separation using silica gel column, derivatization to fatty acid methyl esters, and measurement by gas chromatography for neutral lipid fatty acid (NLFA) and PLFA. Higher NLFA amount and NLFA/PLFA ratio were found in biosolids-amended soil (81.9 nmols $g^{-1}$ and 1.88), grass restoration (81.3 nmols $g^{-1}$ and 1.24), and compost-amended soil (64.2 nmols $g^{-1}$ and 1.35) than chemical fertilizer control (50.5 nmols $g^{-1}$ and 1.17). Upon microbial turnover, neutral lipids became stable soil organic matter directly or through association with clay minerals, leading to high annual soil C sequestration (SOC gain excluding residual biosolids C) at 0.42 Mg $ha^{-1}$in biosolids-amended soil, which doubles the goal of international “4 per 1000” initiative. Annual soil C sequestration was 0.09 Mg $ha^{-1}$ in conventional fertilizer soil, 0.14 Mg $ha^{-1}$ in compost-amended soil, and 0.39 Mg $ha^{-1}$ under grass restoration. Addition of biosolids created organic nutrients and moisture-rich microhabitat that could support cells to thrive in variable or harsh agricultural environments, allocating more assimilated C to storage as K-strategy microorganisms. The soil C sequestration rate was correlated to NLFA (microbial C storage) and NLFA/PLFA ratio rather than PLFA (microbial structure biomass). The significance of our findings is that future management for soil C sequestration should focus on improving soil environment conditions by amending soil with long-lasting, labile and non-labile balanced organic nutrients to stimulate microbial intracellular C storage.

**ABSTRACT**

Soil micro-food webs play a vital role in sustaining soil carbon cycling and stocks through the activities and interactions of individual organisms. However, grassland degradation disrupts these micro-food webs and is expected to reduce soil carbon stocks. This hypothesis was tested along degradation transects that were established in alpine meadows and steppes in arid regions, examining how multitrophic organisms and microbial metabolic efficiency respond to grassland degradation and how these responses relate to soil organic carbon (SOC). Grassland degradation reduced microbial necromass accumulation coefficient (the ratio of microbial necromass carbon to microbial biomass carbon) and increased microbial metabolic quotient (the ratio of soil respiration rate to microbial biomass carbon), indicating that microbes may prioritize SOC decomposition for resource acquisition over growth and necromass accumulation. Degradation led to increased bacterial and fungal diversity, reduced protist and nematode diversity, and simplified the structure of micro-food web (network complexity). Overall, grassland degradation reduced microbial metabolic efficiency, linked to reduced plant biomass, lower soil clay content, and a simplified micro-food web—particularly weakening interactions among microbes, microbivores, and predators—which is associated with SOC loss in degraded grasslands. These findings indicate the necessity of maintaining micro-food web structures to promote soil carbon sequestration in degraded grasslands.

**ABSTRACT**

As a core component of the terrestrial carbon (C) cycle, plant photosynthetic C assimilation regulates soil organic carbon (SOC) sequestration. However, the allocation patterns of photosynthetic C across different soil layers in desert ecosystems remain unclear. Through in situ field $^{13}CO_2$ pulse labeling applied to Alhagi sparsifolia, a keystone desert species, we traced photosynthetic C dynamics over 360 days. This included vertical translocation from plant aboveground to belowground systems (0-30, 30-60, 60-100, and 100-200 cm depths) and subsequent partitioning into SOC, soil microbial biomass (phospholipid fatty acid), microbial necromass (amino sugars), and plant residue (lignin phenols). Over time post-labeling, $^{13}C$ in plants gradually shifted from aboveground to belowground biomass. Although plant residue $^{13}C$ accumulated gradually in the soil, its contribution to SOC was only 0.2%–1.1%, lower than that of microbial necromass (12%–30%). In the 0–100 cm soil layer, microbial necromass $^{13}C$ and its contribution to SOC increased initially and then stabilized over time, while it continued to increase at 100–200 cm depth. Microbial necromass $^{13}C$ dynamics were more strongly associated with SOC than plant residue. In desert ecosystems, microbes are the primary contributors to deep SOC accumulation, more than in surface layers.

**ABSTRACT**

Microbial-derived carbon are the important sources of soil organic carbon (SOC) formation. Particulate organic carbon (POC) and mineral-associated organic carbon (MAOC) are two physical components of SOC. Their protection mechanisms, mean residence time, biogeochemical properties are different because of distinctive sources, which can be better described in aspects of soil carbon accrual, persistence as well as function. Previous study showed that there is difference in SOC accumulation processes between forestland and grassland. However, it remains unknown how do microbial necromass work during SOC accumulation, especially in the formation of POC and MAOC in forestland and grassland. Therefore, we selected artificial forestland and natural grassland on the Loess Plateau in China, by biomarkers (amino sugar) to exploring contributions of microbial-derived carbon to POC and MAOC in natural grassland and artificial forestland, as well as influencing factors. Results showed that accumulation of POC and MAOC in forestland were different from grassland at 0-60 cm soil layers. At 0-60cm soil layer, contribution of MAOC to SOC (73.7%) in natural grassland were higher than that (70.7%) in artificial forestland. However, contribution of POC to SOC (26.6%) in natural grassland were lower than that (29.3%) in artificial forestland at 0-60 cm soil layer. Microbial necromass carbon (MNC) contents in POC were higher than that in MAOC at 0-60 cm soil layer in artificial forestland and natural grassland. MNC contents in POC under artificial forestland was higher than that of natural grassland. MNC in MAOC contents under natural grassland was higher than that of artificial forestland at 0-20 cm soil layer, but lower than that of artificial forestland at 20-60 cm soil layer. These results suggested that vegetation restoration could promote MAOC accumulation and contribute to SOC sequestration, especially natural grassland restoration. These conclusions are significant to know about the mechanism of soil organic carbon formation and accumulation during the artificial and natural vegetation restoration.

## ABSTRACT

Predicting how soil microbial communities respond to drought is a major challenge in terrestrial ecology, especially in heterogeneous landscapes where soils differ in texture, nutrient status, and climatic history. In this study, we combined a controlled laboratory incubation with a coordinated field drought experiment to explore whether background site characteristics and laboratory moisture–response curves can help anticipate ecosystem responses to reduced precipitation. We collected soils from six grassland sites across Italy spanning a broad gradient of pedoclimatic conditions and characterised their microbial and nutrient dynamics under varying levels of water availability.

In the laboratory, soils were incubated at five water-holding capacity (WHC) levels (10–80%) to establish moisture–response functions for a suite of microbial processes. We quantified microbial respiration, microbial biomass C, N and P, microbial growth via $^{18}$O-DNA incorporation, dissolved organic and inorganic nutrients (including dissolved P), and the activities of eight extracellular enzymes involved in C-, N- and P-cycling. These datasets provided site-specific profiles of microbial sensitivity and functional potential across a moisture gradient.

To assess whether these laboratory-derived patterns align with field drought behaviour, an *in-situ* rain-exclusion experiment was carried out in each grassland, imposing a 2.5-month drought during the plant growing season. The same microbial and nutrient variables were measured in the field following drought, enabling a comparison between controlled moisture–response curves and in situ functional responses.

Although data analysis is ongoing, preliminary results point to systematic links between background soil properties, laboratory moisture sensitivity, and field drought outcomes. Relationships appear to be process - dependent, suggesting that some microbial functions may be more predictable from laboratory assays and site characteristics than others. By integrating both laboratory and field manipulations, this work aims to develop a mechanistic and empirically grounded framework for assessing drought impacts on soil microbial communities.

**ABSTRACT**

Microbial- and plant-derived carbons are critical sources of soil organic carbon (SOC), but the specific responses of soil amino sugars and lignin phenols to global change remain unclear. In this study, we conducted 3193 observations across 553 experiments aimed at investigating the potential role of amino sugars and lignin phenols in maintaining SOC accumulation in response to land-use change, nutrient additions, elevated C dioxide ($eCO_2$), warming, and drought. The results showed that land restoration increased amino sugars (35.1%), glucosamine (53.8%), galactosamine (68.6%), muramic acid (33%), lignin phenols (79.3%), and vanillyl phenols (68%), whereas land degradation reduced these compounds, including syringyl. Nitrogen (N) and phosphorus (P) additions enhanced amino sugar, glucosamine, and muramic acid contents, whereas P addition selectively increased glucosamine content. N, P, and potassium additions increased glucosamine (16.8%), galactosamine (17.3%), muramic acid (21.6%), and lignin phenol (4.8%) contents, while $eCO_2$ only increased amino sugar content by 14.6%. Warming increased glucosamine and muramic acid contents, whereas drought had no effect on amino sugar and lignin phenol contents. Soil amino sugars played a more critical role than lignin phenols in SOC accumulation, and their dynamics were influenced by soil nutrient availability and microbial communities under global change. These findings advanced our understanding of the dominant role of microbial residues in SOC accumulation mediated by the nutrient stoichiometry and microbial communities.

**Figure 1**. A world map showing the distribution of ecosystems included in this meta-analysis. Different ecosystem types are represented by different colors, and the sizes of the circles indicate sample sizes.

**Figure 2.** Response ratios of global change factors (GCFs) on the contents of total amino sugars (TAS, a), glucosamine (Glu, b), galactosamine (Gal, c), muramic acid (Mur, d), lignin phenols (VSC, e), vanillyl (VP, f), syringyl (SP, g), and cinnamyl (CP, h). Weighted means and their 95% confidence intervals of response ratios (RRs) are provided. LD, land degradation; LR, land restoration; N, nitrogen addition; P, phosphorus addition; NP, nitrogen phosphorus fertilizer addition; NPK, nitrogen phosphorus potassium fertilizer addition, $eCO_2$, elevated carbon dioxide. The open and closed symbols indicate nonsignificant ($p > 0.05$) and significant ($p < 0.05$) effects, respectively. The numbers on the below side of the means represent the sample size.

## ABSTRACT

Microbial biomass residues have been recognized as significant material contributors to the formation of SOM. However, the turnover of microbial biomass residues with respect to their detailed microbial food web and the mechanism by which material from microbial sources is sequestered in soil organic matter still remains elusive. Here, we setup a laboratory incubation experiment by introducing $^{13}$C-labeled microbial biomass ($^{13}$C-labelled bacterial and fungal biomass residues separately) into the soil. We tracked microbial biomass C through the microbial food web over time using the concentrations and isotopic compositions of biomarker PLFA, and tracked $^{13}$C-amino sugars (from chitin and peptidoglycan) and amino acids (from proteins) in order to shed light onto the mechanism of microbial derived C to SOM. We observed that after 120 days, 46.5% of the bacterial-derived $^{13}$C remained in the soil, compared to 56.55% of the fungal-derived $^{13}$C after 240 days. Combined with the half-life results for the fast and slow decomposition pools of both C sources further confirmed that fungal-derived C is relatively more stable than its bacterial-derived C. We found the PLFA patterns over time demonstrate the pathway of $^{13}$C transformation associated with different groups of microorganisms along the incubation. Specifically, bacterial-derived $^{13}$C was utilized by fungi first, then the label was shifted from fungi to Gram$^+$ bacteria, AMF, actinomycetes; the fungal-derived $^{13}$C was initially assimilated by Gram$^-$ bacteria, followed by sequential transfer to fungi, Gram$^+$ bacteria, AMF, actinomycetes. We also observed the ratio of $^{13}$C-fungal derived glucosamine to $^{13}$C-muramic acid significantly increased before day 14, then levelled off until the end of the experiment in the bacterial-derived $^{13}$C treatment. This further highlighted that bacterial C was stabilized in soil by conversion to fungal biomass that grew on the bacterial biomass. In the fungal-derived $^{13}$C treatment, although fungal-derived $^{13}$C was rapidly decomposed in the early stage of incubation, it re-accumulated later, with the isotopically labeled fungal C ultimately retained in the soil as fungal residues. This indicates that, by the end of the incubation, C-regardless of whether it originated from bacterial or fungal biomass-was ultimately stabilized primarily as fungal necromass. Interestingly, in the bacterial-derived $^{13}$C treatment, the shifts in $^{13}$C-amino acids distribution pattern reflect three phases of the central metabolism. Finally, themetabolism slowed down and thus the TCA cycle was less active and C rather than energy was preserved may thus be an important pathway for soil organic C sequestration in soil. In summary, our study traced the detailed turnover pathways of microbially derived C, elucidated the mechanisms by which this C contributes to soil C stabilization, and provided a scientific basis for a holistic understanding of microbially mediated C cycling processes.

## ABSTRACT

Transforming mine tailings into functional soils requires persistent organic carbon accumulation, yet conventional amendments fail because they prioritize carbon quantity over mineral compatibility. We hypothesize that substrate stoichiometry can steer microbial community composition toward producing necromass chemically optimized for stabilization by reactive mineral surfaces—a stoichiometry–microbiome–mineral (SMM) cascade. Using iron ore tailings as a pedogenic blank slate, we compared low-C:N (alfalfa, ~15) versus high-C:N (maize straw, ~60) amendments under a pioneer grass, tracking mineral weathering, aggregate formation, and necromass fate via amino-sugar biomarkers, NanoSIMS imaging, and Fe K-edge XAFS. Low C/N ratio organic matter input (alfalfa meal) increased the proportion of large aggregates by 8.3% and reduced the C/N ratio of microaggregate-related organic matter to 8.87, indicating selective stabilization of nitrogen-rich microbial compounds. Low-C:N input shifted microbial communities toward bacterial dominance, increasing bacterial necromass accumulation by 8.5% relative to fungal residues. High C/N ratio modifiers (corn stalks) primarily increased the unstable particulate organic matter library without corresponding mineral transformation. NanoSIMS imaging provided direct spatial evidence that microbial-derived carbon (characterized by a high $^{14}N^{-}/^{12}C^{-}$ ratio) preferentially binds to Fe and Al hydroxyl oxide particles rather than existing in pore spaces. This molecular-scale co-localization occurred against a mineral background dominated by goethite (~42%) and ferrihydrite (~18%), confirming ligand exchange and surface complexation as the main retention mechanisms. Our results establish a "metabolic matching" principle: engineering soil genesis from mineral waste requires stoichiometric tuning of organic inputs to the coordination chemistry of the substrate, offering a mechanistic foundation for precision mine reclamation.

## ABSTRACT

Leguminous plants play a vital role in enhancing forest ecosystem productivity through their biological nitrogen fixation capabilities. However, systematic research on how they regulate soil carbon composition formation and stability via rhizosphere processes under different subtropical geological conditions (particularly in karst and non-karst systems) remains limited. This study aims to elucidate the mechanisms by which leguminous plants influence soil carbon pool dynamics and stability through rhizosphere processes, providing theoretical foundations for evaluating carbon sink functions and ecological management in subtropical forests. The research focused on typical leguminous plants and their non-leguminous symbionts in karst and non-karst forests. Soil carbon components were measured including particulate organic carbon (POC), mineral-bound organic carbon (MAOC), and iron-bound organic carbon (FeOC). Plant-derived carbon (lignin phenols) and microbial-derived carbon (aminosaccharides) were analyzed using biomarker methods. Simultaneously, soil microbial biomass carbon, nitrogen, carbon cycle-related enzyme activities, and physicochemical properties were measured. Statistical methods such as redundancy analysis and path analysis were employed to identify key drivers and pathways influencing soil carbon stability. Results showed that leguminous plants significantly enhanced soil carbon stability, with microbial-derived carbon (measured by aminosaccharides) contributing more to carbon stability than plant-derived carbon (measured by lignin phenols) in rhizosphere soils. Both microbial activity and residue accumulation in leguminous plant rhizosphere soils were significantly higher than in non-leguminous plants, confirming the existence of a microbe-centered carbon stabilization pathway. In subtropical forests, leguminous plants do not primarily contribute to stable carbon pools through litter input. Instead, they significantly enhance mineral-bound organic carbon accumulation and stability by stimulating rhizosphere microbial activity and promoting microbial biomass formation and transformation. While this carbon sequestration pathway exists in both karst and non-karst systems, it is particularly pronounced in calcium-rich, high-pH karst soils. This study reveals key regulatory mechanisms of leguminous plants in forest soil carbon sequestration through rhizosphere microbial processes, providing crucial scientific insights for understanding subtropical forest carbon cycling and advancing plant function-based ecological management strategies.

**ABSTRACT**

Home-Field Advantage (HFA) hypothesis states that microorganisms specialized in decomposing local litter result in faster in situ decomposition compared to ex situ, enhancing soil organic carbon (SOC) formation in situ soils. Short-term litter decomposition (e.g., < 3 years) typically exhibits the HFA effect. However, it remains unclear whether long-term (e.g., > 5 years) microbial adaptation to substrates in situ or ex situ leads to a loss of HFA and how this impacts SOC accumulation from plant and microbial sources. To address this issue, we conducted a 7-year *in situ* and *ex situ* decomposition experiment using three typical root litters with different quality: Stipa bungeana (C/N = 81.7), Thymus mongolicus (C/N = 56.6), and Artemisia sacrorum (C/N = 43.2). Our ffndings challenge the conventional perspective by showing that HFA declines over time, likely due to long-term microbial adaptation to ex situ soil. This suggests that microorganisms can eventually acclimate to new environments, thereby reducing initial advantages observed in situ. Despite this, a pre-existing strong HFA accelerated root litter decomposition and SOC formation, increasing SOC by 19.9–152.7% under in situ. This acceleration was primarily due to enhanced in situ microbial "in vivo turnover," as evidenced by signiffcant increases in fungal necromass C (294.6–312.1%) and extracellular polymeric substances protein (EPS-protein, 4.8–92.1%). Conversely, plant residual C contributed more to SOC in ex situ (14.3–17.8 %) than in situ (2.5–9.0 %), indicating stronger physical migration of plant residual in ex situ. Low-quality litter facilitated fungal residual C, EPSprotein, and SOC accumulation both in situ and ex situ, suggesting its suitability for biomass synthesis and microbial residual pool formation. This study clariffes the weakening of the HFA over time and the signiffcant contribution of low-quality litter in increasing SOC. This study elucidates the mechanisms by which root decomposition enhances SOC accumulation, highlighting the critical role of HFA in root litter decomposition dynamics.

## ABSTRACT

Soil microbial response to warming may potentially contribute to the positive priming effect, i.e. accelerating the decomposition of native soil organic carbon (SOC) under the outsourced carbon (C) input. Investigating microbiota that metabolize the outsourced C is essential to deciphering the mechanism of priming effect in response to warming and thus mitigating the SOC loss under warming climate. In this work, we monitored the priming effect at 25, 35 and 45°C over four weeks with weekly addition of $^{13}$C-glucose, and subsequently revealed microbial assemblage metabolizing glucose with the DNA stable-isotope probing (DNA-SIP) method. And a meta-analysis further synthesized bacterial community response to different warming conditions. This study generated novel findings that warming initially inhibited the priming effect, and decreased bacterial α-diversity, K/r-strategists ratio (K/r) and recalcitrant C/labile C gene ratio (R/L) in week 1, suggesting that at the onset of the outsourced C input, the increased proportion of r-strategists preferentially utilize the added glucose over SOC to meet their C and energy demands. Yet, in week 4, positive priming effects were intensified by warming with up to 3.8-fold increase at 45°C. Additionally, the primed C was positively correlated with K/r, R/L, and the abundances of chitin degradation genes in week 4. These functions concurred with an increase in the abundance of resource-acquisition strategists such as *Streptomyces* affiliated to Actinobacteria under warming conditions over time. From week 1 to 4, warming induced a distinctive change in glucose-assimilating bacterial community compositions with a particular decrease in the relative abundance of Actinobacteria while an enriched abundance of Chloroflexi. Taken together, warming-triggered change of priming effect depended on alternation of microbiota and metabolic function over time. These findings provide important insights of how warming mediates microbial metabolic use of fresh C and subsequent SOC mineralization, reflecting the positive feedback between soil C emission and climate warming.

## ABSTRACT

This study aimed to elucidate the spatial distribution patterns of soil organic carbon (SOC) age and soil microbial diversity, and to explore the relationships among microbial diversity, microbial network complexity, and SOC age. In addition, we quantitatively assessed the relative contributions of microbial diversity, network complexity, climate, vegetation, and soil properties to SOC age. Using global measurements of soil radiocarbon ($\Delta^{14}C$) and environmental variables, we developed nine machine-learning models to predict SOC age and identified the optimal predictive model. Based on global soil microbial 16S rRNA gene data combined with environmental variables, microbial network analysis, multiple regression analysis, random forest modeling, and structural equation modeling were applied to examine the relationships between SOC age and soil microorganisms and to identify the primary drivers of SOC age. Soil microbial richness significantly decreased with increasing absolute latitude ($P < 0.001$), showing high richness near the equator and generally lower richness at high latitudes. Among the nine machine-learning models, the rule-based regression model achieved the best predictive performance ($R^2 = 0.77$, RMSE = 0.84). Microbial richness and Shannon diversity indices were significantly negatively correlated with both absolute latitude and SOC age ($P < 0.001$). After classifying global soils into young (44–171 years), middle-aged (172–321 years), and old (322–5,035 years) groups, network density followed the order: young soils (0.400) > middle-aged soils (0.285) > old soils (0.125). Multiple regression, random forest, and structural equation modeling consistently indicated that microbial network complexity explained the largest proportion of variation in SOC age (34%), far exceeding the contributions of vegetation (10%) and climate (6%). Global SOC age is significantly and negatively associated with soil microbial diversity and network complexity. Older SOC is characterized by lower microbial diversity and simpler microbial network structures. Microbial network complexity is a key determinant of SOC age, with a much stronger influence than traditional factors such as vegetation and climate. These findings provide new insights into the mechanisms controlling SOC age and suggest that microbial network properties should be explicitly considered in future simulations of SOC dynamics.

**Result:**

Using publicly available soil microbial diversity datasets, we analyzed their global distribution patterns and spatial variations. The results showed that soil microbial richness decreased significantly with increasing absolute latitude. Microbial richness was relatively high around mid-latitudes (~40°), whereas it was markedly lower at high latitudes (~70°).Furthermore, across nine representative global ecosystems, soil microbial richness followed the order: tropical/subtropical grasslands (4,801) > tropical/subtropical forests (4,213) > temperate forests (4,100) > Mediterranean and montane shrublands (3,830) > croplands (3,580) > temperate grasslands (3,526) > boreal forests (3,461) > deserts (2,960) > tundra (2,469).

Globally, radiometric measurements of soil organic carbon (SOC) were obtained from 4,560 soil samples at depths of 0–3 m, and the corresponding SOC ages were calculated (Figure 1A). A model was constructed using 22 environmental variables with a variance inflation factor (VIF) less than 10, including 11 soil property variables, 2 climate variables, and 9 topographic variables (Figure 1B). Among the nine machine learning models constructed, the CU-based model showed the best predictive performance ($R^2$=0.77, RMSE=0.84), followed by the RF model ($R^2$=0.75, RMSE=0.84), while the MNN-based model showed the worst predictive performance ($R^2$=0.38, RMSE=1.47, Figure 1C). Therefore, the CU model was selected as the optimal model for SOC age prediction analysis, and environmental factors at the same locations as the microbial sampling sites (Figure 1B) were used for SOC age prediction. Of particular note is that the SOC ages predicted by the regular regression model were divided into three groups in ascending order: young soils (44–171 years), middle-aged soils (172–321 years), and old soils (322–5035 years), and these three groups were used for subsequent analysis. Subsequently, the SOC ages corresponding to 484 soil microbial samples worldwide were predicted based on the CU model (Figure 1A). The results show that the age of SOC increases significantly with increasing absolute latitude ($P<0.001$, Figure 1B). In nine typical ecosystems globally (Figure 1C), the SOC ages are as follows: tundra (1281 years) > desert (449 years) > arborescent forest (436 years) > Mediterranean/mountain shrubland (423 years) > farmland (289 years) > temperate grassland (284 years) > tropical/subtropical forest (233 years) > temperate forest (230 years) > tropical/subtropical grassland (131 years).

**Figure 1. Global soil organic carbon age distribution and prediction model construction**

Soil microbial diversity (richness index and Shannon index) showed a significant negative correlation with SOC age ($P<0.001$, Figure 2A). As microbial diversity increased, the age of the SOC decreased. After dividing global soil samples into juvenile, middle-aged, and elderly groups, no significant difference in microbial diversity was found between the juvenile and middle-aged groups, but significant differences were found between the juvenile and elderly groups, and between the middle-aged and elderly groups ($P<0.001$, Figure 2A). Furthermore, network topology parameters (number of edges, average path length, degree centralization, and betweenness centralization) were all significantly correlated with SOC age ($P<0.001$, Figure 2B). Microbial co-occurrence network analysis revealed significant differences in microbial networks among different SOC age groups (Figure 2C). The microbial network structure of the adolescent SOC age group was the most complex, with a network density of 0.400 (Figure 2C); the microbial network structure of the elderly SOC age group was the simplest, with a network density of 0.125 (Figure 2C). The number of nodes, the number of edges, and the average degree of the microbial network structure in the adolescent SOC age group were significantly higher than those in the elderly group, but the modularity of the adolescent group was the lowest (Figure 2C).

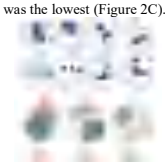

**Figure 2. Relationship between soil microorganisms and SOC age**

Multiple regression models showed that microbial network complexity, vegetation, climate, soil properties, and microbial diversity collectively explained 58% of the variance in SOC age. Among these, microbial network complexity contributed the most to SOC age, followed by vegetation, climate, soil properties, and microbial diversity (Figure 3A). The random forest model yielded similar results, with microbial network complexity, vegetation, climate, soil properties, and microbial diversity explaining 82% of the variability in SOC age. Notably, of the 15 factors in the random forest model, as many as 12 had a significant impact on SOC age (Figure 3B). Among the variables, microbial network complexity had the highest explanatory power. The importance of individual variables was ranked as follows: degree centralization (70%) > NDVI (38%) > number of edges (36%) > average path length (35%) > NPP (33%) > MAT (32%) > MAP (30%) > median centralization (29%) > pH (18%) > SOC (17%) > richness index (16.5%) > Clay+Silt (16%) (Figure 3B). Furthermore, the structural equation model (SEM) explained 54% of the total variance in soil organic carbon age. Negative effect factors included network complexity, vegetation, climate, and microbial diversity, while positive effect factors included soil properties (Figure 3C).

**Figure 3. The explanatory power of the multiple regression model for environmental factors in assessing the global SOC age.**

## ABSTRACT

Soil microorganisms regulate the turnover of organic carbon (C) and strongly influence terrestrial C–climate feedbacks. However, the magnitude and spatial distribution of compensatory thermal adaptation in key microbial processes—respiration, growth, and carbon use efficiency (CUE)—remain poorly quantified at landscape scales. Moreover, how substrate supply modifies these adaptive responses is still unclear, limiting their representation in process-based and Earth system models. Here, we quantified compensatory thermal adaptation and tested substrate modulation along a forest transect spanning temperate, subtropical, and tropical forests in eastern China, where mean annual temperature (MAT) ranged from –4.4°C to 22.4°C. We incubated topsoil (0–10 cm) at 12°C, 20°C, and 28°C with and without exogenous substrate addition, quantified microbial respiration, growth, and CUE, and used linear mixed-effects and multiple regression models to partition the effects of thermal adaptation and substrate availability. We then combined model coefficients with gridded climate and forest datasets to derive spatially explicit estimates of the magnitude of thermal adaptation (MTA) and the magnitude of substrate effects on thermal adaptation (MSTA) across Chinese forests. Across the transect, microbial respiration and growth (and generally CUE) declined with increasing site MAT when measured at the same incubation temperature, consistent with compensatory thermal adaptation; thermal-adaptation model scenarios provided further support for this pattern. Linear regression analyses further showed that the strength of compensatory thermal adaptation increased along the MAT gradient (stronger for growth than for respiration), and that substrate supply simultaneously amplified this adaptive response for respiration, growth, and CUE. Upscaling to Chinese forests showed that the MTA was negative in ~90% of forest areas, indicating that soil microbial generally exhibit compensatory thermal adaptation, while the MSTA was generally positive across most forests, indicating widespread substrate further amplified the compensatory effects. Together, these findings show that microbial communities in warmer forests are strongly thermally adapted and that substrate supply reinforces this compensatory response, there-by constraining the apparent temperature sensitivity of soil C cycling. Explicitly rep-resenting both microbial thermal adaptation and its resource dependence is essential to avoid overestimating positive soil C–climate feedbacks under future warming.

## ABSTRACT

Microbial carbon and nitrogen use efficiencies (CUE and NUE) are critical regulators of soil carbon and nitrogen cycling, with their temperature sensitivities playing a pivotal role in mediating biogeochemical feedbacks under global warming. However, the characteristics and relationship of the temperature sensitivity ($Q_{10}$) for both CUE and NUE under varying temperature backgrounds are still poorly understood. Here, we quantified the $Q_{10}$ of CUE and NUE in 55 soil samples collected from a ~4000 km latitudinal forest transect in eastern China. We further identified key drivers that shaped $Q_{10}$ variability from climatic, edaphic, and microbial factors. On average, $Q_{10}$ was 1.22 ± 0.08 for CUE and 1.46 ± 0.13 for NUE. The strong correlation between the $Q_{10}$ of CUE and NUE suggests a coordinated thermal response of microbial carbon and nitrogen metabolism. Notably, both $Q_{10}$ values declined with increasing incubation temperature, indicating that microbial CUE and NUE are more temperature-sensitive at lower temperatures. At lower incubation temperature interval (12-20 °C), edaphic properties and microbial community attributes (especially soil C/N ratio, DOC/DON ratio, and fungal diversity) were dominant predictors, accounting for 96.9% of the variance in the $Q_{10}$ of CUE. For the $Q_{10}$ of NUE, microbial factors and climatic (particularly fungal diversity and precipitation) explained 96.8% of the variance. In contrast, at the higher temperature interval (20-28 °C), climatic and edaphic properties (especially precipitation and soil N:P ratio) became the primary drivers, explaining 90.6% of the variance in the $Q_{10}$ of CUE. Regarding the $Q_{10}$ of NUE under this conditions, microbial and edaphic attributes (especially soil N/P ratio, DOC/DON ratio, and fungal diversity) were dominant, accounting for 77% of the variance. These findings highlight the importance of temperature context in shaping microbial functional responses and offer novel insights for improving predictions of soil carbon-nitrogen turnover under climate warming.

**ABSTRACT**

Soil organic carbon (SOC) decomposition temperature sensitivity is a key determinant of soil carbon–climate feedbacks, yet its controlling mechanisms remain highly uncertain. Increasing evidence indicates that SOC thermal responses are not solely governed by substrate chemical recalcitrance, but emerge from complex interactions between microbial metabolic activity and soil physico-chemical protection mechanisms. Against this background, we propose an integrative theoretical framework in which soil texture shapes microbial habitats, regulates extracellular polymeric substance (EPS) production, influences aggregate formation and turnover, and modulates the interface exposure of mineral-associated organic carbon (MAOC), collectively determining SOC temperature sensitivity.

Specifically, fine-textured soils can enhance microbe–mineral interactions and aggregate stability via EPS-mediated binding, thereby increasing MAOC stability while reducing substrate accessibility and microbial turnover rates. In contrast, coarse-textured soils tend to increase organic carbon exposure, accelerate aggregate turnover, and enhance microbial accessibility to labile substrates, resulting in higher SOC decomposition temperature sensitivity. We further emphasize that MAOC stability is "conditional," being regulated by interface exposure and microbial activity under warming scenarios, rather than being absolutely stable.

In summary, SOC temperature sensitivity arises from multi-scale interactions among soil texture, microbial physiological traits, carbon availability, and physico-chemical protection mechanisms. We also discuss key future research directions, including the quantitative characterization of MAOC exposure–protection states, coupling microbial carbon use efficiency with temperature responses, and incorporating aggregate turnover dynamics into carbon cycling models. This integrative framework provides novel insights into SOC thermal responses and establishes a conceptual basis for improving soil carbon cycle predictions under climate warming.

**ABSTRACT**

Soil organic carbon (C) is primarily derived from plant and microbial residues; however, the global distribution and contribution of different residues inputs to soil C storage under global change remain poorly understood. We conducted a global meta-analysis including 412 observations from 81 studies on microbial residues and 127 observations from 32 studies on plant residues. The results showed that nitrogen (N) addition increased fungal microbial residue C (MRC, +8.40%), bacterial MRC (+5.25%), and total MRC (+7.44%), thereby contributing to enhanced soil organic C (SOC) formation. Warming enhanced total MRC (+6.89%) but reduced plant-derived C, as indicated by significant declines in vanillyl phenols (−24.60%) and cinnamyl phenols (−16.75%), which was associated with decreased SOC. Decreased precipitation reduced total MRC (−10.54%), whereas increased precipitation significantly enhanced lignin phenols (+54.08%) while reducing total MRC (−11.41%). However, changes in precipitation had no significant effect on SOC content. We found that under N addition, MRC responded more strongly in topsoil than in subsoil, whereas warming exerted stronger effects on both plant- and microbial-derived residues in subsoil layers. This study advances our understanding of how plant and microbial residues respond to global change and highlights the need for greater attention to long-term experiments and subsoil responses to global change in future research.

## ABSTRACT

**Background and Objectives**: The interactive effects of arbuscular mycorrhizal fungi (AMF), elevated atmospheric $CO_2$ ($eCO_2$), and their combination on legume nutrient dynamics and soil fertility remain poorly understood. This knowledge gap extends to the relationship between glomalin-related soil protein (GRSP) and key soil parameters such as organic carbon (C), total nitrogen (N), and enzyme activity.

**Methods**: To address this, we investigated the growth, tissue nitrogen (N), phosphorus (P), and potassium (K) concentrations, and nutrient use efficiency (NUE) of nodulated fababean (*Vicia faba*) inoculated with *Rhizobium leguminosarum* bv. NM353. Plants were grown for 12 weeks under asymmetric ambient $CO_2$ (410/460 ppm day/night) or $eCO_2$ (550/610 ppm day/night), with or without inoculation by the AM fungus *Funneliformis mosseae*.

**Results**: Our results showed that $eCO_2$ significantly enhanced AMF root colonization and nodule biomass. While $eCO_2$ reduced shoot N, P, and K concentrations, it increased total tissue accumulation of these nutrients and their use efficiency, driven by greater biomass production. $eCO_2$ also promoted belowground C allocation but did not alter soil available N, P, or K. In contrast, AMF symbiosis increased the accumulation of C, N, P, and K in both plant and soil pools, effectively enhancing plant nutrient uptake under $eCO_2$. Notably, plant acquisition of soil $NO_3^-$–N and $NH_4^+$–N responded differentially to AMF and $eCO_2$ treatments. We further found that daytime, nighttime, and combined day/night $eCO_2$ levels increased AMF colonization, soil organic C (SOC), total N, and all GRSP fractions in mycorrhizal soils. Daytime $eCO_2$ reduced soil TN in non-mycorrhizal soils, a limitation mitigated by AMF presence. Nighttime and combined $eCO_2$ treatments significantly elevated β-glucosidase and protease activities in both soil types, with effects more pronounced in AMF soils. GRSP concentrations were positively correlated with mycorrhization, SOC, total N, and β-glucosidase activity.

**Conclusions**: In conclusion, the interaction between AMF symbiosis and $eCO_2$ enhances plant C accumulation and soil nutrient uptake, indicating a critical role for mycorrhizal management in legume cultivation under future atmospheric conditions. Our findings underscore that, beyond mycorrhization, the distinct and combined effects of diurnally varying $eCO_2$ significantly influence soil C and N cycling. Future research should employ multi-species AMF and microbial consortia under field conditions to explore these interactions amidst concurrent global change stressors such as warming and drought.

**ABSTRACT**

Global warming can simultaneously increase plant net primary production (NPP) as a carbon (C) input and microbial decomposition of organic matter as a C output, making it challenging to predict its overall impact on soil organic C (SOC) accumulation. To evaluate the effects of global warming on SOC dynamics in paddy soils, current and projected climate conditions were simulated using Open Top Chambers. In the future climate scenario, atmospheric temperature and $CO_2$ concentration were elevated by 2 °C and 200 ppmV, respectively. Chemical or organic fertilizer treatments were added in both climate conditions. In the organic fertilizer plots, cover crops were cultivated during the cold fallow season and fully incorporated as green manure before rice transplanting. Changes in SOC stock during the cropping period were assessed using a net ecosystem C budget analysis, representing the balance between C inputs and outputs. Global warming reduced rice NPP by 9–20% under the same fertilization, while increasing microbial decomposition of organic matter by 28–98%. It also substantially increased dissolved organic matter in the soil without discriminating against chemical composition, further enhancing microbial decomposition. Consequently, SOC accumulation was markedly decreased under future climate conditions. While the cultivation and incorporation of cover crops increased SOC under current climate conditions, this practice was insufficient to enhance SOC accumulation under projected future climates. Overall, under future climate conditions, larger amounts of organic amendments may be required to achieve meaningful increases in SOC storage.

# Decades of no-till coupled with warming improves topsoil soil organic matter accrual via stimulate microbial carbon use efficiency

**Xiaoying Jin[1*], Xiao Wang[1], Zhangliu Du[1]**

*[1]Beijing Key Laboratory of Biodiversity and Organic Farming, College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*

*13664033212@163.com

**ABSTRACT**

Conservation tillage such as no-till has been recommend as a potential strategy to sequester soil organic matter (SOM) and mitigate climate change, but how this alternative farming altered SOM biochemistry remains elusive, particularly under simulated warming condition. Here, we uncovered the SOM composition and origins, and underlying microbial-mediated processes from a conservation tillage trial under warming in North China. Soil samples (i.e., 0-5, 5-15, and 15-30 cm) were collected from four treatments: moldboard plow (MP), moldboard plow with warming (MPw), no-till (NT), and no-till with warming (NTw). Considering tillage effects, NTw (*cf.* MPw) increased both bacterial and fungal biomass in topsoil. Further, NT (*cf.* MP) decreased oligotrophic K-strategists, including Chloroflexi and Gemmatimonadetes. Regardless of warming, no tillage enhanced the relative abundance of recalcitrant dissolved organic matter (DOM), but decreased biodegradable DOM compounds such as carbohydrates, proteins in topsoil. Both biomarker (higher total lignin phenols) and $^{13}$C-nuclear magnetic resonance (higher aromatic and phenolic group) collectively revealed the enhanced preservation of lignin phenols in NTw (*cf.* MPw). No tillage (NT and NTw) significantly increased glomalin-related soil protein (GRSP) in the surface soil, while warming have no effects on those molecules. Moreover, NT enhanced bacterial and fungal necromass relative to MP in the topsoil. Considering warming effects, warming decreased catabolic enzymes activities ($\beta$-1,4-glucosidase and leucine aminopeptidase) under two tillage systems, while exerted the strong positive influence on microbial carbon use efficiency. Collectively, NTw (*cf.* MPw) may have the potential to enhance the process of bacterial anabolism and *in vivo* turnover (reflecting by microbial necromass and GRSP), thus improve microbial carbon pump efficiency and OM formation in a future warmer world. Moreover, no-till treatments (NT, NTw) increased the fraction of refractory DOM (i.e., condensed aromatic structures and tannin) relative to conventional farming. Our work provides insights into the potential benefits of conservation agriculture for long-term carbon sequestration because no tillage improves resilience to the effects of climate warming.

# Context-dependent dominance of plant detritus or microbial necromass in soil organic carbon accrual

**ABSTRACT**

Soil organic carbon (SOC) originates from both microbial and plant sources, yet the scarcity of large-scale paired comparisons between these two carbon sources has left their relative importance a topic of intense debate—spawning conflicting paradigms of SOC formation. Compounding this uncertainty, how shifts in their relative contributions mediate SOC accrual—an essential link for understanding carbon sequestration mechanisms—also remains poorly resolved. To address these unresolved questions, we compiled a comprehensive continental-scale paired dataset of soil amino sugars (microbial-derived) and lignin phenols (plant-derived)—two widely accepted biomarkers for quantifying SOC sources. Using this dataset, we estimated the contents of microbial necromass carbon (MNC) and plant detritus carbon (PDC), and quantified their relative importance via the MNC-to-PDC ratio and its associational pattern with SOC content. Our analysis revealed order-of-magnitude variations in the MNC-to-PDC ratio, both within and across ecosystem types and soil depths. Notably, MNC dominated SOC pools in 68%–70% of grassland soils and 67%–85% of forest soils, whereas PDC prevailed in over 59% of cropland soils and 83% of wetland soils. MNC contributions to SOC increased with soil depth. Moderation analysis identified three distinct scenarios describing the relationship between SOC content and the MNC-to-PDC ratio. Building on these findings, we developed a context-explicit conceptual framework to resolve recent debates regarding how carbon sources influence SOC formation. In this framework, the dominant SOC formation pathway and the relative decomposability of carbon sources—regulated by mean residence time and mineral protection potential, respectively—mediate the SOC and its sources link. Collectively, our results underscore SOC's multi-source nature, challenging the prevailing microbe-centric paradigm that emphasizes the microbial-derived SOC predominance and advocating for a holistic, integrated perspective on SOC genesis that accounts for diverse environmental contexts. Future SOC management strategies should consider the context-specific relevance of SOC sources and formation pathways.

# Thermal acclimation of soil microbial respiration across permafrost ecosystems: contrasting roles of autotrophic and heterotrophic microorganisms

**Ning Tian[1*], Chao Liang[1], Xuefeng Zhu[1], Shi Yan[1]**

[1] *Institute ofApplied Ecology, Chinese Academy ofSciences, Shenyang, China*

*tn1234321@163.com

**ABSTRACT**

Many studies have shown that soil microbial respiration can exhibit thermal acclimation, which suppresses the increase in respiration rates under warming and thereby mitigates the positive feedback between terrestrial carbon cycling and climate warming. Based on this background, we selected soils from four permafrost-region ecosystems in China that represent a gradient in the relative dominance of autotrophic versus heterotrophic microorganisms, and conducted a simulated warming incubation experiment to investigate patterns of thermal acclimation in soil microbial respiration.

Our results showed that in the forest, respiration rates in warming soils were significantly lower than those in control soils, indicating a compensatory response of microbial respiration. Moreover, the effect size of warming on microbial respiration decreased from forest to desert to meadow. In contrast, the swamp meadow exhibited an enhancement response of microbial respiration.To further explore the mechanisms underlying differences in thermal acclimation among permafrost-region ecosystems, we found that both the heterotroph-dominated forest and the autotroph-dominated desert ecosystem exhibited compensatory responses. In forest, warming exerted the strongest negative effects on heterotrophic metabolic indicators, leading to a pronounced compensatory response. In the desert ecosystem, although heterotrophic metabolic indicators did not change significantly, a compensatory response was still observed, likely because the relatively high proportion of autotrophic microorganisms partially offset heterotrophic $CO_2$ release through autotrophic carbon fixation. However, this mechanism requires further verification. In contrast, two ecosystems dominated by autotrophic microorganisms-the swamp meadow and the meadow-exhibited opposite response patterns, with the swamp meadow showing an enhancement response. In the swamp meadow, excessive soil water content resulted in prolonged anaerobic conditions, under which the compensatory effect of autotrophic carbon fixation on warming-induced increases in respiration was weakened or even lost. Meanwhile, warming stimulated heterotrophic microorganisms to upregulate their metabolism, increasing carbon-degrading enzyme activities and accelerating organic carbon decomposition, ultimately leading to increased microbial respiration and an enhancement response. The meadow had lower soil moisture and more adequate oxygen availability, allowing autotrophic microorganisms to effectively fix the released $CO_2$ and resulting in a compensatory response of microbial respiration. Thus, although both meadow ecosystems were dominated by autotrophic microorganisms, differences in soil moisture conditions led to contrasting response patterns.

In summary, this study provides initial evidence for differential roles of autotrophic and heterotrophic microorganisms in regulating thermal acclimation of soil microbial respiration across permafrost-region ecosystems.

**ABSTRACT**

Based on meta-analysis, we demonstrated that warming reduces soil organic carbon (SOC) content. The primary mechanisms identified are as follows: 1) Warming can decrease microbial carbon use efficiency by reducing microbial diversity, thereby lowering SOC content [1]; 2) Warming can reduce microbial biomass by decreasing soil moisture, which subsequently leads to a decline in SOC [2]; 3) A significant reduction in SOC occurs only when the warming magnitude exceeds 2°C, lasts more than 2 years, and affects surface soil layers [3]; 4) Warming amplifies the response of SOC to other environmental factors: it exacerbates carbon loss induced by drought and enhances the carbon gain stimulated by elevated $CO_2$ and nitrogen fertilization [4].

**ABSTRACT**

Global warming is causing the expansion of drylands, which presents significant challenges in understanding the processes of soil organic carbon (SOC) accumulation. Soil microorganisms play an important role in the turnover and stabilization of organic carbon, but their role in dryland ecosystems remains poorly understood. By analyzing soil molecular biomarkers and microbial data from typical dryland ecosystems across a continental-scale aridity gradient in northwestern China, this study explores the role of soil microorganisms in organic carbon accumulation under increasing aridity. The results show that as aridity intensifies, microbial-derived carbon gradually decreases, primarily due to water limitations that suppress microbial community activity and growth. In contrast, plant-derived carbon gradually increases with increasing aridity, as water limitation not only suppresses microbial community activity but also restricts microbial decomposition functions, leading to a reduced ability of microorganisms to decompose plant-derived carbon. These findings challenge the traditional view that microbial-derived carbon dominates SOC accumulation, a perspective that does not hold in dryland ecosystems. It also suggests that, with the continued expansion of drylands in the future, soil organic carbon will primarily be derived from plant sources.

**ABSTRACT**

Excessive nitrogen is a key factor triggering wetland eutrophication and functional degradation. Enhancing nitrogen removal performance via regulation of biological components within wetland ecosystems has become a research focus in wetland science. This report elaborates on the synergistic nitrogen removal mechanisms of wetland plants and microorganisms under complex environmental conditions, including root oxygen release, root exudate-mediated carbon supply, and nitrification-denitrification coupling. It addresses the bottleneck of limited nitrogen removal efficiency under low-temperature and high-salinity stress, and proposes novel techniques and practical applications for synergistic nitrogen removal by wetland plant-microbe consortia.

**ABSTRACT**

Land use change (LUC) alters the soil carbon dynamics and microbial functioning, which in turn influence the ecosystem resilience and climate regulation. The Nilgiri Hill Region (NHR) a UNESCO World Heritage site and global biodiversity hotspot has undergone widespread transformation from native forests to plantations and croplands. Our study evaluated the impact of LUC on soil and microbial profile across six major ecosystems (evergreen forest, deciduous forest, scrubland, forest plantation, tea plantation, and cropland) of NHR. Soil samples from all these ecosystems were analyzed for physical, chemical, and biological properties including metagenomic characterization and carbon pool fractionation. Results revealed that forest ecosystem maintained higher total organic carbon, recalcitrant carbon pools, microbial biomass, and enzyme activities compared with converted lands. In comparasion the tea and cropland exhibited reduced carbon stability, lower microbial efficiency and elevated $CO_2$. Random Forest modeling effectively predicted the carbon distribution, identifying key predictors such as bulk density, aggregate stability, and aggregate associated carbon. Carbon Management Index and Soil Quality Index revealed substantial deterioration of soil health under converted land uses. Metagenomic profiles emphasized a decline in microbial diversity and functional genes associated with carbon sequestration in disturbed ecosystems. These findings highlights that LUC in the NHR decreases recalcitrant carbon concentration and microbial carbon use efficiency, leading to enhanced carbon emissions and degraded soil health. Thus, integrating metagenomic insights with predictive modeling provides a solid framework for understanding soil carbon microbe interaction and developing sustainable land management strategies for climate resilient ecosystem.

**ABSTRACT**

It is generally known that soil organic carbon (SOC) stocks tend to increase with increasing C input, whereas the C sequestration efficiency (CSE), i.e. the conversion ratio of C input to SOC, differs depending on the amount and type of C input. A better understanding of the CSE characteristics is urgently needed to effectively sequester C in agroecosystem, thereby improving soil fertility and mitigating climate change. We studied data from 12 typical long-term dryland experiments, which varied in experimental duration, to clarify the responses of soil CSE to different fertilizations, including no fertilizer, chemical nitrogen, phosphorus and potassium, chemical fertilizers plus manure and straw, and manure only. Variance partitioning analysis (VPA) and extreme gradient boosted tree (XGBoost) regression modelling were used to comprehensively assess the key drivers of CSE in the plough layer. The eight long-term experiments in China indicated that the CSE has remained relatively constant over nearly four decades of fertilization, with SOC linearly increasing with C input. VPA illustrated that the CSE of the main dryland region of China was mostly controlled by edaphic characteristics, especially the soil C/nitrogen (N) ratio and clay content, followed by C input and climate. Manure amendment had the most significant fertilization effect on SOC sequestration with an average CSE of 14.9%, followed by chemical fertilization (9.0%) and straw return treatment (7.9%). Based on the four classical long-term experiments with SOC showing nonlinear changes over time, the negative exponential dynamics of soil CSE was fully captured by the model ($CSE=b+a*e^{-k*Cinput}$, $P < 0.01$). The CSE in the Chromic Luvisol of southeast England experienced a rapid decrease before C input reached 123-315 t C $ha^{-1}$, and a similar trend was observed in the Mollisols of the Central Great Plains of America before C input levels of 93-145 t C $ha^{-1}$. Subsequently, the CSE continued to decrease more slowly towards an asymptotic value. A larger asymptotic CSE value was observed in the manure applied treatments (2.45-10.25%) than in the chemical fertilizer treatments (0.48-3.85%). XGBoost regression modelling identified C input, MAT and total N stock as critical factors for soil CSE over a century of fertilization. Soil CSE tends to remain constant as SOC increases linearly with C input. However, when SOC exhibits non-linear changes, CSE is exponentially decreased and eventually approaches an asymptote. Additionally, our results suggest that manure amendment is a sustainable practice for improving CSE in dryland cropping systems. This study provides empirical evidence and insights into the optimal fertilizer strategy for enhancing CSE under long-term fertilization.

## ABSTRACT

Context: Climate change is projected to threaten food security and stimulate greenhouse gas emissions. Hence, adaptation measures without sacrificing food production are required.

Objective: To assess possible consequences of rice-wheat system under climate change and to propose possible practices for mitigation.

Methods: The Soil-Plant-Atmosphere Continuum SYStem (SPACSYS) model was tested using datasets from long-term experiment (1991-2019) assessing the impact of different fertilisation on crop production, crop nitrogen (N) content, soil organic carbon (SOC) stock, methane ($CH_4$) and nitrous oxide ($N_2O$) emissions in a Cambisol under rice-wheat system. The validated SPACSYS was then used to investigate the possible mitigation strategies from 2024 to 2100 under climate change scenarios (SSP1-2.6 and SSP5-8.5) and the baseline scenario and mitigation management scenarios, i.e., (i) reduced N application rate by 20 % (RNA), (ii) the introduction of mid-season drainage (MSD) and (iii) integrated management combining RNA with MSD (IM).

Results and conclusions: Results showed that SPACSYS performed effectively in simulating yield and N content in grain and straw, SOC stock and $CH_4$ and $N_2O$ emissions. Scenarios analysis elucidated that RNA would not decrease grain yields for either rice or wheat under the two climate change scenarios. Compared to the baseline scenario, low level of climate change scenario considering the $CO_2$ fertilisation effects (SSP1-2.6_$CO_2$) may benefit wheat yield (28 %) and had no effects on rice yield. In contrast, under the SSP5-8.5 scenario, whether $CO_2$ fertilisation effects are considered or not, both rice and wheat yield could face great loss (i.e., 11.8-29.9 % for rice, 8.3-19.4 % for wheat). The winter wheat would not be suitable for planting in the distant future (2070-2100) due to the incomplete vernalisation caused by warming. The switching from winter wheat to spring wheat from 2070 onward could avoid the yield loss by 8.3-19.4 %. Climate change could decrease SOC sequestration rate. Under future climate change scenarios, IM could significantly decrease $CH_4$ emissions by 56 % and $N_2O$ emissions by 24 %, as such reducing the net global warming potential by 69 % compared to no adaptation. Our simulations suggest that under climate change, crop switching in rice-wheat system combining integrated mitigation practices is possible to mitigate global warming and maintain crop production.

Significance: Our results underscore the significance of integrated adaptation of agricultural systems to climate change.

**ABSTRACT**

Elevated atmosphere $CO_2$ has been shown to increase plant biomass production and exacerbate nitrogen deficiency. However, it is poorly understood how elevated $CO_2$ impacts the dynamics of soil organic matter (SOM). This ABSTRACT provides an overview of our short- and long-term experiments to elucidate this in farming soils. Our meta-analysis shows that elevated $CO_2$ enhances overall soil carbon decomposition and rhizosphere priming, but these increases depend on soil nitrogen supply and crop species. In short-term experiments, elevated $CO_2$ increases rhizosphere priming effect which is positively associated with the amounts of root exudates, the activity of SOM-decomposing enzymes and the labile C-to-mineral N ratio in the rhizosphere. The addition of nitrogen generally decreases rhizosphere priming, depending on nitrogen form, crop species and growth stage, but its direct effect on SOM decomposition differs substantially with soil type. Irrespective of crop species, growth stages and nitrogen forms, the rhizosphere priming effect is positively correlated with rhizosphere pH. The long-term $CO_2$ enrichment tends to decrease total SOM in the topsoil but not in the subsurface soils. It also appears to destabilize SOM in sandy soils. Elevated $CO_2$ does not alter the entire community composition of bacteria and fungi in the rhizosphere or bulk soils but enriches some microbial taxa that may accelerate decomposition of recalcitrant SOM. It is concluded that elevated atmospheric $CO_2$ does not favor SOM sequestration, and that the effects of nitrogen supply on SOM decomposition are complex and deserve further investigation.

## ABSTRACT

Soil carbon stocks are affected by a range of global drivers with two of the main drivers being land use and land management change and climate change (Smith, 2008; Smith, 2012; e.g. Figure 1).

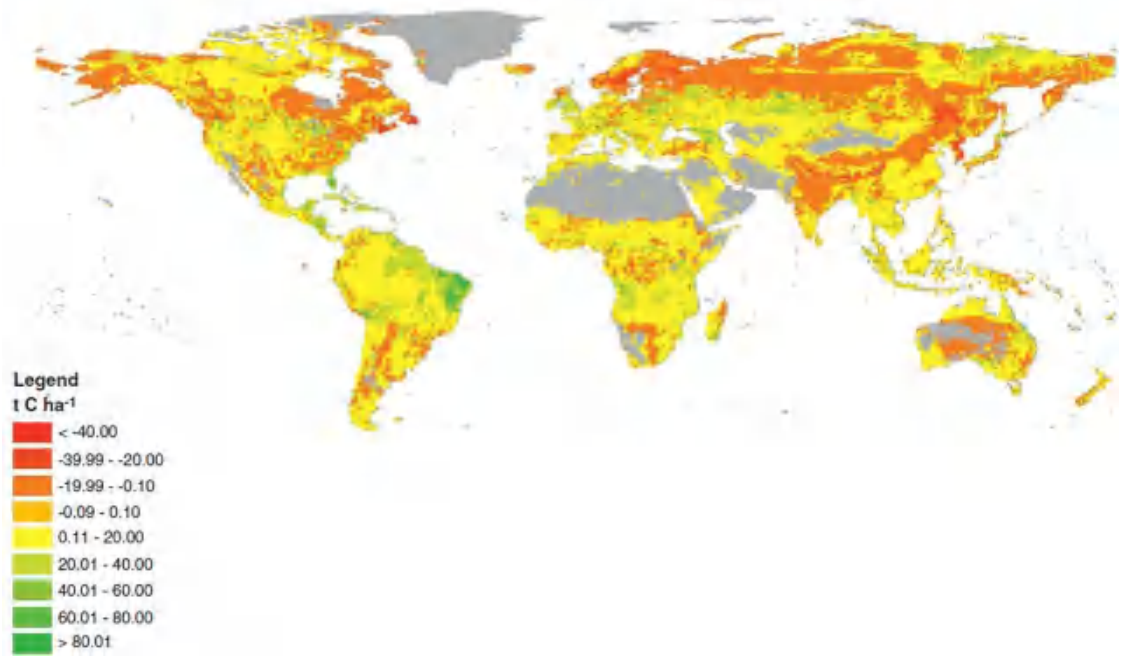

**Figure 1.** Average trend in SOC stock change 1971–2100 across 10 climate scenarios (after Gottschalk et al., 2012).

In this presentation I will draw on 30 years of research into these topics to highlight what we know about the response of soil carbon stocks to land use, land management and climate change, what we still do not know, and what we can do to protect soil carbon stocks form further decline under future climate and land use / land management change (Smith et al., 2024). I include studies representing a range of methodologies, including modelling, measurements, field and laboratory experiments and other forms of evidence.

*E-mail: renkeyu@caas.cn, duanyinghua@caas.cn

**ABSTRACT**

Improving soil fertility is essential for securing future food production. Inherent soil productivity (ISP), which reflects the integrated fertility of the soil, is commonly defined as crop yield under unfertilized conditions. However, due to the high diversity of soil and climate conditions in China, the spatial patterns, limiting factors, and agronomic implications of ISP at large scales remain poorly quantified. In this study, we compiled large-scale field data from 12,737 experiments conducted across China's wheat-growing regions to quantify regional variations in ISP and to evaluate the impacts of ISP improvement on agricultural production. We then developed a random forest model integrating soil, climatic, and management practices to identify the key limiting factors of ISP at the county scale and to assess its improvement potential. The average ISP of wheat fields in China is 3.73 Mg ha$^{-1}$, contributing (ISPC) on average 61% to fertilized yield. ISP exhibits significant regional differences, following the order: North China Plain-irrigated > North China Plain-rainfed > Northwest-irrigated > Northwest-rainfed > Northeast > Yangtze River Plain > Southwest. Each unit increase in ISP is associated with an 8% (6–12%) increase in ISPC, resulting in significant improvements in wheat yield and nitrogen use efficiency (NUE), as well as a significant reduction in nitrogen (N) surplus. A random forest model incorporating soil, climate, and management data explained 74% of the variation in ISP, demonstrating high stability and predictive capability. Future improvements in AP by 12.8 mg kg$^{-1}$, AN by 38.8 mg kg$^{-1}$, TN by 0.38 g kg$^{-1}$, pH by 0.46, SOM by 8.91 g kg$^{-1}$, and AK by 52.1 mg kg$^{-1}$, could increase ISP by 0.35 Mg ha$^{-1}$ and ISPC by 3%. Under these conditions, fertilized wheat yield, NUE, and N surplus would reach 6.46 Mg ha$^{-1}$, 62%, and 87 kg ha$^{-1}$, respectively. These findings highlight the crucial role of ISP in enhancing wheat productivity and NUE, and provide a promising strategy to improve soil fertility that supports national food security while mitigating environmental impacts.

**ABSTRACT**

Soil organic carbon (SOC) is a major terrestrial carbon reservoir and a cornerstone of soil fertility, directly influencing climate change and human well-being. However, it remains unclear how different spectral data sources and artificial intelligence (AI) modeling strategies jointly shape SOC prediction performance, especially across large and heterogeneous agricultural landscapes. This study systematically evaluated the integration of model-data strategies for SOC prediction on the farmland of the Loess Plateau, a region characterized by fragmented croplands and limited carbon stock data. The results show that the hyperspectral-driven model (CARS-SVM) achieved the highest accuracy, but their reliance on regional-scale hyperspectral datasets restricts practical applications. By contrast, the multispectral-environmental integrations model (SPA-BPNN) delivered robust and scalable performance, offering a feasible pathway for regional SOC mapping. This study establishes a transferable methodological framework for optimizing data–model combinations in heterogeneous agricultural landscapes, thereby supporting carbon management in agroecosystems worldwide.

# Decadal extreme drought reduces alpine subsoil carbon stocks

**Jinsong Wang[1*], Ronglei Zhou[1], and Shuli Niu[1]**

[1] *Key Laboratory of Ecosystem Network Observation and Modeling, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China*

*E-mail: wangjinsong@igsnrr.ac.cn

**ABSTRACT**

Grassland soil organic carbon (SOC) stocks are increasingly vulnerable to intensified drought. Yet, how long-term, especially extreme, drought affects these C reserves across soil profiles remains unresolved. Here, we present the response of SOC stocks at various depths (0–60 cm) using an experiment involving a 10-year drought gradient (P, 1/2 P, 1/4 P, and 1/12 P, where P is ambient precipitation) in an alpine grassland. We find that extreme drought (1/12 P) caused significant SOC losses in the subsoil, whereas mild to moderate droughts had no significant effects on SOC at any depth. Under extreme drought, SOC stocks declined by 27% in the 20–30 cm layer and 37% in the 30–40 cm layer, while no significant changes were observed in the topsoil (0–20 cm) and the deeper layer (40–60 cm). Subsoil C losses were primarily driven by reductions in mineral-associated organic C (MAOC) rather than particulate organic C (POC). Multi-year extreme drought disrupted soil-microbe-mineral interactions, as indicated by reductions in soil nitrogen availability, microbial biomass, carbon use efficiency, and mineral-binding agents. These changes collectively undermined the formation and stabilization of MAOC. Our findings suggest that prolonged extreme drought can weaken subsoil C storage and stability, highlighting the need to incorporate subsoil processes into Earth System Models to better predict soil C–climate feedback under future drought scenarios.

## ABSTRACT

Soil organic carbon (SOC) sequestration through sustainable soil management practices (SMPs) is a globally prioritised strategy for climate change (CC) mitigation, improving soil fertility, and enhancing agroecosystem resilience. Despite practices like crop diversification and minimal soil disturbance are known to promote carbon retention and reduce greenhouse gas (GHG) emissions, the net long-term climate benefit - especially in CC-vulnerable perennial systems - remains unclear. Hence, this study, for the first time, assesses the long-term effects of diversified versus monocropping systems on SOC stocks, GHG emissions, and the net $CO_2$-equivalent balance in two Mediterranean orchard case studies: a rainfed almond (CS1) intercropped with *Capparis spinosa* and *Thymus hyemalis* and an irrigated mandarin (CS2) intercropped with various cover crops. Using the process-based ECOSSE model, we simulated how crop diversification and SMPs influence SOC dynamics, under both current and projected future climate scenarios (2040-2069 and 2070-2099 periods). Future climate scenarios project higher temperatures, lower precipitation, and increased evapotranspiration, which indicate greater aridity and subsequent hydrological stress. Modelling results showed that crop diversification significantly enhanced SOC stocks in both case studies. In the CS1, diversification increased SOC stock by up to 85 %, with only minor increases in $CO_2$ emissions and negligible impact on $N_2O$ or $CH_4$ emissions. On the other hand, the CS2 showed a greater increase, with SOC stock rising by up to 114 %, with minor $CO_2$ increases and a notable decrease in $N_2O$ and $CH_4$ emissions. This research demonstrates that crop diversification in Mediterranean orchards substantially enhances SOC stocks and provides a robust strategy for long-term climate mitigation, even under challenging future climate projections.

**ABSTRACT**

Soil organic carbon (SOC) is a key indicator of soil health and agricultural sustainability. Yet, SOC remains low in the Loess Plateau, and carbon sequestration efficiency (CSE) has not been systematically quantified across cropland systems spanning dominant climate zones. Here, we analyzed the spatiotemporal variability of carbon input and CSE in croplands from 1983 to 2023 across typical agroecological regions in the eastern Loess Plateau. Using geostatistical methods, Random Forest, and path analysis, we identified key drivers of SOC accumulation and CSE under varying climates and soil amendment regimes. Our results reveal a clear north-south gradient in SOC stocks, with higher values in the southern region. Overall, carbon input exhibits an increase from north to south, whereas CSE declines from north to south over the period 1983-2023. Elevation, temperature, initial SOC, and manure-derived carbon were dominant drivers of spatial divergence. The overall low CSE across the Plateau may be attributable to carbon loss driven by persistent soil erosion. The relatively low CSE in the south may result from saturation effects, as higher baseline SOC and sustained carbon inputs limit incremental sequestration. These findings offer region-specific insights to support soil fertility improvement and sustainable agriculture, underscoring the need for erosion-sensitive, carbon-informed land management approaches to enhance soil health and resilience in the croplands of the eastern Loess Plateau.

**ABSTRACT**

As an essential source of the natural soil organic matter, dissolved black carbon (DBC) from biochar can generate reactive oxygen species (ROS), playing significant roles in contaminants degradation and chemical stresses to microorganisms. However, little is known regarding the photoproduction sites to ROS generation, mainly because of its extremely complicated composition. Herein, the ROS generation and photoexcited alteration of DBC were investigated. To investigate the mechanisms of ROS generation, it is essential to identify the determining structures of DBC for ROS generation.

The generation mechanisms of hydroxyl radical (•OH), superoxide anion ($O_2^{\bullet-}$) and singlet oxygen ($^1O_2$) were inferred by employing various model chemicals. Results revealed the vital role of OFGs within DBC in the generation of •OH, $O_2^{\bullet-}$, and $^1O_2$. The photo-excited aliphatic carbonyls greatly contributed to $^{\bullet}OH$, $O_2^{\bullet-}$, and $^1O_2$ generation. Ether groups were identified as the main structural source of $H_2O_2$-dependent $^{\bullet}OH$ generation. The novel non-electron transfer process involved carbonyl, ether, alcohol, and ester groups to produce $O_2^{\bullet-}$ was proposed. The generation of $^1O_2$ depended on the aromatic structures within DBC, while simultaneously dominated by molecular configuration, substituent and weight of aromatic groups. Moreover, we demonstrated the nonnegligible •OH generation from aliphatic carbonyls of DBC, the excited-state carbonyl structures could ABSTRACT H proton and result in homolytic cleavage of $H_2O$. Compared to quinonoid groups, the abundant carbonyls within DBC could be the main structures contributing to ROS generation. The stimulation of aliphatic carbonyls within DBC to the generation of ROS deserved more attention. These findings reveal the vital role of oxygenated functional groups within DBC in the photoactive generation of ROS. The new insights revealed in this study may also provide new angles for interpreting the geochemical cycles of DBC, and thus provides new theoretical information for DBC's environmental geochemical behavior.

## ABSTRACT

Organic amendments are widely recommended to enhance soil organic carbon (SOC) in low-fertility soils. Yet, SOC levels remain persistently low in erosion-prone croplands of the Loess Plateau. Here, we investigate how long-term organic fertilization influences soil aggregation and SOC dynamics in loess soils, based on a 33-year maize field experiment with five treatments: no fertilizer, mineral nitrogen-phosphorus (NP) fertilizer, and NP fertilizers combined with three increasing rates of manure (M1–M3). Results showed that higher manure rates (M2 and M3) significantly increased the proportions of macroaggregates (>0.25 mm) and free microaggregates (0.053–0.25 mm) at the expense of the free silt-clay fraction (<0.053 mm) compared to M0. Concurrently, these treatments substantially enriched SOC content in macroaggregates (40%–81%) and free microaggregates (33%–41%), driving a preferential accumulation of particulate organic matter (POM-C increased by 54%–61%) over mineral-associated organic matter (MAOM-C increased by 18%–24%). Consequently, the apparent carbon conversion efficiency (CCE) of exogenous organic inputs was 6.6% in bulk soil, followed by 5.3% in POM, 5.0% in macroaggregates, and 2.4% in free microaggregates. These results indicate that organic inputs drove the redistribution of carbon into larger aggregates, where fresh organic residues reinforced macroaggregate occlusion, protecting POM from decomposition. In contrast, MAOM stabilization was constrained by mineral surface saturation, as limited reactive surfaces restricted further carbon association, resulting in diminished conversion efficiency under high inputs. These findings suggest that promoting macroaggregate formation and POM enrichment is the key practical strategy for maximizing SOC persistence in dryland loess croplands.

## ABSTRACT

Organic amendments (including straw, biochar, and organic fertilizers) are widely adopted to enhance soil fertility and organic carbon (SOC) sequestration in agricultural systems. SOC stability is governed by the balance between particulate organic carbon (POC) and mineral-associated organic carbon (MAOC), yet most empirical evidence is derived from surface soils (0-20 cm), leaving subsoil processes (≥20 cm) poorly constrained. We conducted a comprehensive meta-analysis of 108 peer-reviewed studies published between 1990 and 2025, by synthesizing 651 paired observations to quantify the effects of organic amendments on SOC, POC, and MAOC across soil depths. Results indicate that the effects of amendments are depth-dependent and mediated by climatic and soil properties. All three amendments significantly increased SOC in both topsoil and subsoil. In topsoil, straw (+29.4%, +10.1%), biochar (+120%, +27.4%), and organic fertilizers (+54.9%, +16.6%) increased both POC and MAOC, but the disproportionate increases between the two fractions reduced SOC stability. In subsoil, straw and organic fertilizers promoted balanced increases in POC and MAOC without compromising carbon pool stability, whereas biochar primarily increased POC with minimal impact on MAOC and SOC stability. These findings underscore the critical role of amendment type in regulating carbon fractions across soil depths. Tailoring organic amendment strategies to local climate and soil conditions is essential for optimizing SOC sequestration efficiency and long-term stability.

**ABSTRACT**

Urban greenspaces typically refer to urban wetland, urban forest and urban turfgrass. They play a critical role in carbon sequestration by absorbing carbon from the atmosphere; however, their capacity to retain and store carbon in the form of soil organic carbon (SOC) varies significantly. This study provides a systematic analysis and review on the capacity of different urban greenspace types in retaining and storing SOC in 30 cm soil depth on a global scale. Data came from 78 publications on the subject of SOC stocks, covering different countries and climate zones. Overall, urban greenspace types exerted significant influences on the spatial pattern of SOC stocks, with the highest value of 18.86 ± 11.57 kg $m^{-2}$ (mean±standard deviation) in urban wetland, followed by urban forest (6.50 ± 3.65 kg $m^{-2}$), while the lowest mean value of 4.24 ± 3.28 kg $m^{-2}$ was recorded in urban turfgrass soil. Soil organic carbon stocks in each urban greenspace type were significantly affected by climate zones, management/environmental settings, and selected soil properties (i.e. soil bulk density, pH and clay content). Furthermore, our analysis showed a significantly negative correlation between SOC stocks and human footprint in urban wetland, but a significantly positive relationship in urban forest and urban turfgrass. A positive correlation between SOC stocks and human footprint indicates that increased human activity and development can enhance SOC stocks through effective management and green infrastructure. Conversely, a negative correlation suggests that improper management of human activities can degrade SOC stocks. This highlights the need for sustainable practices to maintain or enhance SOC accumulation in urban greenspaces.

**ABSTRACT**

Initiatives to restore soil fertility and mitigate global warming rely on rebuilding soil organic carbon (SOC). Nitrogen (N) fertilization is crucial for crop yields but affects SOC unpredictably due to varying responses of particulate organic carbon (POC) and mineral-associated organic carbon (MAOC) pools to initial SOC levels. To clarify these effects, here, by combining a global meta-analysis with continental-scale field experiments, we determine that an initial SOC threshold of 15 g C kg−1 controls the effect of N fertilization on POC and MAOC. In SOC-poor soils (< 15 g C kg−1), N fertilizer increases plant-derived C inputs and promotes soil aggregation, favouring POC accumulation. Conversely, in SOC-rich soils, N fertilizer stimulates microbial metabolic efficiency, leading to larger necromass production and stabilization by mineral protection, observed as more pronounced MAOC accrual. Our findings reveal how SOC thresholds shape the response of active and stable carbon pools to N fertilization, with consequences for SOC accrual in cropland soils globally.

## ABSTRACT

Soil organic matter (SOM) is a recognized determinant of nitrogen use efficiency (NUE), but its quantitative control over the fate of fertilizer N remains unclear. Using a $^{15}N$ tracer study within a winter wheat-summer maize rotation, we quantified the recovery of initially applied-N from wheat and subsequent crops in relation to SOM and N-application rates. We found that while N fertilization boosted yields by 85-340% in low-fertility soil, its effectiveness exhibited diminishing returns in high-fertility soils. Crucially, the total recovery efficiency of fertilizer N (cumulative $^{15}NUE$) across three cropping seasons was fundamentally governed by SOM content, following a linear-plateau relationship. The model revealed that maximum $^{15}NUE$ (54.3%) at an optimal application rate (105 kg N $ha^{-1}$) was achieved when SOM exceeded a critical threshold of 21.3 g $kg^{-1}$. Below this threshold, $^{15}NUE$ declined linearly with SOM. Furthermore, residual $^{15}N$ in soil was primarily stabilized in organic forms (58-64%), while recovery by subsequent crops was minimal (≤4.3%), confirming that high SOM minimizes environmental N losses by enhancing sequestration in the soil organic pool. Our findings establish a quantifiable SOM threshold for maximizing NUE, providing a science-based pathway to reduce fertilizer waste and enhance sustainability in intensive agriculture.

## ABSTRACT

Nitrogen recovery efficiency (NRE) is a critical metric for minimizing environmental pollution and ensuring sustainable agriculture. However, its long-term dynamics and underlying drivers remain poorly understood. This study synthesizes data from a 30-year positioning experiment across four key agricultural regions in Northern China to analyze the spatiotemporal evolution of NRE under varied fertilization regimes. Using nonlinear modeling, random forest analysis, and structural equation modeling, we identified the patterns, dominant factors, and mechanistic pathways governing NRE. Key findings revealed that NRE followed a significant nonlinear trajectory over time. Long-term balanced fertilization-particularly the integrated NPKM treatment-consistently enhanced NRE in the later experimental phase (2006-2020), whereas imbalanced fertilization (N-only or NK) led to a marked decline. Soil properties emerged as the primary drivers of NRE variation, with available phosphorus (AP) identified as the key limiting factor. Below a threshold of 22.3 mg $kg^{-1}$, NRE increased sharply with rising AP, reaching up to 59.9%. Notably, grain yield plateaued (8.31 tonnes $ha^{-1}$) only when AP exceeded 29.0 mg $kg^{-1}$, and regional AP thresholds for optimal NRE varied widely (19.0-48.8 mg $kg^{-1}$). Fertilization indirectly influenced NRE by modifying soil nutrient status and interacting with climate, while crop yield exerted a direct, crop-specific effect-positive in maize but negative in wheat seasons.

In conclusion, long-term balanced fertilization nonlinearly enhances NRE by alleviating P limitation and improving soil function. By integrating regional AP thresholds and crop-specific responses, this research provides a scientific basis for spatially tailored nutrient management, supporting the dual goals of agricultural productivity and environmental sustainability.

## ABSTRACT

Understanding how fresh, decomposed, and root-derived particulate organic matter (POM) interact with soil macropores is crucial for enhancing soil organic carbon stocks, yet their spatial relationships remain largely unclear. Therefore, we conducted an 8-year conservation tillage experiment on a Vertisol (wheat-maize rotation, no tillage with straw return) that compared four fertilization regimes: (i) control (no fertilization), (ii) chemical fertilization (NPK), (iii) organic fertilization (OF), and (iv) combined chemical-organic fertilization (NPKOF). X-ray computed tomography was used to quantify POM fractions (fresh POM: FPOM, decomposed POM: DPOM, root-derived POM: RPOM), macropore and biopore structure. Our results demonstrated that all fertilization treatments (NPK, OF, NPKOF) significantly improved soil macropore structure in the 0-10 cm layer, whereas OF and NPKOF increased bioporosity by 4.82-fold and 2.26-fold in the 10-20 cm layer ($P<0.05$). Biopores constitute a major component of percolating pores in the subsoil and are promoted by the application of organic fertilization. Furthermore, OF and NPKOF significantly enhanced fresh POM and root-derived POM content in the 0–10 cm layer and shortened their distance to pores throughout the 0–20 cm layer ($P<0.05$). The three POM fractions exhibited positive correlations with macropore structure characteristics ($P<0.05$), yet no significant correlation was observed between root-derived POM and biopores. Root-derived POM showed preferential accumulation in areas distant from biopores. Overall, our findings demonstrate that long-term organic fertilization is linked to increased POM accumulation, improvements in surface soil macropore structure, and enhanced biopore formation in the subsoil of Vertisols.

**ABSTRACT**

Accurately quantifying long-term dynamics of cropland soil organic carbon (SOC) is essential for elucidating the fundamental mechanisms controlling SOC. SOC process-based models provide an effective framework for reconstructing historical SOC dynamics and projecting future trajectories. The AMG model relies on a small number of readily available inputs and has been applied and validated across diverse cropping systems and soil–climate conditions, making it an effective tool for simulating cropland SOC dynamics over long time periods and large spatial scales.

In this study, the Tuojiang River Basin, a traditional agricultural region in southwestern China, was selected as the case study area. Long-term data from permanent experimental stations (13–27 years) were first used to evaluate the applicability of the AMG model with default parameters. After calibrating the initial $C_S/C_0$ ratio and the potential mineralization rate ($k_0$), the accuracy of simulated cropland SOC stocks improved substantially ($R^2 = 0.87$, RMSE = 0.25, d = 0.90), representing a 23% increase in $R^2$ and a 35% reduction in RMSE compared with the default parameterization (Fig. 1). Multi-scale independent validation further confirmed the robust performance of the improved AMG model at the regional scale.

The improved AMG model, combined with historical spatially explicit input factors, was then applied to analyze century-long cropland SOC dynamics and their driving mechanisms. From 1911 to 2017, cropland SOC stocks increased from 31.2 to 46.9 t C $ha^{-1}$, corresponding to a 50.2% increase (Fig. 2). SOC stocks increased slowly before the 1960s and rose rapidly after the 1980s. Pronounced latitudinal differentiation was observed across the basin, with consistently higher SOC stocks in the upstream Chengdu Plain and lower values in downstream hilly regions. After 1980, the midstream area emerged as a hotspot of SOC accumulation. Between 1911 and 2017, SOC stocks increased by more than 50% in downstream areas such as Zigong and Renshou, whereas increases were below 40% in upstream counties of the Chengdu Plain, including Pengzhou and Jingyang (Fig. 3). Counterfactual scenario simulations indicate that the century-scale increase in cropland SOC was primarily driven by changes in crop residue carbon inputs. Since the 1960s, the widespread use of chemical fertilizers has substantially enhanced crop yields and played a key role in SOC accumulation, while the contribution of climate change to SOC increases was relatively small. Notably, in the upstream Chengdu Plain, interactions between cropland carbon inputs and climate change exerted a significant influence on SOC dynamics. The results offer scientific support for improving cropland soil carbon management in other comparable traditional agricultural regions.

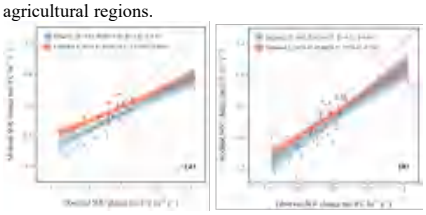

**Fig. 1.** The scatter plot of observed and simulated soil organic carbon stock for 14 LTEs based on the (a) default $C_S/C_0$ size (with default $k_0 = 0.29\ yr^{-1}$ and calibrated $k_0 = 0.193\ yr^{-1}$) and (b) $PARTY_{SOC}$-based $C_S/C_0$ initialization (with default $k_0 = 0.29\ yr^{-1}$ and calibrated $k_0 = 0.209\ yr^{-1}$) applying leave-one-site-out cross validation for all sampling dates at the 14 long-term experiment sites.

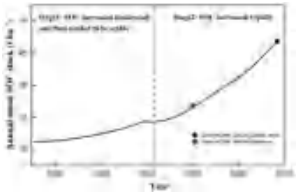

**Fig. 2.** Modelled (line) temporal variations in annual mean cropland SOC stock density in the Tuojiang River Basin simulated using the AMG model. The black and red dots represent the observed SOC stock density.

**ABSTRACT**

While straw mulching has the potential to reduce fertilizer-nitrogen (N) losses in intensively managed cropland, how soil organic carbon (SOC) regulates this fate of fertilizer-N at soil aggregate or profile scales remains unresolved. Here, micro-plots were nested within a four-year field experiment to assess fertilizer-N fates and their linkages with SOC fractions and stabilization processes via $^{15}$N-tracing and $^{13}$C natural abundance analyses. Three treatments were included: (i) conventional N application (FN), (ii) reduced N application (RN), and (iii) reduced N with straw mulching (RS). While RN reduced crop yields compared to FN, RS achieved comparable yields and 7.71% higher N recovery efficiency ($P$<0.05). The $\delta^{13}$C fractionation between aggregates and bulk soil was significantly positively correlated with the fertilizer-N content in the >2 mm and <0.053 mm fractions, indicating that N retention was coupled with SOC stabilization processes. Compared with RN, RS resulted in a 2−3.4 times greater SOC conversion probability into the <0.053 mm fraction and a 1.4 times higher aggregate-associated fertilizer-N content. SOC fractions differentially regulated the profile distribution of fertilizer-N, with nonlabile organic carbon (C) correlated positively, while dissolved organic C correlated negatively but increased plant N recovery. Compared with RN, RS increased the SOC stock by 24%, reduced $NO_3^-$-N accumulation by 37%, and immobilized 36% more N into the microbial biomass ($P$<0.05). Our findings demonstrate that straw mulching increases N recovery by mediating SOC fractionation, stabilization, and microbial N immobilization. These results provide new insights into SOC–N interactions that could aid in the development of optimal soil C and N management strategies.

# Mechanisms of soil organic carbon sequestration within aggregates of black soil under long-term land use change

**ABSTRACT**

Evaluation of soil organic carbon (SOC) dynamics is often constrained by the structural and compositional complexity of the soil matrix. Quantifying the distribution of SOC across aggregate hierarchies is therefore essential for elucidating carbon transfer and stabilization processes within soils, yet such information remains limited. Both the amount and chemical composition of aggregate-associated organic carbon are critical determinants of SOC stability. In addition, soil aggregates function as key microhabitats that structure microbial communities and regulate carbon sequestration. However, the mechanisms linking microbial community assembly and carbon stabilization across aggregate fractions under long-term land-use change remain poorly resolved.

A 35-year field experiment in Northeast China was used to examine the effects of contrasting land uses (cropland, bare land, forestland, and grassland) on soil aggregate structure, microbial diversity, and carbon sequestration potential in a black soil. Soil aggregates were separated by combined wet- and dry-sieving into large macroaggregates (>2 mm), macroaggregates (2–0.25 mm), and microaggregates (<0.25 mm) to quantify aggregate size distribution and stability (water- and mechanically stable aggregates). By integrating FTIR-based characterization of organic carbon chemistry, phospholipid fatty acid (PLFA) analysis, 16S rRNA and ITS sequencing, and PICRUSt2-inferred functional potentials, the biogeochemical mechanisms governing aggregate-associated carbon sequestration following ecosystem transitions were elucidated.

The results highlight the importance of coupled biological–chemical interactions within soil aggregates in regulating long-term SOC stabilization. This study provides a mechanistic framework linking soil microstructure, microbial assembly, and carbon sequestration, thereby contributing to improved multi-scale modeling of soil carbon cycling and offering guidance for sustainable land-use management in black soil regions.

## ABSTRACT

Soil pore structure plays a fundamental role in particulate organic matter (POM) dynamics by regulating water and air exchange within the soil matrix. However, the effects of long-term fertilization on POM distribution, pore characteristics, and their interrelationships may differ between upland and paddy soils. In this study, we examined two long-term fertilization field experiments conducted in contrasting agroecosystems in Jiangxi, China: a 38-year upland field and a 43-year paddy field. Four fertilization regimes were compared: no fertilizer (control), inorganic fertilizer (NPK), double-rate inorganic fertilizer (2NPK), and inorganic fertilizer combined with pig manure (NPKM). X-ray computed tomography (CT) was used to quantify soil pore structure and POM, and machine learning-based image analysis was applied to classify POM into fresh and decomposed fractions based on morphological features. The NPKM treatment significantly increased fresh and decomposed POM volume density by 2.05% and 47.7% in upland soil, and 253% and 103% in paddy soil, respectively ($P$<0.05). NPKM also enhanced air permeability ($K_a$) image-based porosity, connected porosity, >300 μm porosity, and surface area density in both soils ($P$<0.05). In upland soil, strong positive correlations between fresh POM and pore structure parameters suggest a close association between organic matter input and physical structure. In paddy soil, pore structure facilitates the retention of root-derived fresh POM under anaerobic conditions. Overall, our findings demonstrate that long-term manure application promotes both POM accumulation and the development of pore structure in upland and paddy soils, with distinct mechanisms operating under different land-use systems.

**ABSTRACT**

Climate warming exerts positive feedback on soil carbon loss throughout the whole soil profile. Cropland soils hold substantial carbon sequestration potential and play a crucial role in global climate change mitigation and terrestrial ecosystem carbon cycling. Since the 1980s, China has undergone rapid socioeconomic development and implemented extensive land consolidation projects, leading to significant changes in cropland soil organic carbon (SOC). However, the dynamics of SOC across the whole soil profile and their driving mechanisms remain unclear. To address this, we utilized 519 cropland soil profiles (0-1 m, 20 intervals) excavated in 2020 and 234 historical data from the Second National Soil Survey in the 1980s to examine changes in SOC content across the whole profile in China's warm temperate croplands. By integrating machine learning and Partial Least Squares Path Modeling (PLS-PM), we further explored the mechanisms driving SOC changes. Results showed that over the past four decades, SOC at 1 m depth increased by 0.95 g C $kg^{-1}$, corresponding to an SOC stock gain of 14.88 t C $ha^{-1}$-enough to offset 33% of regional cropland carbon emissions. The increase was more pronounced in surface soils than in deeper layers, resulting in a steeper vertical SOC gradient. Soil physicochemical properties emerged as the dominant drivers of SOC variation across the whole profile. The direct influence of climate has weakened over time, its effects have intensified with increasing soil depth. Socioeconomic development and cropland management projects significantly enhanced carbon inputs via increased crop residues, thus promoting SOC accumulation particularly in surface soils. Over time, the net effect of socioeconomic factors and land governance on SOC has shown the largest increase. Our findings highlight that the coordinated advancement of socioeconomic development and land consolidation has driven the enhancement of SOC across the whole soil profile, mitigating carbon losses induced by climate change. This provides new empirical evidence for reversing global soil carbon loss under current warming scenarios.

## ABSTRACT

Red paddy soils are widely distributed in the subtropical regions of China and have long been confronted with issues such as acidification, aluminum toxicity, and organic matter depletion, which constrain the synergistic enhancement of soil multifunctionality. Although the application of organic materials has been proven to mitigate soil degradation, the long-term biogeochemical mechanisms through which they regulate soil multifunctionality remain unclear. This study is based on a 44-year field experiment on a red paddy soil, aiming to evaluate the soil physicochemical properties, organic carbon chemical structure, microbial necromass carbon, and microbial community composition under different organic material applications. The goal is to reveal the response characteristics of soil multifunctionality to long-term organic material application and its key regulatory pathways. The results showed that long-term organic material application significantly increased soil organic carbon content and altered its chemical structure, with the aliphaticity in the pig manure treatment decreasing by 5.11% compared to the Control. Furthermore, compared to the Control, the pig manure treatment increased bacterial, fungal, and total microbial abundances by 66.86%, 96.84%, and 79.66%, respectively. It also increased bacterial necromass carbon, fungal necromass carbon, and total microbial necromass carbon content, and significantly enhanced soil multifunctionality, with the pig manure treatment showing a particularly prominent effect-increasing by 169.53% compared to the Control. Further analysis revealed that soil organic carbon, total nitrogen, total phosphorus, microbial abundance, and microbial necromass carbon were the main factors driving soil multifunctionality, rather than the chemical structure of soil organic carbon. Our findings provide important theoretical and empirical foundations for organic carbon sequestration and sustainable management of red paddy soils.

* Chengji11@126.com

**ABSTRACT**

The application of straw-decomposing inoculants has been demonstrated to accelerate straw decomposition and reduce soil nitrous oxide ($N_2O$) emissions in fields incorporated with straw. However, the mechanisms underlying $N_2O$ emission mitigation following decomposing inoculant application remain unclear. A two-year field experiment was conducted in a subtropical wheat cropping system to elucidate key factors regulating $N_2O$ emissions under straw and straw-decomposing inoculant application. The autotrophic nitrification driven by ammonia-oxidizing bacteria (AOB) and archaea (AOA) was quantitatively partitioned using acetylene and 1-octyne inhibition techniques. Applying straw or decomposing inoculants alone significantly reduced yield-scaled $N_2O$ emissions by 39.75% and 35.83%, respectively. The combined application showed a significantly greater reduction effect (46.47%). Decomposing inoculants promoted wheat plant growth and increased total nitrogen (TN) contents in both straw and grain. AOB dominated nitrification-related $N_2O$ production, while straw, decomposing inoculant, and their combinations significantly decreased AOB-mediated contributions by 9.19%, 7.63%, and 11.23%, respectively. In contrast, straw markedly enhanced the abundances of *nosZI* and *nosZII* genes. Structural equation modeling (SEM) suggested that the decreased $N_2O$ emissions under the combination of straw and decomposing inoculants were synergistically linked to the inhibited abundance of AOB and the enhanced abundances of *nosZI* and *nosZII*. These results suggested that the straw-inoculant combination achieves a concurrence of crop yield enhancement and $N_2O$ emissions reduction, representing a win-win strategy for supporting food security and China's "Dual Carbon" policy.

**ABSTRACT**

Soil stable organic matter serves as the foundation of soil fertility and an indicator of carbon sequestration capacity. Crop rotation and fertilization are practices involving intense and frequent soil disturbance, which inevitably exert significant impacts on stable organic matter. From 2009 to 2024, soil samples were collected from a long-term experimental station (over 15 years) in the lateritic red soil region of China for this study. These samples encompassed different rotation systems—specifically, double-cropping rice, continuous vegetable cultivation, vegetable-vegetable-rice rotation, and a natural uncultivated plot—and various fertilization practices, including no fertilization (CK), chemical fertilizer only (CF), organic fertilizer only (OF), combined organic and inorganic fertilization (CF+OF), and chemical fertilizer with rice straw retention (CF+Straw). The study focused on: (1) the variation processes and differences in soil organic matter fractions; (2) the chemical composition and dynamics of the mineral-associated organic matter (MAOM), representing the stable organic matter pool; and (3) the proportional sources and their evolution of MAOM. The results indicated that the natural uncultivated plot exhibited the highest annual increase rate of SOM. Under the double-cropping rice system, the annual SOM increase rates across fertilization treatments followed the order: OF > CF+OF > CF+Straw > CF > CK. In contrast, for both the vegetable-vegetable-rice rotation and continuous vegetable cultivation systems, only the CF+OF led to positive soil organic carbon sequestration. The sequestration of soil organic matter observed above was primarily driven by a steady increase in particulate organic matter, while the MAOM content remained relatively stable. The chemical composition and proportional sources of MAOM have been determined and are currently being analyzed.This work is expected to provide a theoretical foundation and scientific basis for breakthroughs and innovations in organic matter stabilization technologies in lateritic red soils in South China.

## ABSTRACT

Reclaimed soils in coal gangue backfilling areas are characterized by low productivity and critically low soil organic carbon (SOC). While straw return is a recommended strategy to increase SOC, its high carbon to nitrogen (N) ratio can exacerbate microbial N limitation in these inherently N poor soils. This may trigger a positive priming effect and hence accelerate the loss of native SOC and reduce overall C sequestration efficiency.

This study investigated how N addition modulates SOC dynamics during maize straw return in a 5-year long term reclamation experiment. Results showed that straw return combined with N fertilization—optimally at 270 kg N $ha^{-1}$—significantly increased SOC content, compared to at 216 or 180 kg N $ha^{-1}$ N rate. Nuclear magnetic resonance analysis indicated a concurrent shift toward more stable SOC forms, with increased polysaccharide C, methyl C, aromatic C, carboxyl C, and aliphatic C. Furthermore, tracking amino sugars as microbial necromass biomarkers revealed that high N treatment promoted the accumulation of microbial derived residues, which after 500 days contributed 69.6% to total SOC, with fungal residues being dominant.

High throughput sequencing demonstrated that high N fertilization reduced variability in bacterial and fungal communities by 8.5% and 12.3%, respectively, and lowered bacterial diversity, indicating enhanced community stability. Network analysis revealed stronger fungal bacterial interactions and increased network robustness under 270 kg N $ha^{-1}$. Metagenomic analysis showed a marked enrichment in carbohydrate active enzyme (CAZyme) genes, particularly those involved in cellulose and hemicellulose degradation, pointing to a more efficient microbial straw degradation capacity.

A partial least squares path model identified soil nutrient status as the key driver of microbial community assembly, which in turn regulated the abundance of fungal and bacterial CAZyme genes. Among SOC components, methyl C explained the largest proportion of variation in CAZyme gene abundance, whereas aliphatic C and aromatic C showed no significant correlation, highlighting functional differences among C forms.

In summary, straw return combined with the proposed optimal N fertilization not only elevates SOC content but also enhances its chemical stability in reclaimed-mine soils. Nitrogen facilitates the conversion of straw or organic C into stable, microbial derived C pools by stabilizing microbial community structure, strengthening interspecific interactions, and activating key decomposition pathways. These findings clarify the essential role of N management in straw-based reclamation and provide a thermotical and practical basis for improving soil fertility and C sequestration in post mining landscapes.

# Distribution Characteristics and Influencing Factors of Carbon and Nitrogen Content in Mineral-Associated Organic Matter in Mollisols (Phaeozems) of Northeast China

**Jiayi Duan[1,2*], Shengzhen Ji[1], Jingjing Sun[2], Liang Yang[2*], and Zicheng Yu[1,2]**

**ABSTRACT**

Mineral-associated organic matter (MAOM) is a stable component of soil organic matter (SOM). The carbon and nitrogen contents in MAOM vary under different land use types, while their distribution characteristics and influencing factors under tillage remain poorly understood. In this study, we collected 30 pairs of cropland and natural topsoil samples from Mollisols in Northeast China along a latitudinal gradient from south to north to investigate how mineral-associated organic carbon (MAOM-C) and mineral-associated organic nitrogen (MAOM-N) responds to land use changes in the Mollisols region. We found that MAOM-C content in cropland soils (mean 33.4 $mg \cdot g^{-1}$ soil; ranging from 8.8 to 57.3 $mg \cdot g^{-1}$) is higher than in natural soils (mean 27.3 $mg \cdot g^{-1}$; range 6.9 to 58.0 $mg \cdot g^{-1}$). In contrast, MAOM-N content was higher in natural soils (mean 2.3 $mg \cdot g^{-1}$; range 1.1 to 5.1 $mg \cdot g^{-1}$) than in cropland soils (2.1 $mg \cdot g^{-1}$; 1.2-4.9 $mg \cdot g^{-1}$). MAOM-C and MAOM-N contents in both types of soils exhibit an increasing trend from south to north, due to greater soil organic carbon (SOC) content further north. However, cropland soils—especially those south of 47°N—exhibited a greater proportion of C and N from MAOM in SOM than those in natural soils. This pattern was mostly due to cultivation-induced soil disturbance and elevated temperatures in the south, which may lead to the preferable loss of POM in these soils. Our partial least squares structural equation modeling (PLS-SEM) results showed that temperature had a negative correlation with both MOAM-C and MAOM-N, whereas MAOM-C and MAOM-N were positively correlated with SOC. When natural land is converted into cropland, the effect of soil carbon-to-nitrogen (C/N) ratio on MAOM-C and MAOM-N shifts from being positive to negative, suggesting that, under the influence of tillage disturbance, the C/N ratio becomes the key factor regulating MAOM content. The C/N ratios in MAOM are higher than ones in SOM for both types of soils in the north, suggesting more plant-derived OM being incorporated into MAOM there. Overall, our study demonstrates that MAOM dynamics in Mollisols are controlled by land use and climate, and further modulated by a latitudinal shift in the dominant source of organic matter: plant-derived compounds become increasingly important toward the north, indicating region-specific formation pathways and stabilization mechanisms of SOM.

# Long-term organic farming alters soil organic matter molecular composition through divergent microbial processing pathways

**Zhanlonggang Yu[1*], Zhangliu Du[1]**

*[1]Beijing Key Laboratory of Biodiversity and Organic Farming, College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*

*yuzhanlonggang@163.com

**ABSTRACT**

While organic farming is acknowledged as a potential pathway to boost soil fertility and other functionalities, the underlying mechanisms by which it affect the biochemistry of soil organic matter (SOM) are not yet clear. To fill this knowledge gap, we sampled soils from 0–20 cm layer from three 20-year of fertilization practices in North China: conventional (CON), integrated (INT), and organic farming (ORG). Then, targeted SOM molecular fingerprints were quantified by utilizing three biomarkers such as free lipids, lignin phenols, and amino sugars, along with extracellular enzyme activities. The results showed that ORG increased soil organic carbon (SOC), particulate organic carbon (POC), and mineral-associated organic carbon (MAOC) contents by 101.6%, 231.5%, and 28.4%, respectively, compared to CON. In contrast, ORG (cf. CON) enhanced both microbial-derived lipids (short-chain lipids, $< C_{20}$) and plant-derived lipids (long-chain lipids, $\geq C_{20}$) by 48.9% and 112.3%, while also accelerating aliphatic lipids degradation. Compared with CON, ORG increased lignin phenols by 58.4% and reduced their degree of degradation. In addition, ORG (cf. CON) increased microbial-derived biomolecules, including bacterial (+63.6%), fungal (+71.5%), and microbial necromass C (+66.9%), without altering its relative contribution to SOC. Furthermore, ORG increased hydrolytic enzymes activities, and microbial carbon use efficiency (CUE). Overall, our study highlights that two decades of organic farming promote SOC accumulation through the enhancement of plant- and microbially-derived carbon and microbial carbon processing, providing new mechanistic insights into the soil microbial carbon pump under long-term organic management.

# Spatiotemporal Spectral Reconstruction for Soil Organic Matter Mapping under Complex Cropland Surface Conditions

**ABSTRACT**

Soil Organic Matter (SOM) is a critical indicator of soil health and a key component of the global carbon cycle. High-resolution digital soil mapping is essential for precision agriculture and carbon sequestration assessment. However, in intensive agricultural regions such as the North China Plain (NCP), the accuracy of optical remote sensing is severely hindered by the spatiotemporal heterogeneity of soil moisture and the masking effects of crop residues (e.g., straw) under conservation tillage practices. Traditional methods, which rely on single-temporal images or simple vegetation indices masking, often fail to effectively decouple these complex surface interferences, leading to significant uncertainties in SOM retrieval. To address these challenges, this study proposes a novel Spatiotemporal Spectral Reconstruction Framework that integrates time-series analysis with spatial unmixing. First, at the temporal dimension, we developed a Minimum Soil Moisture (MinSM) synthesis strategy. By leveraging the Soil Moisture Index (SMI) across the full Sentinel-2 time series, this method identifies and composites the spectral reflectance of the driest soil state for each pixel, thereby minimizing moisture-induced spectral attenuation and noise. Second, at the spatial dimension, we introduced a Spectral Unmixing Model based on the reflectance-vegetation coverage feature space. This model dynamically separates pure soil signals from mixed pixels containing crop residues and green vegetation, effectively recovering the soil background spectra in high-residue areas. The proposed framework was validated using 350 topsoil samples collected from the NCP and Sentinel-2 imagery. The results demonstrated that the reconstructed soil spectra achieved high prediction accuracy for SOM, with a coefficient of determination ($R^2$) of 0.83 and a Root Mean Square Error (RMSE) of 2.59 g/kg, significantly outperforming traditional median synthesis and masking methods. Based on this approach, we generated a 10-m resolution annual SOM dataset for the study area from 2015 to 2025. The spatiotemporal analysis revealed a distinct "North-high, South-low" distribution pattern, closely driven by long-term straw return policies. This study provides a robust, transferable paradigm for extracting accurate soil information in complex, human-altered agricultural landscapes.

# Long-term Grassland Conversion Reshapes Deep Soil C and N Cycling: Thermodynamic Destabilization and Microbial Drivers

**Xiang Wang[1*], Yuxin Yan[1]**

[1] *College of Land Science and Technology, China Agricultural University, Beijing, China*

*E-mail: wangxiang@cau.edu.cn

**ABSTRACT**

The conversion of natural grassland to cropland significantly impacts global carbon and nitrogen cycles, yet the long-term, depth-dependent mechanisms regulating these pools remain poorly constrained. This study utilized a chronosequence in Hulunbuir, China, comparing natural grassland with 11- and 40-year cultivated croplands to assess changes in soil organic carbon (OC), nitrogen (N), and dissolved organic matter (DOM) across a 1-meter profile. By integrating high-resolution molecular techniques (FT-ICR-MS), microbial functional gene quantification, and thermal incubation experiments, the study aimed to uncover the biogeochemical drivers of soil stability under land-use change. Results indicated a severe subsoil crisis following conversion, with total N losses reaching 83.6% in deep soils (80–100 cm) after 40 years. Unexpectedly, this depletion was driven by losses in mineral-associated organic matter, typically considered stable. While topsoil OC stabilized over time, subsoil DOM paradoxically accumulated but became thermodynamically unstable, characterized by lower Gibbs free energy and increased microbial processing. Regarding N cycling, medium-term cultivation enhanced nitrification, whereas long-term farming suppressed it, reducing plant-available N. Crucially, land-use change altered thermal sensitivity: agricultural soils showed increased temperature sensitivity for OC decomposition and, under warming conditions, subsoils shifted from acting as nitrous oxide sinks to net sources. These shifts were underpinned by a restructuring of microbial functional gene networks, which exhibited greater complexity in the subsoil. In conclusion, multidecadal agricultural conversion fundamentally destabilizes deep soil C and N reservoirs and heightens vulnerability to climate warming, necessitating sustainable management strategies that prioritize subsoil stability.

# Optimizing and simulating the soil carbon fractions within the BEPS-MEND framework

**Mousong Wu[1*], and Dongjie Yin[1]**

[1] *International Institute for Earth System Science, Nanjing University, Nanjing, China*

*mousongwu@nju.edu.cn

**ABSTRACT**

Terrestrial ecosystems are important carbon sinks and regulate variations in atmospheric carbon dioxide ($CO_2$) concentrations. Accurate estimation of ecosystem carbon fluxes is essential for assessing ecosystem carbon balance and addressing climate change. Ecosystem process-based models are effective tools for simulating carbon fluxes at different spatiotemporal scales. However, existing models still face challenges including high parameter uncertainty, incomplete process mechanisms, and a lack of representation on soil organic carbon fractions. This study is based on the BEPS (Biosphere Exchange Processes Simulator) model, coupled with the MEND (Microbial Enzyme-Mediated Decomposition) microbial enzyme-mediated decomposition carbon pool module, and combined with soil organic carbon fraction data collected, to conduct regional-scale simulations of carbon fluxes in different ecosystems across China. This study will optimize parameters related to key ecological processes such as photosynthesis and soil microbial decomposition, reveal potential relationships between different processes, and explore variation trends of carbon fluxes in regions with different vegetation types in China. The optimized carbon flux simulation framework constructed in this study, which is suitable for complex ecosystems in China, will reveal spatiotemporal co-evolution patterns of key ecological processes and provide dynamic process analysis tools and a scientific basis for decision-making to enhance bottom-up terrestrial carbon sink estimation capabilities, and support the formulation of terrestrial carbon sink management policies under the carbon peaking and carbon neutrality strategic goal.

# Exploring Aerobic Methanotroph Diversity in Terrestrial Habitats: Recent Advances and Challenges for Further Studies

**Svetlana N. Dedysh**[1*]

[1] *Winogradsky Institute of Microbiology, Research Center of Biotechnology of the Russian Academy of Sciences, Moscow, Russia*

*dedysh@mail.ru

**ABSTRACT**

Aerobic methanotrophic bacteria play a key role in the cycling of the potent greenhouse gas methane ($CH_4$) in terrestrial habitats. Despite the century-long history of studying methanotrophs, these bacteria remain an inexhaustible source of exciting discoveries. These include earlier unknown phenotypes of methanotrophic bacteria, new features of their metabolic organization, and novel aspects of their environmental importance. One of the important recent research directions was focused on USCα methanotrophs, which are the key component of the methane-oxidizing communities responsible for atmospheric $CH_4$ oxidation in a number of terrestrial ecosystems, such as the subarctic and arctic tundra, forested subarctic tundra as well as boreal upland soils. The use of novel cultivation strategies resulted in obtaining representative isolates of *Methylocapsa*-affiliated methanotrophic bacteria from subarctic soils. These isolates are the closest currently available phylogenetic relatives of USCα methanotrophs, which open the way for studies on biology and metabolic potential of this earlier uncultured group of bacteria.

Many novel members of the cosmopolitan genus *Methylocystis* have been characterized and the pool of good-quality genome sequences of these bacteria is now available for detailed studies on metabolic potential of these bacteria. As evidenced by cultivation-independent studies, *Methylocystis*-affiliated methanotrophs is one of the most abundant and functionally active groups of $CH_4$-oxidizers in various terrestrial environments.

A number of intriguing hypotheses were published during the last decade regarding the occurrence of methanotrophy in some uncultured groups of prokaryotes, such as the candidate phylum *Rokubacteria* and the lineage within the verrucomicrobial order *Methylacidiphilales* detected in acidic peatlands. The presence of methanotrophic capabilities in these bacteria was verified experimentally, by incubating the soil samples colonized by these bacteria with methane. No response to methane availability was detected for the *Rokubacteria* and for the *Methylacidiphilales*, while a clear increase in a relative abundance was observed for the conventional methanotrophs. The search for methane monooxygenase encoding genes in currently available *Rokubacteriales* metagenomes yielded negative results, although copper-containing monooxygenases were encoded by some members of this order. Similarly, no genome-encoded methanotrophic capabilities were revealed in metagenome-assembled genomes of *Methylacidiphilales*-affiliated bacteria. Therefore, not all claims for the existense of “novel” methanotroph groups could have been proven.

Thus, despite the impressive recent breakthroughs in methanotroph research, the currently assembled picture of methanotroph diversity in terrestrial habitats still has many gaps, which remain to be addressed in further studies.

# Ozone-driven spatial divergence of methane production in rice paddies

**Yang Ji*, Jinfeng Ma, Zhaozhong Feng**

*State Key Laboratory of Climate System Prediction and Risk Management, Key Laboratory of Ecosystem Carbon Source and Sink, China Meteorological Administration (ECSS-CMA), School of Ecology and Applied Meteorology, Nanjing University of Information Science and Technology, Nanjing 210044, China*

* jiyang@nuist.edu.cn

**ABSTRACT**

Tropospheric ozone ($O_3$) pollution is intensifying globally under climate change, yet its effects on methane ($CH_4$) production in rice paddies—one of the largest anthropogenic $CH_4$ sources—remain poorly constrained. Here, using a free-air ozone enrichment (FACE- $O_3$) platform combined with rhizosphere and bulk-soil microcosm incubations, root metabolomics, and microbial ecological analyses, we reveal that elevated $O_3$ induces pronounced spatial heterogeneity in paddy soil methanogenesis. Exposure to 1.5× ambient $O_3$ significantly suppressed $CH_4$ production potential in rhizosphere soils (by 43-66%) but stimulated $CH_4$ production in bulk soils (by 21-158%), demonstrating that $O_3$ impacts on methane cycling are strongly compartmentalized rather than uniform.

Mechanistically, elevated $O_3$ triggered defensive metabolic reprogramming in rice roots, with purine metabolism and 2-oxocarboxylic acid metabolism acting as central regulatory pathways. This metabolic shift redirected carbon allocation from energy metabolism toward secondary defense compounds, reducing the supply of labile carbon to the rhizosphere. Consequently, dissolved organic carbon and microbial biomass carbon declined, constraining acetate-dependent methanogenesis and driving a pathway shift from mixed acetoclastic–hydrogenotrophic methanogenesis toward hydrogenotrophic dominance. In contrast, bulk soils were less directly influenced by root-derived substrates; instead, $O_3$-induced increases in pH and carbon availability favored hydrogenotrophic methanogens, resulting in a transition from acetoclastic dominance to a dual-pathway regime.

Microbial network analyses further revealed that elevated $O_3$ enhanced cooperation and efficiency within bulk-soil microbial communities, while rhizosphere networks exhibited functional degradation. Together, these findings demonstrate that $O_3$ pollution reshapes paddy $CH_4$ production through plant-mediated metabolic controls that differentially regulate rhizosphere and bulk-soil microbial processes. Our results highlight a previously underappreciated pathway by which air pollution interacts with plant physiology to modulate greenhouse gas emissions, with important implications for predicting agricultural methane feedbacks under future climate and air-quality scenarios.

*wernerliesack@gmail.com

**ABSTRACT**

Aerobic methane-oxidizing bacteria (methanotrophs) play a key role in the global methane cycle by mitigating methane emissions from soils to the atmosphere. Among proteobacterial methanotrophs, alphaproteobacterial *Methylocystis* spp. are ubiquitous in wetland soils, where steep redox gradients and fluctuating gas diffusion expose cells to pronounced temporal and spatial variability in methane availability. While methane is the primary carbon and energy source for these organisms, wetlands frequently impose conditions of methane limitation or even complete methane absence. However, the cellular strategies that enable *Methylocystis* spp. to cope with these fundamentally different metabolic states remain poorly understood.

Using *Methylocystis* sp. strain SC2 as a model organism, we investigated physiological and proteomic responses to methane limitation and to complete methane deprivation. Growth experiments combined with proteomics revealed that strain SC2 can utilize hydrogen as an alternative energy source under methane-limited (6% $CH_4$) and oxygen-limited (3% $O_2$) conditions. Supplementation of the culture headspace with 2% $H_2$ resulted in a two-fold increase in maximum biomass yield compared to fully aerobic conditions without hydrogen addition. With decreasing $O_2/CH_4$ mixing ratios, methane utilization was progressively redirected from respiratory metabolism toward fermentation-associated pathways, irrespective of hydrogen availability. This metabolic shift was accompanied by strongly increased production of the membrane-bound Group 1d [NiFe]-hydrogenase in both short-term (19 h) and long-term (37 d) incubations, as well as the cytoplasmic Group 2b [NiFe]-hydrogenase. Group 1d [NiFe]-hydrogenase primarily oxidizes hydrogen at elevated concentrations during mixotrophic growth, with electrons transferred directly into the quinone pool, consistent with the availability of fermentation-derived $H_2$ in wetland soils.

In contrast, aerobic $CH_4$-free conditions induced a distinct hydrogenase expression pattern. The high-affinity, membrane-bound Group 1h [NiFe]-hydrogenase was strongly upregulated within 72 h and remained highly expressed during methane deprivation for up to one month, consistent with its role in scavenging trace or atmospheric hydrogen to sustain maintenance metabolism. Conversely, Group 1d, regulatory Group 2b, and Group 3b [NiFe]-hydrogenases were progressively downregulated, indicating selective repression of low-affinity hydrogenases under prolonged methane starvation. Beyond hydrogen metabolism, extensive proteome remodeling affected pathways involved in methane oxidation, $C_1$ metabolism, and polyhydroxybutyrate (PHB) turnover. While short-term methane starvation (3 h and 72 h) allowed full metabolic recovery upon methane re-addition, cultures starved for up to one month showed only partial recovery, indicating reduced cell viability under prolonged methane deprivation.

**ABSTRACT**

Rice paddies are among the largest anthropogenic sources of methane, where soil temperature strongly regulates microbially mediated methane fluxes. While the roles of bacteria and archaea are well established, the contributions of viruses to these processes remains largely unexplored. Here, we combined metagenomic and metatranscriptomic analyses to determine virus-host interactions in paddy soils incubated under different temperatures. Viral sequences were detected in association with 37% of metagenome-assembled genomes (MAGs) and viral survival strategies shift under warming across different soil types, indicating widespread viral infection across both bacterial and archaeal lineages. Among bacterial hosts, members of Xanthobacteraceae and Burkholderiaceae showed increased transcription of fatty acid metabolism pathways. In archaea, Methanosarcinaceae, the dominant methanogenic family in paddy soils, were identified as the primary archaeal hosts of viral infection. Metatranscriptomic analysis revealed that under elevated temperatures, viruses affect both aceticlastic and methylotrophic methanogenesis pathways within Methanosarcinaceae. These findings highlight the significant role of viruses in regulating the methane cycle in paddy soils and demonstrate that temperature-dependent virus–host interactions can influence key methanogenic processes. Our results highlight an overlooked biological layer controlling methane emissions from rice paddies under climate-relevant temperature shifts.

## ABSTRACT

Elevated tropospheric ozone ($O_3$) concentrations and global warming represent critical environmental challenges; however, their combined impacts, particularly the indirect influences on methanogenesis in paddy soils, remain poorly understood. To clarify how methanogenesis responds to elevated $O_3$ (1.5× ambient) and warming (+2 °C), we sampled surface (0–10 cm) and subsurface (10–20 cm) soils throughout two rice seasons in an $O_3$-T-FACE (Free-Air Controlled Environment) platform and measured $CH_4$ production potential via anoxic incubation. The results showed that elevated $O_3$ levels increased the $CH_4$ production potential in surface soil by 22–836% compared to the control, whereas warming effects varied with the growth stage. Notably, their combined effects amplified $CH_4$ production potential in surface soils by 32–1214%, possibly owing to increases in initial dissolved organic carbon (DOC, 19–38%), microbial biomass carbon (MBC, 10–32%), methanogen abundance (28–97%), and DOC consumption during incubation (29–131%). In subsurface soils, elevated $O_3$ levels and warming individually enhanced $CH_4$ production potential by 5–38% and 4–101%, respectively, with their combined effect increasing it by 29–101%, linked to elevated methanogen abundance (4–290%) and DOC consumption (4–56%). Random forest and Partial Least Squares Path Modeling (PLS-PM) analyses collectively identified soil DOC concentration, DOC consumption, and $CH_4$ cycle-related microbial abundance as key determinants of methanogenesis across soil depths. These results underscore the dual control of abiotic and biotic factors on methanogenesis under future $O_3$ and warming, revealing a "surface sensitivity-subsurface buffering" pattern in paddy-ecosystem responses to elevated $O_3$ and warming.

## ABSTRACT

Against the background of climate change, this study focuses on the synergistic impacts of ozone ($O_3$) pollution and agricultural management practices on methane ($CH_4$) emissions from paddy fields. Based on an open-top chamber (OTC) platform, a split-plot experiment was systematically conducted to investigate the interactive effects of elevated $O_3$ concentration and straw return. Two $O_3$ concentration levels were established: non-filtered ambient air (NF) and targeted $O_3$ elevation of 60 ppb above ambient (NF60), which were combined with two straw treatments: no straw return (CK) and straw return (S). The rice cultivar 'HuiLiangyou' (*Oryza sativa* L.) was used as the experimental material. From the holistic perspective of "plant-soil-microbe", this study comprehensively analyzed rice photosynthetic physiological traits, biomass accumulation, and yield formation processes, as well as soil carbon and nitrogen physicochemical properties (dissolved organic carbon (DOC), ammonium nitrogen ($NH_4^+$-N), pH), $CH_4$ emission flux, and methane production potential (MPP) in paddy fields. Meanwhile, quantitative real-time polymerase chain reaction (qPCR) and high-throughput sequencing techniques were integrated to systematically decipher the abundance of the methane-functional gene (*mcrA*) and the structural characteristics of methanogenic microbial communities in paddy soil. The results demonstrated that $O_3$ and straw return synergistically regulated paddy $CH_4$ emissions through multi-level cascading effects. $O_3$ stress significantly suppressed rice photosynthesis, reduced root biomass, thereby decreasing the supply of rhizosphere carbon and nitrogen substrates, inhibiting the abundance of methanogens (e.g., *Methanobacterium*), and lowering $CH_4$ emission intensity. In contrast, straw return enhanced $CH_4$ production potential by supplementing soil carbon and nitrogen pools, promoting the enrichment of functional microbial communities, and upregulating the expression of functional genes. Notably, the interaction between $O_3$ and straw partially mitigated the negative effects of single $O_3$ stress on rice physiology, while attenuating the enhanced $CH_4$ emissions induced by sole straw application, achieving the synergistic effects of crop damage mitigation and $CH_4$ emission reduction. Partial least squares path modeling (PLS-PM) analysis further clarified that $O_3$ indirectly inhibited $CH_4$ emissions primarily through the "plant physiology-rhizosphere microorganisms" pathway, whereas straw return promoted $CH_4$ production via the "soil carbon and nitrogen-microbial communities" pathway. This study systematically uncovers the multi-path regulatory mechanisms of $O_3$ pollution and straw return on $CH_4$ emissions in paddy ecosystems, providing a scientific basis for $CH_4$ emission reduction and sustainable agricultural management in paddy fields under future climate change scenarios.

**ABSTRACT**

Humus is the main body of soil organic matter and plays an important role in maintaining the stability of soil carbon pools. The formation of soil humus, mediated by the microbial decomposition of plant litter, is pivotal for terrestrial carbon sequestration and climate regulation. In Southern China, lateritic ecosystems face severe degradation characterized by acidification, nutrient depletion, and biodiversity loss. However, sugarcane production in this region generates tens of millions of tons of sugarcane leaf residue annually, conventional disposal methods such as burning fail to utilize this biomass effectively, hindering soil carbon replenishment. Transforming this agricultural waste into stable soil organic carbon represents a critical challenge for restoring lateritic ecosystem functions. Herein, we investigated the humification process of sugarcane leaves in lateritic soil driven by microbiota from various land-use types. We enriched cultivable bacteria and fungi to construct distinct microbial inocula and applied them to sugarcane leaf-amended lateritic soil. High-throughput sequencing and physicochemical analyses were used to track microbiome dynamics and nutrient turnover. The results indicated that the addition of microbiota from vegetable field and forest soil resulted in the highest rate of humus formation compared to controls. Specifically, the abundance of *Cellulomonas*, *Roseomonas*, *Solitalea*, *Hydrogenophaga*, and *Ruminiclostridium* was significantly correlated with the increase in soil organic carbon, humic substances, available phosphorous and available potassium. These findings clarify the mechanism of microbial-mediated humification and offer a practical bio-strategy for restoring degraded lateritic ecosystems and achieving carbon sequestration targets.

## ABSTRACT

Microbial methane oxidation plays a significant role in regulating methane emissions from lakes and reservoirs. However, the differences in methane oxidation activity and methanotrophic community between lakes and reservoirs remain inadequately characterized. In this study, sediment and water samples were collected from the large shallow lake (Dianchi) and deep reservoirs (Dongfeng and Hongjiadu) located in karst area, Southwest China. The results indicated that the rates of aerobic oxidation of methane (AeOM) in lake sediment ranged from 7.1 to 27.7 $\mu g \cdot g^{-1} \cdot d^{-1}$, which was higher than that in reservoirs sediment (1.92 to 11.56 $\mu g \cdot g^{-1} \cdot d^{-1}$). Similarly, the average AeOM in the water column of lake (104.7 $\mu g \cdot L^{-1} \cdot d^{-1}$) was much higher than that of reservoirs (46 $\mu g \cdot L^{-1} \cdot d^{-1}$). The content of sediment organic carbon and dissolved inorganic carbon were important factors that influenced the rates of AeOM in sediment and water column, respectively. 16S rRNA genes sequencing revealed a higher relative abundance of methanotrophs in lake sediments compared to reservoir sediments. The dominant methanotrophic taxa in lake was *Methylococcaceae* (type Ib), while *Methylomonadaceae* (type Ia) was predominant in reservoirs. Meanwhile, anaerobic methane-oxidizing microorganisms *Candidatus Methylomirabilis* and *Candidatus Methanoperedens* were also abundant in sediments of reservoirs. However, metatranscriptomic analysis revealed that the type I methanotrophs, especially *Methylobacter*, was most active in the sediment of both lake and reservoir. Water depth and conductivity could be the key controlling factors of the structures of methanotrophic communities in sediment and water column, respectively. Metagenome-assembled genomes suggested that type I methanotrophs exhibited greater motility, as evidenced by a higher number of flagellar assembly genes, while type II methanotrophs demonstrated advantages in metabolic processes such as carbon, phosphorus, and methane metabolism.

# Elevational patterns and temperature sensitivity of soil methane oxidation in southeastern Tibetan forests

**Yan Tong[1] and Yongcui Deng[1*]**

[1] *School of Geography, Nanjing Normal University, Nanjing, China*

*dengyongcui@njnu.edu.cn

**ABSTRACT**

Methane ($CH_4$) is a potent greenhouse gas, yet substantial uncertainties remain regarding how the temperature sensitivity of soil methane oxidation varies along elevational gradients and the extent to which microbial regulation and long-term thermal adaptation shape these patterns. Here, we investigated soil methane oxidation across 28 forest sites in southeastern Tibet spanning a continuous elevational gradient from 1,404 to 4,513 m. In situ methane flux measurements revealed a pronounced unimodal elevational pattern, with methane uptake increasing with elevation to a maximum at approximately 3,113 m before declining at higher elevations. Consistent with field observations, laboratory incubations conducted at 0, 10, and 20 °C showed peak methane oxidation rates at intermediate elevations (~3,113 m). The temperature sensitivity ($Q_{10}$) of methane oxidation declined with increasing incubation temperature, with higher $Q_{10}$ values at 0–10 °C (mean = 1.41) than at 10–20 °C (mean = 1.13). Moreover, $Q_{10}$ showed a weak, non-significant positive trend with elevation at low incubation temperatures, but a weak, non-significant negative trend at higher temperatures, suggesting contrasting temperature responses across the elevational gradient. Together, these results demonstrate temperature-dependent regulation of soil methane oxidation in cold-region forests and highlight the limitations of representing methane oxidation temperature responses using a single $Q_{10}$ value. Our findings underscore the importance of considering microbial thermal adaptation when predicting future soil methane sink strength under climate warming.

# Functional Diversity and Interactions of CO-utilizing Microbial Communities

**Diana Z. Sousa**

*Laboratory of Microbiology, Wageningen University & Research, Wageningen, The Netherlands*

diana.sousa@wur.nl

**ABSTRACT**

Microbial transformation of one-carbon (C1) gases plays a fundamental role in carbon cycling across diverse anoxic environments. We investigate the physiology, metabolic diversity, and interactions of microorganisms capable of utilizing CO and $CO_2/H_2$ as carbon and energy sources under anoxic conditions, providing mechanistic insight into C1 metabolic processes.

In anaerobic enrichment cultures, CO conversion is typically dominated by methanogenesis, reflecting the strong thermodynamic coupling between CO oxidation and methane formation. However, at elevated CO concentrations, methanogenic activity is inhibited, leading to a metabolic shift in which acetate becomes the primary product of CO conversion via acetogenic carboxydotrophs. Under conditions where methanogenesis is suppressed, alternative metabolic routes can emerge within the community, enabling further transformation of acetogenic products. In this context, we have shown that enriched and defined microbial communities can redirect carbon and electron fluxes from CO toward the formation of elongated even- and odd-chain carboxylic acids and alcohols, driven by metabolic interactions between acetogens, propionigenic bacteria, and chain-elongating bacteria.

Genomic surveys across diverse anoxic environments consistently reveal genes encoding carbon monoxide dehydrogenases (CODHs), indicating that the potential for CO utilization is widespread, whereas the majority of carboxydotrophic microorganisms remain uncultivated. To address this gap, we focus on the isolation of CO-utilizing microbes from constrasting environments, using cultivation strategies adapted to different physicochemical constraints. Our work has recovered carboxydotrophs from anaerobic sludges, volcanic and geothermal sediments, and high-salinity environments, including novel thermophilic members of the Bacillota lineage, the new genus *Thermobium azorense*, and hydrogenogenic CO utilizers affiliated with *Thermincola* and *Carboxydocella*. Recognizing that conventional enrichments may bias against slow-growing or CO-sensitive taxa, we are further developing refined isolation strategies to recover underrepresented carboxydotrophic lineages, advancing our ability to link genomic potential with physiological function across taxonomic and ecological space.

# Culturing the Uncultured Anaerobes from the Perspective of Microbial Growth Curves

**Lei Cheng**

*Key Laboratory of Development and Application of Rural Renewable Energy Biogas Institute of Ministry of Agriculture and Rural Affairs China*

chenglei@caas.cn

**ABSTRACT**

Anaerobic microorganisms, e.g methanogenes, inhabit diverse anoxic environments and play a fundamental role in global biogeochemical cycles. Recent advances in DNA sequencing have revealed a striking gap between the vast microbial diversity found in anoxic environments and the small number of anaerobes – fewer than 0.1% of the estimated millions of anaerobic species in nature have been cultivated. This challenge reflects the “great plate count anomaly”, where most microorganisms observed in nature fail to grow in laboratory conditions. Overcoming these limitations requires a shift in cultivation strategies. Here, I will introduce a growth-curve-guided strategy that uses real-time monitoring of microbial growth (primarily at the species level) to inform approaches that leverage relative growth advantages and improve the recovery of target microorganisms. By prioritizing growth performance over abundance and selectively removing non-target microbes, this approach offers a more predictable and adaptable framework for isolating methanogens from complex communities.

**ABSTRACT**

For paddy soils undergoing straw returning, microbial-driven $N_2$ fixation is an important natural pathway for soil nitrogen enhancement. However, the types and activities of microorganisms, especially $N_2$-fixing microorganisms, during the anaerobic degradation of rice straw in paddy soil are still poorly understood. Herein, we use $^{15}N$ isotope method and a range of molecular methods including metatranscriptome sequencing to study how rice straw degradation affects microbial $N_2$ fixation. Using untreated control (CK), Straw, and Straw+N (Urea) treated soils it was found that the degradation of rice straw only vigorously promoted $N_2$ fixation activity of soil microorganisms in treatment Straw. Firmicutes was the dominant phylum that degraded rice straw and was also a main driver for $N_2$ fixation. Proteobacteria and methanogens of the Euryarchaeota phylum were another two major $N_2$-fixing taxa during anaerobic degradation of rice straw. The metatranscriptomic approach demonstrated the non-negligible role of methanogens in $N_2$ fixation although their proportion in total microorganisms was extremely low. Urea addition not only terminated the $N_2$ fixation activity of microorganisms in paddy soil but also changed the composition of control (CK), Straw, and Straw+N (Urea) treatment soils the methanogenic community and reduced methane production. These results revealed a panoramic view (global insight) of active diazotrophs during the early anaerobic degradation of rice straw in paddy soil.

## ABSTRACT

Manganese (Mn) tailings pollution poses a severe threat to soil quality and human health. Phytoremediation is effective for Mn tailings pollution, but the mechanisms of plant-microbe interactions in this process need further investigation. By inoculating *Koelreuteria paniculata* roots with *Priestia megaterium* (PM), we assessed changes in soil properties, plant physiology and heavy-metal uptake, then mined the root transcriptome for genes linked to Mn-tailings tolerance. Soil organic carbon, total nitrogen, total phosphorus, available nitrogen, available phosphorus, microbial biomass carbon, microbial biomass nitrogen content, soil β-glucosidase, acid phosphatase, and leucine aminopeptidase activities were increased by inoculation with the strain PM. Under 100% Mn tailings, plant biomass, net photosynthetic rate, stomatal conductance, transpiration rate, total chlorophyll content, and the activities of superoxide dismutase, peroxidase, and catalase were significantly increased after PM inoculation, with respective increases of 17.6%, 32.8%, 35.9%, 216.9%, 59.5%, 116.2%, 179.2%, and 279.4%. Meanwhile, after inoculation with strain PM, the malondialdehyde content of *K. paniculata* decreased significantly. Inoculation with the strain PM increased the percentages of iron (Fe)/ Mn oxide-bound and organic-bound Mn and copper (Cu) in the soil, as well as the accumulation and bioconcentration factors of Mn and Cu. After inoculation with strain PM, the key genes involved in antioxidant response (*UGT72E*, *IF7MAT*, *FG3*, *WRKY25* and *WRKY52*), plant photosynthesis genes (*IDO*, *crtZ*) and growth regulation genes (*ARR-A*) were significantly up-regulated. These findings highlight key genes involved in plant growth and antioxidant responses, offering insights for future phytoremediation strategies.

**ABSTRACT**

Glacier retreat on the Tibetan Plateau, driven by rapid warming, is exposing vast areas of iron-rich parent material, yet the impact of this process on nitrous oxide (N2O) emissions remains unknown. Here we show that chemo-denitrification, the abiotic reduction of nitrite by ferrous iron (Fe(II)), dominates $N_2O$ production in Tibetan glacier forelands. In proglacial wetlands and meadows, chemo-denitrification contributed 50–69% of total $N_2O$ production from denitrification, and in three additional glacier retreat zones (Jiali County, Mount Everest, Cho Oyu) its contribution exceeded 60%. Unlike tropical peatlands where chemo-denitrification outcompetes an active microbial community, here denitrification functional genes and microbial activity was extremely low. Consequently, $N_2O$ is produced abiotically through Fe (II) driven nitrite reduction without subsequent microbial consumption a "naturally dominant" mode distinct from the "competitively dominant" mode observed elsewhere. With glaciers on the plateau shrinking by 0.5% per year, the expanding Fe (II)-rich forelands are becoming an overlooked source of abiotic $N_2O$. Our findings challenge the paradigm that denitrification is primarily a biological process and call for inclusion of iron-driven chemo-denitrification in Earth system models to accurately project high-alpine greenhouse gas emissions under continued warming.

## ABSTRACT

Rice cultivation contributes to methane (CH4) emissions to the atmosphere and represents approximately 10% of total agricultural emissions. While Asia dominates global rice production, rice paddies in temperate regions such as Europe and North America also contribute significantly to GHG budgets. Accurate estimation of greenhouse gas emissions from rice paddies is increasingly crucial for evaluating agricultural management strategies aimed at mitigating global warming, as well as for reporting emission inventories at regional and national scales. While emission models are well-established for tropical regions, their performance in temperate zones such as Europe and North America remains limited and poorly validated leading tohigh uncertainty. This study addresses this gap by focusing on rice-producing regions in temperate regions including Europe and the USA, which are characterized by high mechanization, artificial irrigation, and comparable agronomic practices.

A systematic literature review was performed to identify field-based studies measuring $CH_4$ emissions using non-steady state closed chamber technique in temperate rice systems. The review yielded 40 eligible publications, supplemented by proprietary data from UpToFarm Srl, a spin-off company of the University of Torino, resulting in a dataset of 223 statistical units. For each unit, $CH_4$ emission factors were calculated as the average daily emission rate (kg $CH_4$ $ha^{-1}$ $d^{-1}$) over the cropping season. Explanatory variables describing water and residue management, soil and climate characteristics, and agronomic inputs were compiled.

Generalized Linear Mixed Models (GLMMs) and Generalized Additive Mixed Models (GAMMs) were used to explore the relationships between $CH_4$ emissions and environmental and management factors. GAMMs performed better than GLMMs according to Akaike Criterion (AIC). The most accurate model identified soil pH, water management during cropping cycle and seeding, nitrogen and carbon inputs, and soil sand content as significant predictors. Non-linear effects were detected for pH, nitrogen inputs, and sand fraction, with country and year included as significant random effects. These Our findings emphasize the importance of local agronomic and environmental conditions in determining $CH_4$ emissions in temperate rice systems and highlight the need for region-specific approaches to improve emission estimates. Including data from Europe and the USA not only strengthens global model reliability but is essential to inform sustainable policy design in these under-represented but high potential emission regions.

[2] *Isaev Centre for Forest Ecology and Productivity, Russian Academy of Sciences, Moscow, Russia*

[3] *Izrael Institute of Global Climate and Ecology, Moscow, Russia*

[4] *Federal Agricultural Kursk Research Center, Kursk, Russia*

* olgasukhoveeva@gmail.com

**ABSTRACT**

This study focused on evaluating the influence of qualitative (categorical, nominal) factors on $CO_2$ emissions from soil, that is, soil respiration (SR), at a single biome scale. The factors were as follows:

- "Region" − represented by four regions (Chuvashia, Ryazan, Tula and Kursk regions) and characterizing the geographical location within the European part of the forest-steppe biome. It was a generalized indicator of local conditions, including soil type and economic activity of farms;
- "Year" − corresponded to five years of measurements (2020–2024). The factor should be interpreted as a cumulative characteristic of weather and the state of soil and vegetation cover;
- "Ecosystem" − the seven types of ecosystems were categorized as either agricultural (croplands, pastures and hayfields) or natural (grasslands and forests), as well as livestock facilities (stockyards and compost piles).
- "Crop" − an additional factor addressed with the arable soil group. We analyzed the influence of crops grown during the measurement period (winter and spring wheat, barley, oats, corn, soybeans, sunflowers and fallow).

SR measurements were performed using closed chamber technique in different ecosystems over a short period at the height of the growing seasons. Multivariate non-parametric analysis (three-way PERMANOVA and ANOSIM) was employed.

The results showed that the geographical location of a particular site (region) within the forest-steppe biome did not affect the rate of soil $CO_2$ efflux, whereas the type of land use (ecosystem type) and current environmental conditions were the key controls. SR was found to be similar in perennial plant communities (pastures, hayfields, grasslands, forests), lower in croplands, and an order of magnitude higher in livestock facilities. Consequently, these results suggested that distant sites may not reveal spatial variability in SR. The similarity of the SR in different regions of the forest-steppe biome was consistent with the observation that soil organic carbon contents were often comparable between different ecosystems. However, this indicator was characterized by high variability, with a tendency to increase from north to south and to decrease in arable soils. Overall, the average SR rate varied slightly spatially and could therefore be considered a sustainable characteristic of the biome, alongside climate, soil type, and vegetation cover. For the forest-steppe biome (excluding livestock facilities), the average SR rate was 0.227 g C·m-2·h-1 (mean), 0.239 g C·m-2·h-1 (weighted mean), 0.167 g C·m-2·h-1 (median) in the middle of the growing season.

# Agricultural Management and Soil Leakiness: Drivers of Methane Oxidation and Nitrification

**Ruchen Tian[1*], Sharise Capriles[3], Kyle Mason-Jones[2,3], Wim van der Putten[2] and Paul Bodelier[1]**

**ABSTRACT**

Upland soils play a crucial role in climate regulation by acting as both sinks and sources of greenhouse gas (GHG). Compared to natural upland ecosystems, agricultural soils often exhibit higher "leakiness" owing to intensive management practices such as high nitrogen inputs and frequent soil disturbances, which weaken methane ($CH_4$) sink capacity while enhancing nitrous oxide ($N_2O$) emissions. Although the effects of individual agricultural practices on soil methane and N-cycling dynamics have been widely examined, the combined and interacting impacts of multiple co-occurring practices remain poorly understood. This study investigates how interacting agricultural management practices jointly influence soil methane oxidation potential, nitrification potential, and GHG fluxes through biotic and abiotic pathways. We analyzed 207 soil samples collected from agricultural grassland and arable fields all over the Netherlands, representing contrasting management intensities and soil types. By integrating management data, soil physicochemical properties, and microbial community profiles, we identify likely drivers of $CH_4$ oxidation and nitrification processes. Methanotrophic (MOB) and ammonia-oxidizing communities, comprising ammonia-oxidizing bacteria (AOB), archaea (AOA), and complete ammonia oxidizers (comammox), are profiled to reveal their functional and ecological responses to management intensity. The combined analyses aim to construct a predictive framework linking management practices to soil "leakiness," defined by the balance between sink and source function. Our findings are expected to improve mechanistic understanding of how integrated agricultural management modulates microbial processes driving GHG dynamics, and to provide insights for designing management strategies that enhance soil functioning and climate change mitigation.

**ABSTRACT**

Changes in land use have been identified as a main cause of carbon (C) and nitrogen (N) changes in soils across different regions of the world. In Europe, where there is a wide variety of climates and soil types, the role of land use and land use change on C and N dynamics may be complex showing different patterns depending not only on the specific land use and geographical region but also on the intensity of the land use. Furthermore, the effects on soil C and N can influence the production, transport, and emission of soil gases.

In this context, the aim of this study was (i) to assess how land use affects soil greenhouse gas (GHG) emissions in different European regions, and (ii) to determine whether land use intensity influences the emission of soil gases. Sampling areas were located in five European biogeographical regions and countries: Mediterranean (Spain), Atlantic (Spain), Alpine (Switzerland), Continental (Germany) and Boreal (Latvia). Five different land use types were selected in each biogeographical region. The selection of land uses in each region varied according to the most common land uses: agricultural (all five regions), seminatural (all five regions), forest (Alpine, Boreal and Continental), industrial (Alpine and Mediterranean), mining (Atlantic, Boreal, Mediterranean and Continental), urban (Atlantic, Mediterranean and Continental), and wetland (Alpine, Atlantic and Boreal). Within each land use and region, three intensity levels were selected ranging from the most to the least degraded condition.

In spring 2024, soil sampling was conducted in each biogeographical region. Ten composite soil samples (each composed from 5 points) were collected from the 0-20 cm layer for each combination of land use and intensity, resulting in a total of 750 soil samples. Air-dried soil samples (<4 mm) were pre-incubated for 48 h under uniform soil moisture and temperature conditions and subsequently incubated for 72 h in airtight containers. During the incubation period, multiple air samples were collected to determine the concentration of carbon dioxide ($CO_2$), methane ($CH_4$) and nitrous oxide ($N_2O$).

Considering all biogeographical regions, land uses showed significant differences in cumulative $CO_2$ and $N_2O$ emissions. Seminatural and wetland uses showed higher cumulative soil $CO_2$ emissions than urban and industrial uses, while agricultural use showed greater $N_2O$ emissions than seminatural, urban, mining and industrial uses. Regarding biogeographical regions, the Alpine and Boreal regions showed the highest cumulative $CO_2$ and $N_2O$ emissions, respectively.

This study highlights the key role of land use and land use change in soil C and N dynamics, and consequently in the production and emission of $CO_2$ and $N_2O$ in European soils. Therefore, land use planning is crucial for reducing soil greenhouse gas emissions and achieving carbon neutrality targets established by the European Commission for the coming decades.

# Greenhouse Gas Emissions from Soils and Ways to Reduce Them

**Pete Smith**[1*]

[1] *Institute of Biological & Environmental Sciences, University of Aberdeen, Aberdeen, UK*

*pete.smith@abdn.ac.uk

**ABSTRACT**

Greenhouse gas emissions from soils account for 15% of the global increase in climate warming (radiative forcing) experienced today. Soil emissions of the three main anthropogenic greenhouse gases are 0.1 Pg C $yr^{-1}$ of carbon dioxide, 3.7 Tg $N_2O$-N $yr^{-1}$ of nitrous oxide and 30 Tg $CH_4$ $yr^{-1}$ of methane (Figure 1). Various aspects of human activity, especially land-use and management, contribute to these emissions.

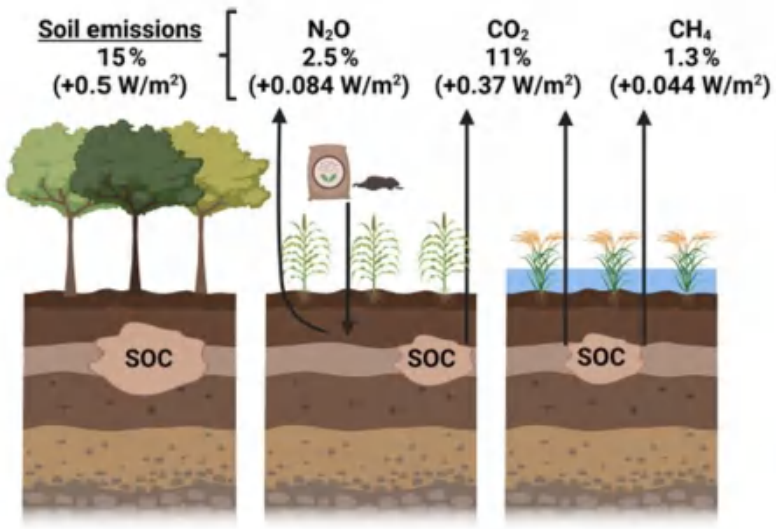

**Figure 1.** Anthropogenic emissions of greenhouse gases (carbon dioxide ($CO_2$), nitrous oxide ($N_2O$), and methane ($CH_4$)) from soil, and their contribution (15 %, +0.5 $Wm^{-2}$), to the overall increase in warming (radiative forcing) due to well-mixed greenhouse gases (+3.32 $Wm^{-2}$) (Kopittke et al., 2024)

In this presentation I will draw on 30 years of research into these topics (Smith et al., 2012) to highlight what we know about soil emissions of greenhouse gases and their responses to land use and land management, what we still do not know, and what we can do to reduce net greenhouse gas emissions from soils (Smith et al, 2008).

## ABSTRACT

Agriculture emerges as a prominent contributor to $CH_4$ and $N_2O$ emissions in China. However, estimates of these two non-$CO_2$ greenhouse gases (GHGs) remain poorly constrained, hindering a precise understanding of their spatiotemporal dynamics and the development of effective mitigation strategies. Here, we established a consistent estimation framework that integrates emission-factor approach, data-driven models and process-based biogeochemical models, to identify the magnitudes, spatial variations, and long-term trends of agricultural non-$CO_2$ GHG emissions in China's mainland from 1980 to 2023. Over the study period, the average total agricultural non-$CO_2$ GHG emissions amounted to 722.5 ± 102.3 Tg $CO_2$-eq $yr^{-1}$, with livestock $CH_4$, cropland $CH_4$, cropland $N_2O$ and livestock $N_2O$ contributing 41% (297.4 ± 64.3 Tg $CO_2$-eq $yr^{-1}$), 31% (225.0 ± 69.6 Tg $CO_2$-eq $yr^{-1}$), 18% (130.6 ± 9.4 Tg $CO_2$-eq $yr^{-1}$) and 10% (69.4 ± 20.2 Tg $CO_2$-eq $yr^{-1}$), respectively. Approximately 70% of these emissions were concentrated in the eastern region beyond the Hu Line, with emission hotspots identified in South-central China, East China, and the Sichuan Basin. Our analysis revealed three distinct temporal stages of total emissions during the study period: rapid growth (1980–late 1990s), slow growth (late 1990s–middle 2010s), and a stabilization stage (since the middle 2010s). These stages reflect the evolving trajectory of agriculture in China, from the expansion of agricultural yields, to the transformation of agricultural practices, and ultimately the pursuit of sustainable development. However, the temporal trajectory of emissions varied significantly across different regions, highlighting divergent levels of agricultural development. This study presents a comprehensive, gridded, and consistent estimate of agricultural non-$CO_2$ GHG emissions in China, offering valuable insights for policymakers to develop tailored strategies that adapt to local conditions, enabling effective emission reduction measures.

# Rainfall-induced hot moments of $N_2O$ emissions in sandy agricultural soils managed with winter cover crops

**Sapana Parajuli*, Frank Oliver, Binaya Parajuli, and Rongzhong Ye**

*Department of Plant and Environmental Sciences, Clemson University, Clemson, SC 29634, United States*

*Pee Dee Research and Education Center, Florence, SC 29506, United States*

*sparaju@clemson.edu

**ABSTRACT**

Intensive fertilization in sandy Coastal Plain soils often results in substantial nitrogen (N) loss due to the soils' poor water- and nutrient-holding capacity and rapid leaching. Winter cover crops are therefore incorporated to retain soil residual N and reduce runoff and soil erosion. However, their effects are complicated by the diversity of species, varied management practices, and environmental conditions. A field study was conducted in a corn-cotton system at the Pee Dee Research and Education Center (Florence, South Carolina, U.S.A.), in which four cover crop treatments were tested (cereal rye, hairy vetch, rye-vetch mixture, and a fallow control). High-frequency gas sampling was employed to quantify "hot moments" of gaseous emissions, including nitrous oxide ($N_2O$) and ammonia ($NH_3$), with manual and automated chambers. Lysimeters were installed to measure liquid N losses, while soil samples were simultaneously collected to monitor N pools (i.e., extractable NH4, NO3, dissolved organic N, and microbial biomass). Preliminary data suggested that "hot moments" of $N_2O$ emissions did not occur after fertilization but were triggered by rainfall following high soil moisture content and water-filled pore space (WFPS). The magnitude varied with cover crops. The rye-vetch mixture produced the highest $N_2O$ fluxes, concurrent with the highest WFPS and $NO_3$ availability, favorable for denitrification. A similar "hot moment" of N leaching was also observed after rainfall, with the most significant loss occurring in the fallow controls, highlighting the potential of cover crops to reduce N leaching loss, most notably with cereal rye. Likewise, $NH_3$ volatilization was the highest and sustained in control plots following fertilization. These findings demonstrate that rainfall is the primary driver of gaseous N loss in the tested sandy soils, especially in soils where external organic C (rye residues) and N (vetch) were added together. However, these emissions can be effectively mitigated by targeted cover crop selection.

## ABSTRACT

Wetland is one of the most significant sources of methane ($CH_4$). Although global warming and elevated atmospheric carbon dioxide concentrations ($eCO_2$) are expected to affect the $CH_4$ cycle, the response of $CH_4$ emission in natural wetland and paddy has been observed to be inconsistent. This variation is likely due to the complex interactions among soil, plant, and microbial processes that regulate $CH_4$ dynamics, leaving the underlying mechanisms across global studies unknown. Here, we conducted a meta-analysis to elucidate the effects of warming, $eCO_2$, and their co-effects on $CH_4$ cycling in wetland. Our results demonstrate that $eCO_2$ significantly increased $CH_4$ emission in paddy (18.57%) but had no significant effect on that in natural wetland, attributed to $eCO_2$-induced increase in belowground biomass and methane production potential in paddy. Conversely, warming promoted $CH_4$ emission in natural wetland (26.71%) but had no substantial impact on $CH_4$ in paddy. This difference is due to the lower mean annual temperature in natural wetland compared with paddy, where warming promotes plant growth and methanogen activity. Notably, the combined effects of $eCO_2$ and warming on paddy $CH_4$ emission were markedly greater than their individual effects, with a synergistic increase of 44.63%. Furthermore, the impact of $eCO_2$ on $CH_4$ emitted by natural wetland was enhanced with time, likely due to different extent of plant-induced priming effect and progressive nitrogen limitation, while $CH_4$ emissions from paddies declined greatly with time. Our findings emphasize the pivotal role of wetlands in the global methane cycle and highlight the complex responses of $CH_4$ emissions to climate changes.

# $CO_2$ fixation by soil algae in agricultural lands

**Tomoki Tanaka, Kozue Sawada, and Jun Murase***

*Graduate School of Bioagricultural Sciences, Nagoya University, Nagoya, Japan*

*murase@agr.nagoya-u.ac.jp

## ABSTRACT

In the soil carbon cycle, microorganisms are primarily decomposers and converters of plant-derived organic matter, and the significance of $CO_2$ fixation by soil microorganisms has not been fully considered. In this study, we evaluated $CO_2$ fixation by soil algae in agricultural lands and analyzed its spatio-temporal variation and its relationship with environmental factors.

Soil $CO_2$ fluxes were measured under dark and light conditions (800 μmol $m^{-2}$ $s^{-1}$) in rice paddies and upland fields at the Togo Field, Field Science Center, Graduate School of Bioagricultural Sciences, Nagoya University, using an LED-equipped chamber placed on the soil, avoiding vegetation. Among 347 measurements, 263 (75%) showed lower $CO_2$ flux under light than under dark conditions, suggesting that a part of the $CO_2$ released by soil respiration was reabsorbed at the soil surface by algal photosynthesis at many sites. The rate of $CO_2$ uptake (net primary production, NPP) by soil algae accounted for 0–100% (median 24%) of soil respiration (D flux), with additional atmospheric $CO_2$ uptake detected for some cases. NPP positively correlated with D flux, temperature (soil and air), and moisture (soil water, humidity, precipitation).

Light-induced $CO_2$ uptake (200 μmol $m^{-2}$ $s^{-1}$) also occurred in indoor incubations (25 °C) using 0–5 cm soil cores (n = 68) from multiple sites. NPP in these cores correlated positively with D flux, soil moisture, and chlorophyll a; in paddy soils, it also correlated with water-extractable $NH_4^+$-N. Random Forest regression of field and indoor data identified D flux and soil moisture as the most important predictors of NPP.

D flux and NPP were measured over time in cores prepared under wet and dry conditions, respectively, with water loss during incubation replenished as needed. Both paddy and field soil cores under wet conditions (33% and 20% of water content, respectively) showed NPP equal to or higher than D flux throughout the period. Under dry conditions, NPP remained equal to or higher than that on the first day of incubation until moisture content dropped to 20% in paddy soil cores and 12% in field soil cores, after which NPP decreased further when moisture content dropped to 7.4%. After rewetting, NPP increased within a few hours in both paddy and field cores, reaching a maximum in 4 days in paddy and 2 days in field cores. NPP at this point was equivalent to that before soil drying proceeded. When soil moisture content decreased again, NPP decreased, as it did during the initial drying conditions.

These results demonstrate that photosynthesis by soil algae contributes significantly to the carbon balance of agricultural soils. Algal photosynthetic activity closely tracks soil respiration and moisture levels, tolerates moderate desiccation, and recovers rapidly after rewetting, indicating adaptive responses to fluctuating soil water conditions.

## ABSTRACT

Cover crops and no tillage are recognized for mitigating greenhouse gas (GHG) emissions and enhancing carbon storage, yet their effects on the net GHG balance remain uncertain. This study evaluated the impacts of tillage and cover crop management without chemical fertilizers on greenhouse gas budget (GHGB), and GHG intensity (GHGI) in Hokkaido, Japan. Study period was from September 2023 to September 2024. Four treatments were established: conventional (C), tillage without fertilizers (TNF), no tillage without fertilizers (NTNF) and no tillage without fertilizer with rye cover (NTNFR). Bark manure (3.75 t $ha^{-1}$) was applied to all plots on September 28, 2023, and inorganic fertilizer (15:110:80 $N:P_2O_5:K_2O$) was used only in C. Rye used as green manure in NTNFR was terminated in soil surface before soybean sowing. Emissions of $CO_2$ from heterotrophic respiration (Rh) from bare plot, $CH_4$, and $N_2O$ were measured throughout experiment using static closed chamber. GHGB was calculated as the sum of global warming potentials (GWP) of Rh, $CH_4$, and $N_2O$ emissions, plus carbon output from soybean grain and weed, minus carbon inputs from net primary production (NPP) of weed, soybean, rye, and inputs from seed and bark manure.

Soybean yield did not significantly differ among treatments. Annual GWP was not significantly different, though values tended to be higher in TNF (19.2 Mg $CO_2$-eq $ha^{-1}$) and lower in C (14.6 Mg $CO_2$-eq $ha^{-1}$), likely due to higher Rh in TNF (5.10 Mg C $ha^{-1}$) versus C (83 Mg C $ha^{-1}$). Higher Rh in TNF compared to C likely attributed to significant positive correlation with water content in both TNF and C which may have accelerated the Rh in higher soil water condition. Nutrient limitations in the TNF may have reduced plant biomass, in turn reducing transpiration demand. This conserved soil moisture compared to C, created more favorable conditions for microbial activity, stimulating higher Rh in TNF. Although GHGB did not differ significantly, values were numerically higher in TNF (12.6 Mg $CO_2$-eq $ha^{-1}$), followed by NTNF (11.2 Mg $CO_2$-eq $ha^{-1}$), NTNFR (8.97 Mg $CO_2$-eq $ha^{-1}$), and C (8.45 Mg $CO_2$-eq $ha^{-1}$). Lower annual Rh in C contributed to lower GHGB, while higher $GWP_{CO_2}$ in TNF likely contributed to greater GHGB. GHGB tended to be lower in the NTNFR, possibly due to reduced NPP of soybean associated to N immobilization by high C:N rye, which suppressed soybean growth. Reduced soil disturbance under no tillage, with high C:N rye mulch, might slow organic matter decomposition, contributing to lower GHGB. Results suggest that integrating cover crop, such as rye, under no tillage management is essential for reducing GHGB. However, GHGI tended to be lower in C and higher in NTNF, suggesting lower and higher yield efficiency in each management, respectively. To mitigate GHG emissions in these systems, adopting slow decomposing organic amendments (biochar), integrating compost or manure, and optimizing cover crops or weed management is recommended.

# Coupling expression of nitrifying and denitrifying genes induce high $N_2O$ emissions in strong ammonia oxidizing soils

## ABSTRACT

Ammonia oxidation contributes to nitrous oxide ($N_2O$) emissions both by direct production and by fueling denitrification. Urea or ammonia-based fertilizers account for about 70% of annual nitrogen fertilizer use globally. Soil ammonia oxidation and its coupled processes are therefore significant contributors to $N_2O$ emissions. However, the mechanism of microbial activities underpinned the coupled processes leading to $N_2O$ production remains unclear. Here, by using a robotized incubation and gas monitoring system (Robot) and meta-genomic and transcriptomic technique, we studied the dynamic and relationship of $O_2$ consumption, gas production ($N_2O$, nitric oxide NO, nitrogen $N_2$), gene expression of nitrification and denitrification and composition of active microorganisms in an alkaline agricultural soil of Northern China, which has a strong ammonia oxidizing rate and is a global $N_2O$ hotspot. The results showed that, in the ammonium application treatment, the rapid consumption of $O_2$ in the soil was accompanied by the production of NO and $N_2O$. Especially in the period of aerobic to anaerobic transition, the production of NO and $N_2O$ showed an increase of nearly 5 times. In the ammonium with ammonia oxidizing bacteria (AOB) inhibitor treatment, the $O_2$ consumption of soil decreased to the same level as that of control treatment. The production of NO and $N_2O$ was almost completely inhibited. Nitrogen application caused simultaneous expression of nitrification (amoA, amoB, and hao) and denitrification (nirK, narG, and narH) genes in the early aerobic phase, and increased expression of denitrification (nirS, norB, and nosZ) genes in the late anoxic phase. Moreover, the expression of some genes activated in the early stage (such as hao, narG and narH) remained until the late stage, which was consistent with the high emission of $N_2O$. AOB inhibitors significantly inhibited the gene expression in the early aerobic stage (amoA, amoB, hao, nirK, narG and narH) and the late anoxic stage (norB), but the inhibitory effect on amoA, amoB and nirK genes gradually decreased with the extension of culture time. This indicates that the consumption of soil $O_2$ by strong ammonia oxidation is an important driving force of $N_2O$ production, with subsequent coupled processes such as hydroxylamine oxidation-reduction, nitrite reduction, nitrate reduction, and nitric oxide reduction occurring synchronously. Coupled expression of nitrification and denitrification genes during $O_2$ consumption was a major reason for the high $N_2O$ emissions from strong ammonia oxidation. Our results provide new evidence for understanding the microbial mechanism of high $N_2O$ emission caused by strong ammonia oxidation.

# Effects of Elevated $CO_2$ Concentrations and Temperature on Soil Inorganic Nitrogen and Greenhouse Gas Emissions in Winter Wheat

**ABSTRACT**

The response of greenhouse gas emissions from farmland soils to climate change is a prominent issue in the realm of agricultural adaptation to climate change. This experiment investigated the effects of elevated $CO_2$ concentration and temperature on greenhouse gas emissions from winter wheat soil. Measurements included the contents of nitrate nitrogen and ammonium nitrogen in the winter wheat soil under conditions of elevated $CO_2$ concentration (600 μmol/mol) and elevated temperature (ambient temperature +2°C), as well as greenhouse gas emission fluxes and cumulative seasonal emissions. The global warming potential (GWP) and greenhouse gas emission intensity (GHGI) for the growing season were calculated in conjunction with winter wheat yield. The results showed that under elevated $CO_2$ concentration and temperature, soil nitrate nitrogen content increased significantly at the jointing stage. Soil ammonium nitrogen content increased to varying degrees across three growth periods under these conditions. Compared to the control (T0C0), the cumulative seasonal $CO_2$ emissions under warming alone (T1C0), elevated $CO_2$ alone (T0C1), and the combined treatment (T1C1) increased by 20.73%, 22.18%, and 23.28%, respectively. However, the cumulative seasonal $N_2O$ emissions increased significantly only under T0C1, while decreasing by 26.35% and 18.41% under T1C0 and T1C1, respectively, compared to T0C0. The cumulative seasonal $CH_4$ uptake under T1C0 decreased significantly by 93.56% compared to T0C0, while T0C1 and T1C1 had no significant effect. The winter wheat yield under T1C0 decreased significantly by 19.93% compared to T0C0, whereas it increased by 15.36% and 9.88% under T0C1 and T1C1, respectively. The GWP under T1C0, T0C1, and T1C1 increased significantly compared to T0C0. The GHGI increased significantly under T1C0 compared to T0C0, while it decreased under T0C1 and T1C1, though not significantly. In summary, under conditions of elevated $CO_2$ concentration and temperature, the cumulative seasonal emissions of $CO_2$ and $N_2O$ changed to varying degrees, while the cumulative seasonal $CH_4$ uptake decreased significantly under warming treatment. The projected GWP from the three greenhouse gases in the wheat field is environmentally unfavorable. This study provides an estimation of greenhouse gas emissions from northern wheat fields under conditions of elevated $CO_2$ and temperature, offering theoretical support for formulating future agricultural emission reduction measures.

# Evaluation of Greenhouse Gas Emission Characteristics by the Use of Organic Resources and No-Tillings in Organic Agricultural-Based Corn Plantations

**Da-Eun Kim[1], Young-Don Lee, and Jin-Ho Joo***

*[1] Kangwon National University, (Department of Biological Environment, Kangwon National University, Chuncheon 24341, Korea)*

* jhjoo@kangwon.ac.kr

**ABSTRACT**

As climate change driven by global warming accelerates, the world is facing an increasingly severe climate crisis. These changes are primarily attributed to the continuous increase in greenhouse gases ($CO_2$, $CH_4$, $N_2O$), among which agriculture is recognized as a major emission source. Although agriculture is essential for food production, excessive fertilizer use and agricultural machinery operations substantially contribute to greenhouse gas emissions. Consequently, developing field-applicable management practices that reduce greenhouse gas emissions from the agricultural sector is a critical challenge for climate change mitigation. No-tillage systems reduce emissions by minimizing soil disturbance, and their mitigation potential is further enhanced when combined with organic amendments. However, comparative evaluations of greenhouse gas emissions and carbon balance under no-tillage conditions using conventional mineral fertilizers and diverse organic amendments remain limited.

This study was conducted in an organic maize field located in Sinbuk-eup, Chuncheon, Korea. Six treatments were established under no-tillage conditions: Control, NPK, Oil_Cake, Compost, Oil_Cake+Green manure (OG), and Compost+Green manure (CG). Greenhouse gas emissions were measured weekly using the static closed chamber method with three replicates per treatment and analyzed using gas chromatography. Based on the measured emissions, Total Global Warming Potential (Total GWP), Net Global Warming Potential (Net-GWP), Net Ecosystem Carbon Balance (NECB), and Greenhouse Gas Intensity (GHGI) were calculated.

Under no-tillage conditions, all organic amendment treatments exhibited lower Total GWP compared to the NPK treatment, with CG showing the greatest reduction. Net-GWP values were more negative in organic amendment treatments, indicating net carbon uptake, and the highest carbon sequestration was observed in CG. NECB was also higher in organic amendment treatments than in the NPK treatment, again peaking in CG. GHGI was lowest in the CG, demonstrating the highest efficiency in reducing greenhouse gas emissions per unit yield.

These results indicate that under no-tillage conditions, cropping systems utilizing organic amendments (NPK, Oil_Cake, Compost) are more effective than conventional mineral fertilizer systems in reducing greenhouse gas emissions, lowering GWP, and improving ecosystem carbon balance while maintaining productivity. In particular, the CG treatment showed the most favorable overall performance. As practical agricultural systems often rely on integrated management strategies rather than single practices, further research is needed to evaluate combined effects of diverse organic amendments and tillage systems.

# $N_2O$ fluxes after application of organic and mineral fertilizers to acidic tea soils in Kenya

**Smith, T.L.[1], Burgess, P.J.[1], Otten, W.[1], McKenna P.[1], Wanyoike, G.[2], Tuwei, G.[2], Sakrabani, R.[1], Girkin, N.[3], Mayr, A.[4]**

## ABSTRACT

Kenya is the world's largest tea exporter; the relatively consistent warm and wet climate in the western highlands region allows year-round tea production. Tea plants are grown in acidic soil conditions (pH < 5.0) and typically receive high annual applications of nitrogen (N) fertilizer, in part to replenish the N removed in the harvested leaves. Because the production and application of N fertilizer produce most of the greenhouse gas emissions associated with tea production, there is interest in new methods of meeting the nutritional requirements of tea with lower environmental impacts.

A meta-analysis of fertilizer-induced nitrous oxide ($N_2O$) emissions from tea soils, using data primarily from China and Japan, found a mean fertilizer-induced $N_2O$ emission factor (EF) of 2.31% (Wang et al., 2020) which is notably higher than the standard IPCC $N_2O$ wet-climate EF of 1.6%. However, in a recent paper, we used an established process-based crop-soil model predicting that tea soil acidity suppresses the nitrification-denitrification pathway, leading to lower $N_2O$ emissions (Giannitsopoulos et al., 2023). Hence, the aim of this study is to determine the actual $N_2O$ emissions under field conditions from acidic tea soils in East Africa.

In 2024, we established a field-based experiment in the Kericho region of Kenya, which was designed to examine environmental performance and yield of five fertilizer types: two organic pelletized compost fertilizers, two mineral fertilizers (urea and NPK), and a novel carbon-capture based organo-mineral fertilizer (OMF). These five fertilizers were tested at six different rates (0-450 kg N $ha^{-1}$ yr-1) to explore dose-responses. The five fertilizer treatments had varying carbon-to-nitrogen ratios, and during 2024-2025 the effects of fertilizer application on $N_2O$ emissions were determined using a portable Gasmet analyser.

In contrast to our model predictions, the field observations indicated that $N_2O$ emissions from four of the five fertilizer types were broadly consistent with an EF of 1.6%, although this varied with application rate. This presentation will quantify the observed incremental $N_2O$ emissions across fertilizer types and rates when applied to acidic Kenyan tea soils. It will also propose how these results can be used to update our existing process-based model of $N_2O$ production pathways in acidic soils. This combination of plot-scale measurements with modelling of C and N interactions can therefore be used to create new guidelines to support climate-smart tea production in acidic agroecosystems.

# Microbial phosphorus cycling: A key driver of $CO_2$ emission in phosphorus-supplied subtropical forest soils

**ABSTRACT**

Subtropical forests are key global soil organic carbon (SOC) sinks, whose stability is important for mitigating global climate change. Current understandings indicate that phosphorus (P) availability could promote SOC decomposition by alleviating microbial P limitation. However, it is uncertain if this mechanism holds across soils or field-scale P supply levels in acidic subtropical forests where SOC is held stable by iron (Fe) oxides. We formulated an alternative mechanism that: P supply increases its competitive capacity for Fe-binding sites, leading to SOC desorption as dissolved organic carbon (DOC). The DOC satisfies the enormous microbial C need during P cycling to drive $CO_2$ emissions. We utilized a forest P-addition platform to test our hypothesis across four P supply levels: 0, 25, 50, and 100 kg P $ha^{-1}$ $yr^{-1}$, for one year. We found that increasing P supply significantly increased DOC release, Fe-bound P formation, and microbial biomass P (MBP), but not microbial biomass C. The significantly positive relationship between available P and DOC, and between MBP content and $CO_2$ emission, indicated that the released DOC alleviates microbial C need induced during P acquisition, thereby driving $CO_2$ emission. Mixed-effect and multivariate models identified MBP as the primary driver of $CO_2$ emissions. In addition, the insignificant alterations in C-degrading genes and reductions in C-degrading enzyme activity with P supply indicated the sufficiency of the released DOC for microbial use without further significant SOC degradation. Our study provides an alternative mechanism by which P regulates soil C cycling in acidic subtropical forest soils, offering critical insights for improving process-based C models.

# The Carbon-Iron Coupling Mechanism of Organic Carbon Turnover in the Rice Root Zone Under Redox Gradients

**Yan Li[1*], Siyang Liu[1,2], and Jinshui Wu[1]**

## ABSTRACT

In paddy soils, the root zone is a hotspot of carbon cycling, where turnover is governed by redox conditions and iron. Yet, how iron mediates organic carbon (OC) mineralization and transformation across these redox gradients remains unclear. We therefore established a simplified rhizosphere microcosm system by using soil columns equipped with artificial roots. Four redox potential gradients of the soil column were constructed by adjusting water conditions (60%, 80%, and 100% of soil water saturation, plus 3 cm flooding), and $^{13}C$-labeled glucose or oxalic acid were used as model root exudates for investigating the iron-mediated OC allocation and transformation. The results showed that: (1) Both soil redox potential (Eh) reduction and exogenous carbon input significantly increased the cumulative emissions of $CH_4$ and $CO_2$. Under 100% saturation and flooding conditions, the incremental emission of $CH_4$ was significantly higher than that of $CO_2$ in glucose- and oxalic acid-amended treatments, and vice versa in the unsaturated water content. Compared with glucose, oxalic acid treatment under flooding conditions induced negative priming effects on both $CH_4$ and $CO_2$ during the early incubation stage. (2) Exogenous carbon inputs elevated the dissolved organic carbon (DOC) content under 60% of soil water saturation. DOC aromaticity responded oppositely to decreasing Eh, it increased under glucose treatment but decreased under oxalic acid treatment. The $^{13}C$-DOC pool displayed a unimodal temporal pattern, reaching its maximum concentration at day 20. A positive correlation was observed between soil Eh and SOC content in all exogenous carbon amendment treatments. The incorporation of $^{13}C$ into the SOC pool was significantly more pronounced with glucose addition relative to oxalic acid. The oxalic acid treatment stimulated the generation of iron-bound OC (Fe-OC), predominantly through the pathway of $^{13}C$ enrichment within the Fe-OC fraction. (3) The activities of carbon cycle hydrolase and oxidase were significantly affected by the redox gradient and simulated rhizodeposited carbon input. Cellobiohydrolase activity decreased with decreasing Eh and showed a negative correlation with $CH_4$+$CO_2$ emission rates. Moreover, phenol oxidative activity was higher in the saturated water treatments than in the unsaturated water treatments and was positively correlated with the rate of gas emission. Glucose and oxalic acid addition significantly increased the activities of phenol oxidative activity and catalase oxidases. Both the “iron gate” and “enzyme latch” mechanisms synergistically regulated $CH_4$ and $CO_2$ emissions. The findings provide critical parameters and a scientific basis for predicting rhizodeposited carbon sequestration potential in subtropical iron-rich paddy soil, and optimizing water management strategies to enhance carbon storage and mitigate greenhouse gas emissions in rice cultivation systems.

**ABSTRACT**

Soil structure regulates the production and emission of nitrous oxide ($N_2O$) from soils mainly through influencing substrate availability and gas transport, which are strongly intertwined with soil moisture. However, the interaction between soil structure and water content in controlling $N_2O$ emissions remains inadequately quantified. This study conducted laboratory incubation experiments with disturbed (sieved) and undisturbed (intact) soil cores under different soil moisture levels (i.e., 40, 60, 80 and 100% water filled pore space (WPFS)). Soil carbon dioxide ($CO_2$) and $N_2O$ fluxes were continuously monitored during the 21-day incubation period, during which $O_2$ concentration profile was occasionally measured and relative soil gas diffusivity was measured at the end of experiments. The results show that the $N_2O$ fluxes from the disturbed soil cores were 2~25 times higher than those from the undisturbed cores, which are similar to field observations. Nevertheless, the difference in the relative soil gas diffusivity between them was not obvious, especially under high moisture conditions. Therefore, the overestimated soil $N_2O$ emission from sieved soil experiments was attributed to increased substrate availability caused by disturbance rather than changes in gas diffusivity. An additional finding of a significant exponential correlation between $N_2O$ and $CO_2$ flux under the same moisture condition, regardless of whether the soil was sieved or intact, further demonstrated that the key impacts of physical protection of organic carbon and thus $O_2$ consumption on soil $N_2O$ emission. Overall, this study highlighted the physical protection of soil aggregates on carbon sequestration and $N_2O$ mitigation.

# Coupling of nocturnal water vapor and $CO_2$ uptake in arid soils: Comparative analysis from three arid soils

**Thuc T. Nguyen[1*], Nadav Bekin[1], Nurit Agam[1] and Elad Levintal[1]**

[1] *The Jacob Blaustein Institutes for Desert Research, Ben-Gurion University of the Negev, 84990, Israel*

*nguyan@post.bgu.ac.il

**ABSTRACT**

Nocturnal water vapor absorption and $CO_2$ uptake by dry soils are widely observed phenomena in arid ecosystems. Although empirical evidence suggests a correlation between these processes, the nature of their relationship, whether causal or coincidental, remains unclear. One hypothesis is that water vapor absorbed at night provides sufficient moisture for $CO_2$ dissolution and subsequent reactions with soil carbonates, thereby facilitating $CO_2$ uptake. Alternatively, $CO_2$ fluxes may be governed by physical processes, such as diurnal temperature-driven air expansion and contraction. Understanding the link between water vapor absorption and $CO_2$ uptake is crucial for understanding hydrological–carbon cycle interactions in drylands and improving predictions of global carbon dynamics. However, direct evidence of water vapor input influencing $CO_2$ uptake is limited. In this study, we combine field work and modeling to examine the role of water vapor input in driving $CO_2$ uptake by comparing (1) two sites with similar soil textures but differing distances from the sea, and (2) two sites with similar proximity to the sea but different soil textures. Our results showed that the site closer to the sea absorbed more water vapor and exhibited greater $CO_2$ uptake. In contrast, although the site with finer-textured soil absorbed more water vapor, it did not show greater $CO_2$ uptake. These results suggest that the mechanisms governing $CO_2$ uptake may vary across sites. While geochemical processes modulated by water vapor absorption could be a major mechanism, other mechanisms—such as thermal convection—may play a significant role, particularly in soils with higher permeability.

*[2]Hubei Jianghan Plain Scientific Observation and Research Station of Farmland Ecosystem, Central China Normal University, Wuhan 430079, China*

*yijun@ccnu.edu.cn

**ABSTRACT**

Rice paddies are a globally significant agricultural ecosystem: they supply a major portion of human food and play an important role in regional and global carbon cycles and greenhouse-gas budgets. Climate change strongly regulates the farmland carbon cycle, yet the influence of extreme temperature events on carbon fluxes across subtropical Chinese farmland remains poorly characterized. Our objectives are to quantify how heatwaves (*HW*), Drought, and their co-occurrence modulate water and carbon fluxes in subtropical paddy fields. Continuous meteorological and eddy-covariance observations (2021–2024) were coupled with XGBoost-SHAP analyses, generalized additive models (*GAMs*), and nonparametric tests, including the Kruskal-Wallis test (net ecosystem exchange (*NEE*) $p < 0.01$; ecosystem respiration (*Re*), water-use efficiency (*WUE*), evapotranspiration (*ET*) $p < 0.001$; gross primary productivity (*GPP*) not significant), to identify dominant drivers, nonlinear thresholds, and flux responses under four climatic regimes (Normal, HW, Drought, HW-Drought). The paddy system acted as a persistent carbon sink, with strong NEE uptake and annual cumulative NEE of−492.10、−463.10、−547.26 and −532.73 g C $m^{-2}$ in 2021–2024 rice growth period. Compound HW-Drought events substantially weakened sink strength: mean daily NEE was least negative under HW-Drought (−3.59 ± 4.79 g C $m^{-2}$ $d^{-2}$) versus Normal (−6.31 ± 4.03 g C $m^{-2}$ $d^{-1}$), while RE increased and GPP remained comparatively stable. ET rose and WUE declined under compound stress (ET in HW-Drought = 5.97 ± 0.97 mm $d^{-2}$; WUE: Normal = 3.09 ± 0.97 vs HW-Drought = 2.43 ± 0.42 g C $kg^{-2}$). XGBoost-SHAP captured major flux variability (NEE $R^2 = 0.933$; Re $R^2 = 0.801$; ET $R^2 = 0.906$) and identified incoming solar radiation (*Rg*) as the primary control on NEE and ET, with air temperature (*Ta*) and soil volumetric water content (*SWC*) dominating Re. GAMs fitted to SHAP responses revealed nonlinear thresholds (e.g., Rg ≈ 116 W $m^{-2}$ and RH ≈ 67% for NEE; Ta breakpoints and SWC ≈ 0.425 $m^3$ $m^{-3}$ for Re) where predictor effects reversed sign. Overall, compound hot-dry extremes may disproportionately boost respiration relative to photosynthesis, potentially reducing carbon sequestration while increasing evaporative loss. We discuss adaptive field management (precision water regulation, heat-/drought-tolerant cultivars) to bolster paddy resilience and sustain carbon-sink function under intensifying extreme climate regimes.

# No tillage reduces nitrous oxide emissions in Winter and early Spring globally

**Mengyang Wang[1], Yixuan Zhang[1], Jiahao Yang[1], Chuxin Xie[1] Tingyu Cui[1], Jinbo Li[1]***

[1]* *College of Resources and Environment, Northwest A & F University, Yangling Shaanxi, China*

*jinbo.li@nwafu.edu.cn

## ABSTRACT

As a core Climate-Smart Agriculture (CSA) practice, conservation tillage significantly mitigates nitrous oxide ($N_2O$) emissions. Although freeze-thaw cycles during winter-early spring trigger substantial $N_2O$ pulse emissions, the mitigation potential of conservation tillage during this period remains unquantified. Through a global meta-analysis of 62 publications, this study demonstrates that: (1) Conservation tillage (no-till and reduced tillage) reduced $N_2O$ emissions by 16% during the winter-early spring period; (2) No-till achieved a significant reduction of 18%, whereas reduced tillage showed no statistically significant effect; (3) Climatic factors (mean and minimum temperatures of the coldest quarter), soil properties (soil texture and SOC), and the duration of no-till implementation were identified as key factors influencing the mitigation efficacy of no-till. In contrast, precipitation in the coldest quarter and nitrogen input exhibited no independent effects, likely suppressed by seasonal low temperatures. This study provides valuable data to support the development of $N_2O$ mitigation frameworks in agricultural systems and contributes to informing effective strategies for controlling global agricultural $N_2O$ emissions and mitigating the greenhouse effect.

# Organic amendments regulated the pattern and product stoichiometry of nitrate reduction processes in arable soils

**Zhijun Wei[1]*, Hua Xu[1], and Xiaoyuan Yan[1]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China*

*zjwei@issas.ac.cn

**ABSTRACT**

Organic amendments are widely recognized for improving soil health and multifunctionality in agroecosystems, yet their effects on nitrate reduction pathways and associated soil greenhouse gas emissions remain poorly understood. We show that organic amendments in upland arable soils increased the contribution of fungal denitrification to total $N_2O$ emissions while lowering the $N_2O/(N_2O+N_2)$ ratio, primarily by strengthening fungal–bacterial mutualistic interactions among denitrifiers. The magnitude and partitioning of $N_2O$ and $N_2$ emissions were further regulated by soil nitrate availability. In flooded paddy soils, biochar application significantly reduced $N_2O$ fluxes and $N_2O/(N_2O+N_2)$ ratios, driven by shifts in the abundance and composition of nitrate-reducing microbial communities. Biochar simultaneously increased denitrification and dissimilatory nitrate reduction to ammonium (DNRA) rates, and shifted more $NO_3^-$ partitioning toward DNRA process. These effects were mainly attributable to enhanced carbon availability and altered nitrate-reducer community structure. Collectively, our results demonstrate that organic amendments in arable soils can mitigate the environmental impacts of nitrogen fertilization by regulating nitrate reduction pathways, thereby advancing our mechanistic understanding of nitrogen cycling in agroecosystems.

# Root Exudate Chemistry Drives Divergent Carbon Fates in Rice Paddies

**Kaiye Ye**[1*]

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Changshu National Agro-Ecosystem Observation and Research Station, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China.*

*Yekaiye@issas.ac.cn

**ABSTRACT**

Paddy ecosystems play a dual role in climate change, acting as significant sources of methane ($CH_4$) emissions while possessing substantial carbon sequestration potential. Root exudates, the primary carbon input, critically influences both soil organic carbon (SOC) stability and $CH_4$ emission, yet the underlying mechanisms remain poorly understood. This study employed continuous $^{13}C$ labeling of two contrasting rice cultivars, a conventional japonica (CXJ) and a hybrid japonica (HZY), to trace the flow of root carbon and its impact on $CH_4$ dynamics. A key finding was that the cultivar with higher biomass and root carbon input (HZY) did not result in elevated $CH_4$ emissions.

Metabolomic profiling of root exudates revealed fundamentally divergent strategies. CXJ roots were enriched in the glyoxylate and dicarboxylate metabolism pathway, leading to secretion of labile organic acids like citric acid. These compounds rapidly decompose in soil to provide acetate, a direct precursor for methanogenesis, explaining the higher $CH_4$ emissions in CXJ. In contrast, HZY roots exhibited a coordinated “chemical suppression” strategy, with enrichment in pathways for glucosinolate and cyanoamino acid. The associated exudates, such as isothiocyanates, thiocyanates, and riboflavin, may divert microbial electron flow towards competitive processes like sulfate reduction, potentially mitigating the emission risks from its substantial carbon input. The distinct fate of root carbon was corroborated by soil $^{13}C$ partitioning. Soils under HZY accumulated more $^{13}C$ in the mineral-associated organic carbon (MAOC) fraction, indicating a direct, abiotic pathway to stabilization. Correspondingly, soils under CXJ showed greater $^{13}C$ enrichment in microbial residual carbon, indicating an indirect, microbially mediated pathway that first fuels microbial growth and turnover before entering the stable pool.

Our results demonstrate that root exudate chemistry critically determines the fate of root carbon, either promoting its long-term mineral stabilization or facilitating its microbial conversion to $CH_4$. Targeting root exudate profiles that promote biochemical suppression of methanogenesis and direct mineral association could enable the dual goals of enhancing soil carbon storage and reducing greenhouse gas emissions from paddy ecosystems.

# Contrasting warming responses of anaerobic microbial communities explain variation in methane Q10 across paddy soils

## ABSTRACT

Rice paddies are among the largest anthropogenic sources of methane ($CH_4$), yet large uncertainties remain in predicting how $CH_4$ production responds to warming across different climatic regions. In particular, the microbial processes underlying variation in the temperature sensitivity (*Q10*) of $CH_4$ production are still poorly constrained. To address this, we investigated warming responses of anaerobic $CH_4$ production and associated microbial functions in paddy soils originating from contrasting mean annual temperature (MAT) regimes.

Soils were collected from four rice-growing regions in China spanning low (4–9°C) and high (14–16°C) MATs and incubated anaerobically at 15°C and 30°C. $CH_4$ production, dissolved organic carbon, and fermentation products were quantified, and microbial communities were characterized using quantitative PCR, amplicon sequencing, genome-resolved metagenomics, and metatranscriptomics.

Methane production showed consistently higher *Q10* values in soils from low-MAT regions, whereas soils from high-MAT regions exhibited stronger warming-induced changes in microbial composition and functional gene expression. Across all soils, higher *Q10* values coincided with lower abundances of genes involved in polysaccharide depolymerization, hydrogenotrophic methanogenesis, and reduced average genome size, indicating limited microbial capacity for rapid carbon turnover. In contrast, pathways related to fermentation and acetate metabolism became relatively more prominent at higher *Q10* values. Transcripts associated with methylotrophic methanogenesis declined under warming in all soils, while acetoclastic and hydrogenotrophic pathways responded differently depending on MAT origin.

Together, these results show that variation in the temperature sensitivity of $CH_4$ production reflects differences in how anaerobic microbial communities process organic carbon under warming, rather than uniform temperature effects. Accounting for microbial functional organization across climatic gradients is therefore critical for improving predictions of soil methane emissions in a warming climate.

## ABSTRACT

Nutrient-enriched biochars could add value to raw biochars by enhancing nitrogen bioavailability. However, their effects on greenhouse gas emissions (GHG) from soil and crop growth in boreal regions remain unclear. We aimed to investigate the impacts of three different types of activated biochar: cattle slurry-enriched biochar ($BC_{org}$), mineral fertilizer-enriched biochar ($BC_{min}$), and pure water-activated biochars ($BC_{wat}$), on GHG emissions, including carbon dioxide ($CO_2$), nitrous oxide ($N_2O$), and methane ($CH_4$) from a fertile boreal Stagnosol with a clay loam texture. For this purpose, we added activated biochars to a long-term biochar field experiment (est. 2010) at the University of Helsinki's research farm in Helsinki, Finland. The initial experimental design consisted of three separate split-plot field experiments (subfields) in the same field area, each with four replications, with biochar rates of 0, 5, and 10 Mg/ha added to the main plots, and different N fertilizer levels (30%, 65%, or 100% of the recommended level) applied to the subplots. A similar setup was now used in our study, except that we added 15 Mg/ha of activated biochars to plots that had previously received 5 Mg/ha. Thus, each subfield was treated with one type of activated biochar, followed by a three-year crop rotation of barley (2023), faba bean (2024), and spring wheat (2025). Emissions of $CH_4$, $CO_2$, and $N_2O$ were measured 8 times after sowing, using a closed chamber method with two cylindrical metal chambers installed on plots treated with new biochar and on control plots. Upon sampling, a 2 × 5 mL gas sample was drawn and injected into a pre-evacuated gas vial at 0, 20, and 40 minutes after closing the chamber. The temperature inside each chamber was recorded. The concentrations of $CH_4$, $CO_2$, and $N_2O$ in the collected samples were determined by a gas chromatography system (Agilent 7890B GC System). Average $CO_2$ emissions were highest in 2023 compared to 2024 in all treatments, due to the freshly added biochars in 2023. $BC_{wat}$ resulted in decreased $CO_2$ emissions ($p < 0.05$) only during the early vegetative growth phase (2-3 weeks after sowing) in both years. The slight reductions in mean $CO_2$ emissions by $BC_{min}$ were mostly not significant except for a week in June 2024 following a period of heavy rain. Average $CO_2$ emissions were generally reduced by the addition of $BC_{org}$ ($p < 0.05$, in 3-4 weeks after sowing) in 2023, but increased in 2024. Mean $N_2O$ emissions were generally lower in 2024, because faba bean required less fertilizer input relative to barley (2023). $BC_{org}$ and $BC_{min}$ increased $N_2O$ emissions in 2023 (p-values < 0.05) during the early vegetative phase only (1-3 weeks after sowing), but no significant effects were observed in 2024. Adding $BC_{wat}$ did not affect $N_2O$ emissions. Emissions of $CH_4$ were generally not affected by any of the treatments. The full results on the impact of the differently activated biochars on GHG emissions will be detailed in the poster.

# Inhibition and the mechanisms of ethene on methanogen

**ABSTRACT**

Anaerobic environments function as both a source and a sink within the global methane cycle, with microbially produced methane contributing over half of the annual atmospheric methane emissions. During bioremediation of chlorinated ethenes contamination, substantial ethene accumulation occurs, and almost inhibited methanogenesis, which are key processes in anaerobic systems. This study systematically elucidates the inhibitory mechanism of ethene on methanogenesis, employing *Methanosarcina barkeri* Fusaro as a model methanogen, and methanogenesis consortia enriched from river sediments. We demonstrate a clear dose-dependent and pathway-specific inhibition by ethene. In pure culture, ethene selectively suppressed acetoclastic methanogenesis compared with methylotrophic methanogenesis. Without ethene, methane production by *M. barkeri* Fusaro peaked at 956.2 ± 111.4 μmol by day 25. At 0.33% ethene in the gas phase, the methanogenesis period extended to 50 days without significant reduction in final yield. Increasing ethene to 1.67% reduced methane production to 189.63 ± 61.42 μmol over 60 days, while 3.33% ethene completely inhibited activity throughout the incubation of 100 days. Proteomic analysis indicated that at 0.83% ethene in gas phase, expression of the acetyl-CoA decarbonylase/synthase complex (CODH) and the methyl-coenzyme M reductase alpha subunit (McrA), which are key enzymes in the acetoclastic methanogenesis pathway were up-regulated by approximately 22-fold and 2-fold, respectively, concurrent with a prolonged methanogenesis period. This suggests ethene likely disrupts enzymes activity, potentially via interaction with nickel/iron sulfur cofactors. In sediment-free microcosms (fourth transfer), the ethene-free cultures reached maximum methane production (5080.4 ± 250.2 μmol) by day 7. In contrast, with 6.67% ethene, production peaked later (day 20) at a lower level (3945.2 ± 354.4 μmol), indicating suppression of both the rate and total yield of methanogenesis. Ethene also markedly shifted methanogens community structures: methylotrophic methanogens (e.g., *Methanomethylovorans*) declined, whereas hydrogenotrophic methanogens (e.g., *Methanosarcina*) became more dominant. These findings deepen our understanding of environmental stress responses in methanogens and offer a scientific basis for evaluating and mitigating ecological risks during anaerobic bioremediation of organohalide contamination sites.
