Unravelling the antibiotic resistance in nature is crucial for predicting and mitigating its worldwide impacts amidst rapid global change. While biological factors are considered as crucial drivers of ecological processes. However, their roles in driving the evolution of antibiotic resistance, a global health concern, remain poorly understood in complex natural soil ecosystems. Whereas predatory protists and predatory bacteria are primary predators of bacteria, we have poor understanding about mechanisms underlying the influence of the bacterivorous predators on bacterial antibiotic resistance within a multitrophic soil ecosystem. Here, through quantitative PCR and amplicon sequencing, we assessed effects of soil predatory protists on predatory bacteria and antibiotic resistance genes (ARGs) across a gradient of protist concentrations under the control of bacteria's competitors – fungi. Our findings reveal that high-protist predation significantly increased the relative abundance of dominant predatory bacteria between days 15 and 45 of the microcosm incubation. Aligning with a rising abundance of predatory bacteria and antibiotic-producing bacteria, the relative abundance and diversity of soil ARGs significantly increased under high protist concentrations, regardless of fungal effects. Many ARGs encoding key antibiotic deactivation and efflux pumps were enriched in response to predatory protists within complex inter-group interactions. Moreover, these enriched ARGs were strongly associated with both predatory bacteria and predatory protists. More profound effects of predatory protists on predatory bacteria and soil ARGs were identified in the presence of fungi. Our study provides novel evidence about crucial effects of predatory protists on shaping the predatory bacterial community and driving bacterial antibiotic resistance under complex multitrophic interactions in a natural soil. These findings pave the way for future research aimed at mitigating this global health issue and uncovering other ecological processes.

# Soil Health Under Climate Change Era: Restoration Strategies using Nanobiotechnology and Soil Engineering

**Vishnu D. Rajput* and Tatiana Minkina**

*Academy ofBiology and Biotechnology, Southern Federal University, Rostov-on-Don, Russia*

* E - mailrvishnu@ sfedu. ru

**ABSTRACT**

Past few decades, due to intensive agriculture cultivation, the soils are getting huge amount of chemical-based fertilizers/pesticides, which is directly/indirectly affecting the soil microbiota; especially rhizospheric microbiome. These soil microbes are playing significant role to help plants to uptake nutrient, make unavailable elements to available form, and responsible for decomposition to enhance soil fertility. Soils are not only suffering with agro-chemical inputs, but it also facing various abiotic-abiotic stresses, including heavy metals and emerging contaminates accumulation such as nanoparticles, microplastics, pharmaceuticals and personal care products. The organic matter is continuously decreasing, and soil are losing its fertility and productivity. Due to the population explosion under this climate change era, to achieve the "Zero Hunger" goal in sustainable way is a challenging issue. It is necessary to solve the fundamental tasks that are of frontier importance for soil science today. The recent research developments, and combination of various emerging technologies such as nanotechnology, carbon or biochar materials, genomic, synchrotron, neutron, microbiome and metabolome, and genome editing tools open new avenue to restore soil health via soil engineering; especially rhizospheric microbiome. Thus, our focus on research is to edit soil rhizospheric microbiome and study its responses, determine dynamics, nature and features of interactions in the soil-microbe-plants system. To analysis of the processes occurring in rhizosphere in presence of nanoparticles, nanofertilizers and nanocarbon materials using synchrotron-neutron methods and NBIC (Nano-, Bio-, Information, and Cognitive) technologies to improve the soil fertility, to restore degraded soils, artificial soil system. Analyzed the processes and mechanisms of interphase interactions between the surface of soil particles, plant roots and microbes with the participation of nanoparticles. The structure and functions of the rhizosphere, and the possibilities for optimize its condition is critical to design the artificial ecosystem. Thus, the advanced technologies that is capable to decode the biological and ecological processes, and interactions in rhizosphere system were used such as genomic, synchrotron, neutron tomography methods and computer modeling with microscopic methods. The neutron computed tomography helped to construct a 3D combined image ofthe rhizosphere structure at the micro-level, whereas, omics technologies characterized the microbiome and metabolome ofthe rhizosphere.

# Dynamics of Native Low Molecular Weight Organic Substances (LMWOS) and Their Relationship to Soil Quality Indices in Gray Lowland Soil

**Nuanaon Nobchulee[1*], Yoshinaga-Kiriake Aya[2] Kihara Shunta[2], and Nihei Naoto[1,2]**

*[1] Soil and plant Multi-Dynamics Research Unit, Fukushima Institute for Research, Education and Innovation(F-REI), Fukushima, Japan*

*nobchulee.nuanaon.t6r@research.f-rei.go.jp

**ABSTRACT**

Low molecular weight organic substances (LMWOS) specifically carbohydrates, organic acids (OAs), and amino acids (AAs) in an agricultural soil system are recognized as integral components of soils together with inorganic constituents. However, their fundamental dynamics remain poorly understood. Although numerous studies have reported that LMWOS influence crop growth, systematic evaluations of their dynamics and storage characteristics in soils from the perspective of sustainable soil fertility management are still limited.

In this study, we investigated changes in LMWOS dynamics induced by rewetting and their relationships with soil microbial communities and soil quality indices. Gray lowland soil, a widely used agricultural soil type was air-dried, debris removed and subjected to a controlled rewetting process by adjusting the moisture content to 60% of the maximum water holding capacity (WHC). The sample were then incubated at 27°C to monitor the basal fluctuations of organic LMWOS at specific time intervals. To track these native LMWOS, Gas Chromatography-Mass Spectrometry (GC-MS) was employed to analyze water-extractable carbohydrates, OAs, and AAs.

The results of the 14-day incubation revealed that the LMWOS dynamics varied significantly over time, with particularly rapid changes in carbohydrate and OAs concentrations occurring within the first few days after the onset of incubation. To further evaluate the relationship between these LMWOS dynamics and soil health, quality indices were quantified using standard laboratory protocols: pH was measured in a soil-water suspension; total carbon (TC), total organic carbon (TOC), and total nitrogen (TN) were determined using an elemental analyzer; free $NH_4^+$ was analyzed following soil extraction; and microbial biomass carbon (MBC) was measured via the fumigation-extraction method. In addition, next-generation sequencing (NGS) analysis of soil microbial communities is currently underway. This integrated approach provides a mechanistic basis for understanding soil fertility regulation under fluctuating moisture conditions.

**ABSTRACT**

Biochar use as a soil amendment can improve soil functions, enhances microbial activity, and increases crop production. However, due to its high sorptive capacity, it may interfere with traditional methods for determining soil microbial biomass, specifically chloroform fumigation-incubation (FI) and fumigation-extraction (FE). This study aimed to assess the impact of biochar on microbial biomass determination using traditional methods and a new $CO_2$ high pressurization (CO2HP) technique. Five treatments were set up: unamended soil (control), and soil amended with two types of biochar, produced at 440 °C (B440) or 880 °C (B880), at two application rates (20 or 40 t $ha^{-1}$). Following cell lysis by fumigation or CO2HP, released microbial C ($\Delta C_{mic}$) was estimated by determining microbial respiration over a 10-d incubation (FI and CO2HP-I methods, respectively) or by extracting soluble organic C (FE, and CO2HP-E, respectively), while released microbial N ($\Delta N_{mic}$) was estimated by determining extractable total N exclusively by FE and CO2HP-E methods.

Without biochar, $\Delta C_{mic}$ estimates were similar across FE, FI, and CO2HP-E methods. Contrarily, CO2HP-I method greatly overestimated $\Delta C_{mic}$ compared to the other three methods, particularly at the higher biochar rate, suggesting that the adsorption of $CO_2$ within biochar pores during CO2HP treatment and subsequent slow release during incubation could have produced artifacts. The presence of B880 resulted in a decrease in $\Delta C_{mic}$ values, which might have been caused by an acclimation of microbial biomass to new habitat. Contrarily, the addition of B440, increased $\Delta C_{mic}$ when determined by the FE method, compared to FI and CO2HP-E methods. This suggested an overestimation of extractable C after fumigation, possibly due to adsorption of $CHCl_3$ by the B440 biochar, rich in functional groups, that might have bound $CHCl_3$. We concluded that biochar interfered with the determination of $\Delta C_{mic}$and $\Delta N_{mic}$ as a function of both type and amount added.

**ABSTRACT**

Earthworms are widely recognized as "ecosystem engineers" due to their crucial roles in organic matter decomposition, soil structure formation, and nutrient cycling. Earthworm casts impact the soil environment through aggregate formation, thereby enhancing water retention, stimulating microbial activity, facilitating nitrogen mineralization, and carbon storage. Previous studies have shown that presence of earthworms promotes soil aggregate formation, increases organic carbon and nitrogen contents, and enhances soil enzyme activity and microbial diversity. However, most studies have focused on single species or treated earthworms as a functional group, with few examining how species-specific differences influence soil functions. Comparative studies focusing on earthworm species distributed in Japan are still limited, leaving many aspects unexplored. This study aims to clarify species-specific differences in earthworm effects on soil modification functions by examining multiple species.

Miyakejima and Mikurajima, which represent different stages of ecosystem development, were selected as study sites for the rearing experiments. Collected earthworm individuals were reared individually for two weeks under controlled conditions using soil from their native habitats. After the rearing period, species identification was conducted based on morphological observation, and DNA analysis performed by an external laboratory. Soils containing earthworm casts were collected and analyzed for total nitrogen and organic carbon content, exchangeable cation, and water-stable aggregate to evaluate the physicochemical properties of the soil. In addition, three-dimensional visualization of cast internal structure was conducted using micro-X-ray computed tomography, enabling non-destructive analysis of the pore structure and the spatial distribution of organic matter and minerals in soil aggregates collected at earthworm sampling sites.

Results showed that total nitrogen content was higher in soils influenced by earthworm individuals collected from Miyakejima and Mikurajima compared to the control. While total organic carbon content did not increase uniformly across individuals, several individuals exhibited higher values than the control. Water-stable aggregate analysis revealed that for earthworms collected from both Miyakejima and Mikurajima, the proportion of aggregates smaller than 2 mm increased after rearing experiment compared to the control, while the proportion of aggregates between 0.25 and 0.5 mm decreased. Although body size is considered to influence soil modification functions to some extent, the results of this study suggested that other factors, including species-specific differences also play an important role.

In summary, by integrating soil biological, chemical, and physical analysis of soil properties, this study provides a comprehensive evaluation of species-specific earthworm-driven soil modification mechanisms.

* carlos. lozanofondon@ crea. gov. it

## ABSTRACT

In this study, we conducted a pedological and ecological assessment of a *Tuber Magnatum Pico* (i.e., white truffle) productive area where silvicultural management activities have been carried out, to track the response of the soil community. The aim was to identify biological proxies for soil health monitoring in white truffle productive areas, in addition to production itself.

The most frequent tree species in the area of interest, white and black poplars, have been subject to a succession of silvicultural interventions carried out in 2000, 2018, 2020, and 2021. In October 2021, three months after the last silvicultural intervention, a soil survey was conducted. Four homogeneous-management plots were identified along the river section where the area of interest is located. Two soil pits were described and classified as Calcaric Fluvic Cambisols with two different hydromorphic phases. Five sampling points were defined at each plot. We determined the soil parameters such as soluble carbon and nitrogen, organic matter, and carbonates; the soil microarthropod community, the microbial biomass using the dsDNA technique, and enzymatic activities such as arylsulphatase, β-glucosidase, chitinase, leucine, acid and alkaline phosphatases, bis-phosphatase, and inorganic pyrophosphatase. Multivariate linear modelling, together with comparative community analyses, was applied to the soil biological dataset. An effect of the silvicultural management was identified across the four plots. The plot where the most recent intervention was performed always showed higher rates of biological activity in all the biogeochemical cycles considered (i.e., C, N, S, and P). Overall, microbial biomass and P-cycle-related enzymatic activities were strongly associated. The plot intervened in 2020 showed the lowest soil biological activity, as well as the most unbalanced microarthropod community composition (i.e., taxa presence vs. taxa abundance), which is related to disturbed environments, as supported by scientific literature. In addition, truffles release substances that inhibit vegetation development; they can also affect the development of soil communities. In fact, when considering soil biogeochemical variables instead of soil properties when performing constrained correspondence analysis (CCA) on the microarthropod community, most of the 50% of the total variance is accounted for by the first two ordination components. This is proof of the high importance of trophic interconnections and ecological relationships shaping biological communities within the soil. Moreover, fungivorous taxa were more frequently found in samples from unbalanced communities and in higher-productivity plots. Similarly, predators were almost absent across all communities, which is associated with ecosystem imbalances. Finally, a strong relationship between the microarthropod community, arylsulphatase, and pyrophosphatase was identified.

## ABSTRACT

Soil nematodes play key roles in various soil processes, such as carbon and nutrient cycling, and the regulation of microbial activities. Their effects are often studied by comparing sterilized soils (nematode-free) with soils reinoculated with nematodes in microcosms, although these approaches frequently introduce unintended effects on soil properties, microbial communities, and plants, complicating causal inference and effect size estimation. An optimal partial sterilization method should selectively remove nematodes while minimizing unwanted side effects, yet systematic evaluations of the efficiency and side effects of commonly used methods remain limited. This study evaluated the effectiveness of dry heat, microwaving, freeze-thaw cycles, and gamma irradiation for selective nematode removal. Our results show that only freeze-thaw cycles (-80 °C to 22 °C, 72 h each) and microwave irradiation (135 s, 800 W) were highly effective for a sandy loam soil (700 g 1.4 g/cm$^3$, 50% water filled pore space), reducing nematode abundances in bare soil after two weeks and in planted soil after eight weeks to levels statistically indistinguishable from zero. The repeatability and side effects on soil physicochemical and microbiological properties of these two methods were then tested in soils with light (loamy sand) and heavy (silt loam) textures, compared to complete sterilization by autoclaving and an unsterilized control. No nematodes were detected in the microwaving and autoclaving treatments after six weeks of incubation, while 0.2% and 2.0% of the free-living nematodes observed in the control persisted in the freeze-thaw treatment in loamy sand and silt loam soils, respectively. Freeze-thaw and microwaving caused milder alterations to soil physicochemical properties than autoclaving. Leaching and soil powder inoculation significantly mitigated the increased mineral nitrogen content and suppressed microbial biomass carbon in all sterilized treatments, while enzymatic activities remained unaffected. Finally, a germination assay with *Lactuca sativa* assessing phytotoxic effects of these treatments on seedling emergence and early growth showed that the microwaving treatment resulted in similar seedling emergence compared to the control in both loamy sand and silt loam soils, while the autoclaving treatment showed only 47% or no germination in loamy sand and slit loam soils. In conclusion, microwaving emerged as the most promising technique, achieving complete nematode removal while minimizing adverse side effects, offering a practical tool for studying the functional roles of soil nematodes.

*Rafael.borges.valadares@itv.org

**ABSTRACT**

Soil health is a multidimensional concept rooted in the integrated functioning of biological, chemical, and physical processes. However, current assessment frameworks often underrepresent the biological dimension, frequently relying on proxy measures that lack functional specificity. We propose a diagnostic approach that elevates biological indicators to the same analytical depth as physicochemical attributes, utilizing high-throughput molecular tools to directly decode soil microbial functionality. We developed a scalable soil health panel that unifies multi-proxy data within a function-oriented framework. This methodology enables the direct quantification of biological processes central to soil ecosystem services, such as nutrient cycling, carbon stabilization, and plant-microbe interactions. Biological data are derived from high-throughput omic techniques, where functional genes are curated and mapped to ecosystem-relevant categories: carbon and nitrogen dynamics, phosphorus mobilization, sulfur cycling, and stress-response mechanisms. A key innovation is the operational scalability and organizational workflow of the framework. By automating pipelines and increasing throughput, we significantly reduced per-sample costs and enhanced reproducibility. This optimization democratizes access to advanced molecular diagnostics, making the tool viable for both landscape-scale revegetation projects and smallholder farmers. The panel is currently deployed across diverse contexts, including large-scale restoration programs (500,000 ha), land restoration initiatives, regenerative agriculture, and integrated crop-livestock-forestry (ICLF) systems. Results demonstrate the framework's sensitivity as an early-warning system: in ICLF and regenerative areas, we observed a significant increase in C-fixation related genes, reflecting enhanced metabolic potential for carbon sequestration. In restoration sites, functional indicators captured early belowground recovery—specifically shifts in microbial nutrient cycling and symbiotic potential—well before changes in vegetation or bulk soil chemistry became detectable. By placing biology on equal footing with chemistry and physics through rigorous, scalable molecular diagnostics, this approach offers an actionable understanding of soil health. The framework supports resilient land

## ABSTRACT

Elevated $CO_2$ alters rhizosphere carbon inputs and microbial activity in wheat, yet it is unclear whether these responses are consistent across genetically distinct wheat lineages and rhizosphere compartments. We compared fungal community composition and nutrient-cycling enzyme activities in the inner and outer rhizosphere of seven ancient wheat varieties and one modern variety grown under ambient and elevated $CO_2$ (+300 ppm) using an open-top chamber field system. Across genotypes, the inner rhizosphere maintained a relatively stable fungal community dominated by Ascomycota under elevated $CO_2$, showing limited compositional change. In contrast, the outer rhizosphere exhibited pronounced shifts in fungal composition, particularly in Basidiomycota and Mucoromycota, together with stronger beta-diversity responses, indicating higher sensitivity to elevated $CO_2$ and greater genotype-dependent variation. Elevated $CO_2$ generally reduced leucine aminopeptidase and β-glucosidase activities across varieties, consistent with increased carbon availability and relative nitrogen limitation. However, several ancient wheat varieties maintained higher β-glucosidase activity or showed enhanced alkaline phosphatase activity, indicating distinct nutrient acquisition strategies under carbon-enriched conditions. These results demonstrate that $CO_2$ responses of the wheat rhizosphere are strongly compartment-dependent and vary among genetic lineages, with ancient wheat varieties showing greater functional flexibility under elevated $CO_2$.

[*]batutan70@gmail.com

**ABSTRACT**

To assess the functional diversity of the microbiome, we employed Community Level Physiological Profiling (CLPP) assay—multisubstrate testing (MST) using the Eco-Log system (Russian analog of BiologTM assay) based on standard analitical protocols [1]. The samples were prepared and analyzed according to previously described methods [2].

The study involved a sample from the upper horizon (0–20 cm) of agro-sod-podzolic soil (Albic Glossic Retisols (Loamic, Aric Cutanic, Ochric) in the Chashnikovo Training and Experimental Soil Ecology Center (Solnechnogorsk municipal okrug, Moscow oblast).

Several functional biodiversity indicators were used. These are includes the number of substrates consumed (N) in a range from 0 to 47 that represents here the functional biodiversity index, average metabolic work (W), calculated by summing the non- zero optical densities of cells with substrates consumed dividing by their amount; and the rank distribution shape coefficient of the substrate utilization spectra (d), which applies as a measure of system destabilization or perturbation, with values ranging from 0.01 to 2.00. In the microbial systems studied, the d coefficient serves as a valuable indicator of the health and stability of the soil microbial community, with lower values indicating a thriving and stable community. Conversely, higher values of the coefficient indicate the presence of a disruptive factor affecting the microbial system. Based on the d coefficient, microbial communities can be classified as either good (d = 0.01–0.4), depressed (d = 0.4–0.8), stressed (d = 0.8–1) or damaged (d >1) according to the classification proposed by. Pot experiments were conducted in which *Avena sativa* was grown in sod-podzoic soil contaminated with the antibiotics tylosin, tetracycline, and ciprofloxacin. Uncontaminated soil served as a control. The pots were uniformly illuminated, and the soils were maintained at identical moisture levels. Two months after planting, an analysis was conducted.

Of the antibiotics studied, tylosin proved to be the most characteristic. Soils treated with this antibiotic formed a distinct cluster in a cluster analysis of the spectrum of consumed substrates, suggesting the formation of a specifically functioning community when exposed to this antibiotic. Soils treated with tetracycline and ciprofloxacin did not show a clear specificity. However, tylosin even slightly increased the total metabolic activity of the community, as well as functional biodiversity and stability (changed from 0,6 to 0.1) while other antibiotics had no such effect.

**ABSTRACT**

Environmental pollution with antibacterial drugs has become one of the most pressing issues. Beyond the widely studied mechanisms of resistance spread and horizontal gene transfer, which necessitate the development of new drugs for effective treatment, there exists a less studied problem of the ecological impact of antibiotics on soil biological health.

Vegetation experiments were conducted, growing *Avena sativa* on sod-podzolic soil contaminated with antibiotics: tylosin (concentration 3.33 mg/kg), tetracycline, and ciprofloxacin (at concentrations of 33.3 mg/kg). Soil without antibiotics served as the control. The vegetation vessels were uniformly illuminated, and identical moisture levels were maintained in all soils. Two months after sowing, enzymatic soil analysis was performed for peroxidase activity [1] and urease activity [2], which are traditional soil bioindicators. Basal and substrate-induced soil respiration were also measured, based on which microbial biomass and metabolic coefficients (q$CO_2$) of the soil under oat cultivation were calculated. Growth parameters of the oats (dry biomass, plant length) were measured. Statistical analysis was performed using the F-test criterion at $\alpha$=0.05.

Microbial biomass in the soil contaminated with tylosin decreased by 4.4%, whereas contamination with tetracycline stimulated it by 6.4%. Ciprofloxacin did not significantly affect microbial biomass. However, the metabolic quotient q$CO_2$ (the ratio of basal to substrate-induced respiration of soil microorganisms) differed only in the ciprofloxacin treatment and was 0.098 compared to 0.131 in the control, indicating a stimulatory effect of ciprofloxacin. Tetracycline inhibited soil enzymatic activity. Peroxidase activity was 13.37% lower, and urease activity was 40.7% lower compared to the control. Tylosin, in contrast, stimulated peroxidase activity (by 31.4%), while urease activity slightly decreased (by 5.3%). Ciprofloxacin stimulated peroxidase activity (by 40.6%) but, like tylosin, inhibited urease activity by 19.7%. The growth parameters of oats showed significant differences under tylosin and tetracycline contamination. Ciprofloxacin did not have a significant effect on plant growth and development.

From the obtained data, we can conclude that antibiotics have a complex effect on soil and plants. In some cases, stimulation of a parameter is observed, while in others, its inhibition occurs.

## ABSTRACT

Soil-borne pathogens in grassland soils threaten livestock productivity and ecosystem stability. Understanding pathogen distributions and the drivers shaping their population dynamics is thus critical for ecosystem health and management. Here, we surveyed 244 sites across China's natural grasslands and used absolute quantitative amplicon sequencing to quantify soil-borne fungal pathogens in 985 soil samples. We found that temperature strongly shapes the richness, relative abundance, and absolute abundance of soil-borne pathogens. In addition to temperature, relative and absolute pathogen abundance were further moderated by distinct drivers, with relative abundance primarily shaped by plant species richness and absolute abundance by soil properties. We further mapped the current and future distributions of soil-borne pathogens under different climate scenarios, identifying geographically distinct hotspots for different measures of pathogen pressure (*i.e.*, diversity and relative/absolute abundance). Our findings highlight that pathogen richness, relative abundance, and absolute abundance are governed by distinct ecological processes, and we argue that integrated multi-metric assessments are essential for accurate disease risk predictions and to guide adaptive grassland management under climate change.

# Coupling of Intraspecific Root Traits and Rhizosphere Fungal Communities in Cynodon dactylon across Hydrological Gradients of a Reservoir Drawdown Zone

**Xiaoxiao Wang[1]*, MeiFeng Luo[1], KunShan[1], Ping Huang[1]**

*1 State Key Laboratory of Lake and Watershed Science for Water Security, Chongqing Institute of Green and Intelligent Technology, Chinese Academy of Sciences, Chongqing 400714, China*

**ABSTRACT**

Background and Aims Root traits are key predictors in shaping plant-fungal relationships. However, the potential influence of intraspecific root functional traits on plant adaptation, as well as on rhizosphere fungal communities and functional guild dynamics in response to hydrological gradients, remains poorly characterized.

Methods We conducted an in situ field investigation across reservoir riparian zones, quantifying intraspecific root traits, including morphological and architectural traits, and sequencing the rhizosphere fungal community of the dominant species *Cynodon dactylon* (L.) Pers. This study investigated how intraspecific root functional traits correlate with changes in rhizosphere fungal community along hydrological gradients.

Results Our study revealed intraspecific divergence in *C. dactylon* root traits across hydrological gradients, demonstrating a resource collaboration axis spanning from a 'do-it-yourself' ('DIY') strategy characterized by high specific root length to an 'out-sourcing' strategy with thickened roots and elevated root tissue density. The shifts in root traits aligned with opposing microbial responses—general rhizosphere fungi proliferated along the 'DIY' axis at lower elevations, whereas AMF abundance was positively associated with 'out sourcing' traits at higher elevations. Root traits collectively demonstrated stronger explanatory power over AMF community assembly compared to general fungal communities, with root average diameter, fractal abundance and branching rate emerging as key predictors of symbiotic specificity.

Conclusion *C. dactylon* shifts root strategies from 'DIY' to 'out-sourcing' along hydrological gradients, promoting general fungi at low elevations and AMF at high elevations. Root diameter, fractal abundance, and branching rate critically shape AMF assembly, highlighting trait-mediated fungal adaptation. Our findings underscore intraspecific root trait variation as a critical lever through which plants regulate rhizosphere processes, with implications for understanding microbial functions in rhizosphere and the selection of plants for enhanced soil ecosystem services.

**ABSTRACT**

Cereal–legume intercropping is widely recognized as an environmentally sustainable agricultural practice. It enhances soil biodiversity by increasing the heterogeneity of root exudates, resource availability, and microhabitats, which may influence fungal communities inhabiting soil and plant tissues as components of the holobiont. Understanding how such systems shape fungal communities across plant-associated niches is essential for evaluating their ecological functioning.

Fungal alpha diversity showed a strong niche-dependent pattern, with the highest diversity in bulk soil, followed by the rhizosphere, and markedly lower diversity in roots and especially in aboveground plant tissues. In bulk soil, diversity was highest under barley monocropping, lower under pea monocropping, and intermediate under intercropping. A similar pattern was observed in the rhizosphere. In roots and shoots, fungal diversity was clearly reduced and showed only minor differences among cropping systems. Overall, alpha diversity decreased along the soil–plant continuum, indicating strong host filtering with weak modulation by cropping system.

Beta diversity analyses revealed clear differentiation in fungal community composition among niches, with cropping system effects varying by compartment. Across all niches, fungal communities differed markedly between soil-associated habitats (bulk soil and rhizosphere) and plant-associated habitats (roots and shoots), with additional modulation by cropping system.

In bulk soil and the rhizosphere, fungal communities were dominated by saprotrophic and soil-associated genera, particularly *Mortierella*, *Fusarium*, *Gibellulopsis, Didymella*, and *Cladosporium*. They were only weakly influenced by crop identity. Under intercropping, the rhizosphere showed a more even distribution of dominant genera, indicating increased compositional heterogeneity.

Root-associated fungal communities were more strongly shaped by host selection and were dominated by *Fusarium*, *Gibellulopsis*, *Didymella*, and *Cladosporium*. Differences among cropping systems were more pronounced in roots, with intercropping exhibiting a more balanced dominance structure than monocropping.

Aboveground fungal communities were highly simplified and clearly distinct from those in the belowground compartments, dominated mainly by *Alternaria*, *Cladosporium*, *Didymella,* and *Bipolaris*. Cropping system effects were most potent in shoots, where intercropping promoted a more even community structure, while cereal monocropping showed stronger dominance of individual genera. These results indicate that pea–barley intercropping can subtly reshape fungal community composition, particularly in plant-associated compartments, potentially enhancing microbial heterogeneity in agroecosystems.

# Regulation of selenium uptake and translocation and hyphal contribution rate in soybean by co-inoculation with AMF and Rhizobium

**Shenghao He[1], Jiao Li[1*]**

[1] School of Resources and Environment, Northeast Agricultural University, Harbin, 150030, PR China

*E-mail address: lijiao0829@126.com

**ABSTRACT**

Selenium (Se) is a beneficial trace element that plays an important physiological role in plant growth. Arbuscular mycorrhizal fungi (AMF) and *Rhizobium* are common symbiotic microorganisms in the soybean rhizosphere. However, under inoculation conditions, the contribution of the AMF hyphal pathway to Se uptake and its uptake and translocation mechanisms remain poorly understood. In this study, a rhizobox experiment was conducted with three inoculation treatments: non-inoculation (NM), single inoculation with *Funneliformis mosseae* (*F.m*), and co-inoculation with *Funneliformis mosseae* and *Rhizobium* (*F.m+Rh*), combined with four selenite application levels: (1) no selenite addition to either the rhizosphere or hyphal compartments (0-0-0); (2) selenite addition only to the rhizosphere compartment (0-Se-0); (3) selenite addition only to the hyphal compartment (Se-0-Se); and (4) selenite addition to both compartments (Se-Se-Se). The results showed that exogenous selenite application and co-inoculation significantly increased the photosynthetic rate of soybean, promoted root growth, and enhanced nutrient uptake, thereby markedly improving plant growth ($p < 0.05$). At the same selenite level, Se concentrations in both the shoots and roots of soybean under the co-inoculation treatment were significantly higher than those under single AMF inoculation (5.74%-6.69%) and NM treatment (13.44%-15.77%; $p < 0.05$). Selenite application to the hyphal compartment significantly increased Se uptake by soybean, indicating that AMF hyphae were able to cross the rhizobox barrier and effectively acquire Se from the hyphal compartment. Notably, under single AMF inoculation, the contribution of the hyphal pathway to Se uptake ranged from 7.12% to 8.28%; whereas under co-inoculation with *Rhizobium* and AMF, the synergistic effect of *Rhizobium* significantly enhanced the Se uptake capacity of the AMF hyphal pathway, increasing its contribution to 12.84%–14.31%. Overall, the synergistic interaction between AMF and *Rhizobium* markedly enhanced the contribution of the hyphal pathway to Se uptake in soybean. This study offers new insights into the systematic understanding of Se uptake and transport mediated by the mycorrhizal hyphal pathway, and provides theoretical support for improving Se utilization efficiency and advancing sustainable production of Se-enriched soybeans.

# Driving Mechanisms of Antibiotic Resistance Genes in Urban Forest Soils

**ABSTRACT**

Urban forest soils play a critical role in maintaining urban ecosystem services but are increasingly subjected to anthropogenic pressures, including contamination by heavy metals and polycyclic aromatic hydrocarbons (PAHs). Understanding how urbanization shapes soil biogeochemical processes, microbial community structure, and the propagation of antibiotic resistance genes (ARGs) is essential for assessing ecosystem health and risks. This study investigated the spatial patterns of soil chemical properties, heavy metals, PAHs, nutrient cycling functional genes (C, N, P), ARGs, and bacterial communities across urban-suburban gradients in urban forest soils. Results showed acidic soil conditions (pH < 7) across all sites, with urban centers exhibiting higher levels of nutrients (K, Ca), while cation exchange capacity (CEC) and total organic carbon (TOC) were significantly elevated in suburban areas. A clear urbanization gradient was observed in heavy metal accumulation: Zn and Pb were most enriched at site S, Cr peaked at site G, and V and Ni concentrations were higher in urban (R, G) than in suburban (S, M) sites. No significant spatial variation was detected for arsenic (As), and PAH concentrations did not differ significantly between urban and suburban zones, although residential areas showed the highest concentrations for most PAHs.

A total of 198 ARG subtypes associated with 20 antibiotic classes were detected. Multidrug resistance genes were the most abundant, followed by genes conferring resistance to macrolides-lincosamides-streptogramines, vancomycin , bacitracin, and beta-lactams . Efflux pumps were the predominant resistance mechanism. Significant differences in ARG composition were observed along the urbanization gradient (PERMANOVA: $R^2 = 0.359$, $p = 0.001$), with the highest Shannon diversity at site M and the lowest at site U. Bacterial alpha diversity was higher in suburban areas, and community structure differed across the gradient, governed mainly by stochastic assembly. Potential ARG hosts were primarily Acidobacteria and Proteobacteria, with Acidobacteria more abundant in suburban zones. ARGs were positively correlated with As but negatively correlated with PAHs (Phe, Chr, BbF). Furthermore, PLS-PM analysis indicated that ARGs were collectively influenced by heavy metals, PAHs, keystone taxa, and nutrient cycling genes, with heavy metals and keystone taxa promoting ARG abundance, while PAHs exhibited an inhibitory effect.

In conclusion, urbanization significantly alters soil biogeochemical properties, microbial functional potential, and ARG dissemination in urban forest ecosystems. The interplay between heavy metals, PAHs, keystone bacterial taxa, and nutrient cycling genes collectively modulates ARG dynamics. These findings underscore the need for integrated management strategies to mitigate contamination and preserve soil ecological functions in urban forests.

# Urbanization-driven forest soil greenhouse gas emissions: Insights from the role of soil bacteria in carbon and nitrogen cycling using a metagenomic approach

**ABSTRACT**

The escalation of greenhouse gas (GHG) emissions from soils, driven by rising population densities and urban sprawl, underscores the critical role of soil microbial communities in urban forests in both the production and consumption of GHGs, thereby supporting sustainable green development. However, the functional roles and underlying mechanisms of soil bacteria in regulating GHG emissions from forests during urbanization remain insufficiently understood. In this study, we quantified the fluxes of carbon dioxide ($CO_2$), methane ($CH_4$), and nitrous oxide ($N_2O$) from Cinnamomum camphora forest soils along an urbanization gradient. Using 16S rRNA amplicon sequencing and metagenomic approaches, we systematically analyzed the structure and potential functions of soil bacterial communities involved in carbon (C) and nitrogen (N) cycling.

Our results demonstrated that $CH_4$ and $CO_2$ emissions were significantly higher in urban forest soils (sites U and G) compared to suburban soils (sites S and M). Notably, $N_2O$ emissions at the urban center (site U) exceeded those at the other three sites by 24.0% (G), 13.8% (S), and 13.5% (M). This emission pattern was closely associated with increased bacterial alpha diversity, enhanced microbial interactions, and elevated abundances of C- and N-cycling genes, particularly those involved in denitrification. Furthermore, soil pH and metal content (K, Ca, Mg) influenced the distribution of key bacterial taxa (e.g., Methylomirabilota, Acidobacteriota, and Proteobacteria) and functional genes (e.g., napA, nosZ, nrfA, nifH) implicated in $N_2O$ reduction. Heavy metal content (Fe, Cr, Pb) emerged as a primary driver of $CH_4$ emissions, likely through modulation of methanogenic (e.g., Desulfobacterota) and methanotrophic (e.g., Proteobacteria, Actinobacteriota, Patescibacteria) bacterial communities.

This study further reveals that the structure and function of soil microbial communities play a crucial regulatory role in GHG emissions. Urbanization-induced changes in environmental factors, such as nutrient inputs, heavy metal accumulation, and alterations in soil physicochemical properties directly affect microbial metabolic pathways and indirectly influence C and N transformation processes by reshaping inter-species interaction networks. Consequently, scientifically informed urban planning and near-nature forest management strategies that optimize soil microbial community structure and enhance carbon sequestration and nitrogen conversion efficiencies may serve as effective approaches to mitigate urban GHG emissions and promote sustainable urban development. These findings provide a theoretical foundation and practical guidance for microbial-mediated low-carbon management of urban forest ecosystems.

# Can soil protists improve plant growth?

**Thi Bao-Anh Nguyen[1], Hang-Wei Hu[1]**

[1] *School of Agriculture, Food and Ecosystem Sciences, Faculty of Science, The University of Melbourne, Parkville, VIC, 3010, Australia.*

*E-mail: thibaoanh.nguyen@unimelb.edu.au

**ABSTRACT**

Plant-associated microbiome is considered to play a crucial role in enhancing plant nutrient cycle, plant growth promotion, plant disease suppression and stress tolerance. However, we still lack knowledge about roles of soil protists in plant growth. Here, we elucidate effects of soil protists on plant growth and their association with bacterial communities by growing tomato plants in an agricultural soil inoculated with soil protists via a pot experiment. Our results reveal that protists significantly promoted the plant growth of tomato. Soil protists increased plant length and dry weight, as well as alpha diversity (Shannon index) of bacteria. These protists are strongly associated with plant-beneficial bacterial taxa in performing their functions. Novel findings in this study advance our understanding about the importance of protists in soil and plant microbiomes, implicating potential applications of beneficial protists and bacteria as biofertilizers or bio-stimulants to improve crop performance and sustain agricultural production in future.

*c.freeman@bangor.ac.uk

**ABSTRACT**

Peatlands and other wetlands store a disproportionate share of the Earth's soil carbon because primary production has long outpaced microbial decomposition under waterlogged conditions. The enzymic latch hypothesis, proposed in 2001, offered a mechanistic explanation: environmental constraints such as $O_2$ availability, suppress phenol oxidase, allowing phenolic compounds to accumulate and inhibit key hydrolase enzymes, thereby "locking" organic matter into place. Over the subsequent twenty-five years, this concept has significantly shaped thinking, experimentation, and management strategies in wetland biogeochemistry.

This talk will first revisit the original evidence for the latch and its extension from northern peat bogs to fens, marshes, and mangrove soils, where phenolic inhibition and redox constraints have been invoked to explain high carbon storage and distinctive greenhouse gas fluxes. It will then synthesise a growing body of work that refines or challenges the hypothesis, including studies that find only mixed or ecosystem-specific links between phenolics, enzyme activities, and decomposition, or that highlight the controlling roles of pH, plant functional groups, and microbial community composition. Finally, it will consider how the enzymic latch framework has informed peatland restoration and "engineering" approaches, such as rewetting, phenolic amendments, and mineral interventions, and assess what this means for predicting wetland feedbacks to climate change in a future of altered hydrology, salinity, and disturbance regimes.

# Nonlinear response of anaerobic methane oxidation to water table drawdown in peatlands under climate warming

**Lichao Fan[1*], Xiaodong Xu[1]**

[1] *Northwest A&F University (College of Natural Resources and Environment, 712100 Yangling, Shaanxi, China)*

lcfan@nwafu.edu.cn

**ABSTRACT**

Anaerobic oxidation of methane (AOM) is a significant but underappreciated methane sink in global wetlands, yet its mechanistic response to hydrological gradients due to climate warming and drought remains poorly unexplored. Using $^{13}CH_4$-labelled microcosm incubations in peat soils across water-table depth (WTD, from 15-45 cm) and temperature gradients (5, 15, 25°C), we observed that AOM rates increased with increased WTD irrespective of incubation temperature, that reached a peak AOM rate (1.68 ± 0.25 μg C $g^{-1}$ peat $d^{-1}$) at ~30 cm WTD, thus decline sharply beyond this depth. Random forest and mixed linear models illustrated this phenomenon was driven by the substrate availability, alternative electron acceptor content (Fe(III)), and microbial metabolic activities (RT-qPCR data). Thermodynamic assessment indicates that the 30 cm WTD also represented the threshold for AOM temperature responsiveness; deeper drainage shifts it into a diffusion-limited regime, with higher $Q_{10}$ values reflecting an "energy-compensation paradox". Moreover, combing with a global meta-analysis across water-table gradients in peatlands, that corroborated the nonlinear response of AOM to water table decline. We are the first to uncover an eco-thermodynamic threshold mechanism whereby WTD regulates AOM, thereby providing critical insights for improving methane-cycle models and informing peatland management and restoration.

## ABSTRACT

**Background:** The extensive invasion of *Spartina alterniflora* across the Chinese coast poses a major ecological threat [1,2]. Although its successful expansion often faces the widespread phosphorus (P) limitation common in coastal wetlands [3], the intrinsic physiological and ecological mechanisms supporting its persistent survival and expansion in low-P environments—particularly whether its soil P acquisition strategy has undergone adaptive shifts—remain unknown.

**Methods:** To systematically reveal the biogeochemical mechanisms underlying its invasion success, we conducted a large-scale comparative study spanning nearly a 20° of latitude across its native (North America, 15 sites) and invaded ranges (China, 10 sites). This study is the first to analyze the adaptive mechanisms of *S. alterniflora* from an integrated perspective of "soil P forms—plant P-acquisition strategies—resource allocation trade-offs." We adopted a sequential biologically-based-phosphorus (BBP) fractionation method to quantify the composition of the soil bioavailable P pools by simulating rhizosphere processes (such as carboxylates exudation, enzymatic hydrolysis, and proton secretion), and combined this with the analysis of plant traits and environmental factors to explore the intrinsic link between P-acquisition strategies and growth-reproduction.

**Results:** The soil total phosphorus (TP), inorganic phosphorus, and active P fractions (especially citrate-P) in the Chinese invaded wetlands were significantly lower than those in their native North American salt marshes, confirming the typical P-limitation characteristic of China's coastal wetlands. However, contrary to the low-nutrient background, the proportion of total BBP-extracted P in the invaded soil was significantly higher than that in the native range (+24.5%), and this proportion showed a significantly increasing trend with increasing latitude. This difference primarily stems from the substantial portion of sparingly soluble mineral-bound HCl-P (accounting for 83.6% of TP) in the invaded soil, whereas the native range was dominated by the more labile citrate-P (accounting for 40.6%). This shift demonstrates that *S. alterniflora* can convert sparingly soluble P into available P through mechanisms such as rhizosphere acidification and enzymatic mineralization, thereby forming a "low stock-high efficiency" resource acquisition strategy. Plant trait—soil P fraction association analysis further indicated that the invaded populations exhibit a significantly different P utilization—trait response pattern compared to the native populations. Within the invaded range, $CaCl_2$-P and HCl-P significantly promoted seed set rate, with weaker promoting effects on above-ground biomass and plant height; conversely, in the native range, growth was primarily promoted by more labile P such as citrate-P, with a weak correlation to reproduction. This suggests that in the invaded wetlands, *S. alterniflora* prioritizes the allocation of mobilized P to reproductive organs rather than sustaining high biomass production. As latitude increases, the proportion of HCl-P significantly rises, and the strong correlation between seed set and HCl-P indicates that, in high-latitude soils dominated by mineral-bound P, *S. alterniflora* enhances its ability to mobilize recalcitrant P and preferentially allocates the acquired P to reproduction. This mechanism provides a clear explanation for the “higher reproductive output at higher latitudes” observed along the Chinese coast. This "P-mining" strategy—enables it to secure offspring dispersal and population expansion in P-limited environments, thus constituting the core physiological and ecological mechanism of its invasion success.

**Conclusion:** In summary, this study revealed the key mechanisms underlying the successful invasion of *S. alterniflora* in China's coastal wetlands: (1) The invaded area is characterized by soil background features of strong P fixation and low P bioavailability, with its P pool dominated by the sparingly soluble mineral-bound HCl-P. *S. alterniflora* can efficiently mobilize these recalcitrant P fraction through mechanisms such as rhizosphere acidification, complexation, and enzymatic mineralization, significantly increasing the proportion of potentially bioavailable P in TP. (2) The mobilized P is preferentially invested in reproductive structures rather than being used to substantially increase vegetative growth, thus forming a resource allocation strategy of "low-cost growth—high-efficiency reproduction," which significantly enhances its dispersal and invasion ability. (3) This strategy is significantly strengthened along the latitudinal gradient, exhibiting higher recalcitrant P mobilization capacity and stronger reproductive inclination in high-latitude, P-fixation-intensive environments, reflecting adaptive resource reallocation driven by nutrient stress. This mechanism implies that the mobilization of soil stable P pools by *S. alterniflora* may accelerate the P turnover in wetland ecosystems through potentially impacting the ecosystem C-N-P dynamics, and further the long-term carbon sequestration potential and ecosystem stability of wetlands. Therefore, understanding this P-driven invasion mechanism provides a new theoretical basis for predicting plant invasion trajectories, formulating nutrient management-based wetland restoration strategies.

**ABSTRACT**

Wetlands can be a significant source of $N_2O$ under current global climate change regime with the soil-water interface representing a biogeochemical hotspot for microbial activity. However, the role of soil-water interface in controlling $N_2O$ emissions remains poorly understood. We hypothesized that the millimeter-scale redox gradient across the soil-water interface generates corresponding distinct niche for N-cycling microorganisms that collectively regulate the production and consumption of $N_2O$ over the same spatial scale. The abundance, transcriptional activity and spatial organization of different N-cycling guilds across the soil-water interface were characterized in mesocosms from three different paddy soils with different $N_2O$ emissions. Results demonstrated millimeter-scale stratification of N-cycling microbial activity across the soil-water interface, and in particular within the first 10 mm of flooded soils. Ammonia-oxidizing microorganisms were only transcriptionally active in the top 4 mm, suggesting a previously underestimated contribution to $N_2O$ emissions from wetlands. Variation in $N_2O$ accumulation was observed across the soil-water interface, with the highest concentrations measured at either the soil-water interface or in the deeper anoxic layer of paddy soils. Despite this difference, $N_2O$-reducing microorganisms exhibited high transcriptional activity at the soil-water interface in all soils, suggesting that there is a microbial-mediated sink for $N_2O$ across the soil-water interface that can reduce $N_2O$ produced from both oxic and anoxic layers. This work demonstrates an underappreciated and essential role of the microbial hot zones at soil-water interface in regulating $N_2O$ emissions from wetlands.

# Climate warming suppresses the preservation of metal-associated organic carbon in peatlands

## ABSTRACT

Peatlands represent a critical terrestrial carbon sink, yet the stability of distinct organic carbon pools under climate warming remains poorly understood. Here, we investigated the distribution and drivers of metal-associated organic carbon (Bound OC) in peat cores along an elevational gradient (620-2626 m) in the Changbai Mountains to elucidate its response to climate warming. Our results showed a marked heterogeneity in Bound OC and its properties with peat depth. The contents and proportion of Bound OC, as well as reactive iron contents, were significantly higher in anoxic environments than in oxic environments, with *Sphagnum*-dominated peatlands under anoxic conditions exhibiting the highest values. Although the Bound OC proportion was generally less than 10%, the OC:(0.5Fe+Al) molar ratio was approximately 20, suggesting that Bound OC primarily forms through co-precipitation and confirming the operation of an 'iron gate' mechanism in carbon-rich peatlands. Mixed linear models revealed that increased peat temperature, serving as a proxy for climate warming, led to a significant decrease in Bound OC contents and proportion, as well as in the contents of reactive metal oxides and their activation degrees. Furthermore, the influence of vegetation (*Sphagnum* vs. non-*Sphagnum*) on Bound OC and its properties, quantified using site-weighted response ratios, was strongly mediated by redox conditions. In oxic environments, *Sphagnum* sites enhanced the Bound OC proportion and OC:(0.5Fe+Al) molar ratio compared to non-*Sphagnum* sites; however, this positive effect diminished with rising temperature. Conversely, in anoxic environments, *Sphagnum* was initially less effective at promoting these properties, yet this disadvantage attenuated as temperature increased. Microbial analyses and structural equation modeling demonstrated that *Sphagnum* modulates Bound OC dynamics by regulating iron respiration and microbial biomass carbon, with its role as a "rusty carbon sink" engineer being dependent on redox status. Specifically, warming suppressed Bound OC proportion in oxic environments by reducing *Sphagnum* coverage and metal oxides, whereas in anoxic environments, it acted by stimulating microbial activity and diminishing metal oxides. In summary, this work demonstrates that climate warming threatens the peatland carbon stock by disrupting mineral protection mechanisms and highlights the necessity of incorporating the interactive effects of redox potential and vegetation into climate-carbon models.

**ABSTRACT**

Nitrogen (N) availability critically regulates soil carbon (C) fixation in wetland ecosystems, yet the microbial mechanisms driving this process remain unresolved. Through a gradient of N inputs (CK:0, N1: 3g N $m^{-2}$ $yr^{-1}$, N2: 10 g N $m^{-2}$ $yr^{-1}$, N3: 17 g N $m^{-2}$ $yr^{-1}$, N4: 24 g N $m^{-2}$ $yr^{-1}$) combined with metagenomic sequencing, we demonstrate that moderate N (N2) input significantly enhanced soil key hydrolytic enzyme activities (e.g., β-glucosidase, cellobiohydrolase, N-acetylglucosaminidase), increased microbial biomass C and N contents, and promoted the accumulation of total C, N and phosphorus in the surface soil (0-15 cm). In contrast, high N (N4) input suppressed these enzyme activities and led to significant soil acidification and a decline in nutrient availability. Soil C fixation capacity, indicated by RubisCO activity and K01681 gene abundance, peaked under N2 treatment but declined under N4 treatment. Metagenomic profiling showed that N2 treatment enriched several microbial C fixation pathways (e.g., reductive citrate cycle, dicarboxylate-hydroxybutyrate cycle, 3-hydroxypropionate bi-cycle, and calvin-benson-bassham cycle), whereas all were suppressed by N4 treatment. High N also reduced microbial diversity, enriched acid-tolerant Proteobacteria, and suppressed Actinobacteriota. Correlation and structural equation modeling demonstrated that N input shaped mineral-associated organic C (MAOC) dynamics primarily through its restructuring of the microbial community, which in turn governed C fixation capacity. Our findings establish a mechanistic framework linking N-induced changes in soil properties and microbial traits to C fixation, providing insights for predicting wetland C dynamics under nutrient enrichment.

**ABSTRACT**

Particulate organic matter (POM), a major component of natural organic matter (NOM) in aquatic systems, plays a crucial but poorly understood role in dark reactive oxygen species (ROS) generation. The mechanisms of POM-mediated ROS formation under dark conditions, especially through interactions with environmental reductants, remain unclear. This study revealed that thiols exhibited superior activation capacity for POM-mediated ROS production, with hydroxyl radical (•OH) yields 1.4-6.1 times higher than that of dissolved Fe(II). Batch experiments demonstrated that thiol donated electrons via -SH groups, with surface-active quinones on POM facilitating electron transfer, as evidenced by 13C NMR, FTIR, and XPS analyses. Model experiment and DFT calculation confirmed that quinones lower the energy barrier for Cys oxidation, thereby initiating RS• and SQ•- production through organic free radical chain reactions. This process facilitated •OH production in Cys/BQ system (120.7 μM), which was further confirmed by the marginal •OH enhancement in Fe(II)/BQ system (from 9.9 ± 0.5 μM to 16.9 ± 0.2 μM). Kaolinite particulates in POM further enhanced •OH yields by 88% through surface-mediated radical chain propagation. This ROS-mediated process not only enhanced Cys transformation, but also altered POM surface properties and facilitated As(III) oxidation. These findings provide a deeper understanding of the role of POM in environmental redox chemistry and its implications for contaminant transformation and geochemical cycling, and pave the way for further research into the behavior of free radical intermediates in environmental applications.

# Water level regulation for reducing carbon emissions in urban restored wetlands

**Ouyang Kangting[1*], Yuan Chaolei[1]**

*[1] School of Agriculture and Biotechnology, Sun Yat-sen University, Shenzhen, China)*

*ouykt3@mail.sysu.edu.cn

**ABSTRACT**

Iron reduction and oxidation play a key role in stabilizing soil organic carbon (SOC). However, few studies have examined the impact of water level regulation on iron cycle and carbon emissions in restored wetlands. Here, we conducted in-situ measurements of $CO_2$ and $CH_4$ fluxes and sediment physicochemical properties at sites with different water depths in Haizhu Ramsar wetland of the Pearl River Delta, China. We found that water level fluctuations contributed to higher carbon emissions from shallow marshes than from open water zones. Then, we collected 36 soil cores from the shallow marshes of the wetland and did a water level and Fe(II) concentration manipulation experiment. We detected carbon emissions of 2.78, 3.13, and 2.88 mg·C $m^{-2}$·$d^{-1}$ when the soil cores were submerged in 15, 30, and 45 cm of water, respectively. When water level increased, soil oxygen declined, Fe(II) increased, Fe(III) decreased, and SOC bound to iron minerals accumulated. Microbial community analysis revealed that the relative abundances of iron-reducing bacteria did not significantly change but methanogens increased with water level. Adding 0.01 M Fe(II) strengthened carbon emissions, and the enhancement was smaller when water level was higher. Overall, our findings suggest that deltaic tidal wetland restoration could reduce soil carbon emissions when water level was raised.

# Planting density constrains soil organic carbon pools during native plant restoration following Spartina alterniflora removal across invasion chronosequences

**Jingfeng Wang[1*] and Junhong Bai[1]**

[1] *State Key Laboratory of Wetland Conservation and Restoration, School of Environment, Beijing Normal University, Beijing 100875, P R China*

*E-mail Address of Presenting Author: jfwang1032@mail.bnu.edu.cn

**ABSTRACT**

Coastal wetlands are important global carbon sinks but are increasingly affected by biological invasions and intensive management. Large-scale removal of *Spartina alterniflora* alters soil environments in Chinese coastal wetlands, yet its effects on soil organic carbon (SOC) sequestration and microbial mechanisms remain unclear.

Here, we conducted a controlled pot experiment using soils from the Yellow River Delta representing native *Suaeda salsa* marshes and areas previously invaded by *S. alterniflora* for 7 and 16 years. Native vegetation was restored under low and high plant density treatments. We combined metagenomic sequencing with microbial network and metagenome-assembled genome (MAG) analyses to examine how invasion history and plant density interactively regulate SOC dynamics. SOC content and SOC/TN increased significantly with increasing invasion duration. High plant density restoration enhanced SOC accumulation in invaded soils but had no significant effect in native soils. SOC accumulation did not increase monotonically with invasion duration; instead, significant gains occurred only under high plant density.

The abundance of carbohydrate-active enzyme (CAZyme) genes showed inconsistent responses to invasion history and plant density and was only weakly correlated with SOC accumulation. In contrast, microbial network analysis revealed that invasion duration increased network complexity, and high plant density further enhanced this effect. Functional redundancy (FR), quantified as the average number of microbial taxa associated with each CAZyme gene, increased markedly with invasion duration under high plant density and showed a strong positive correlation with SOC accumulation. MAG analysis indicated that enhanced functional redundancy was driven by community turnover and increasingly deterministic assembly processes. Community assembly analysis further showed that deterministic processes dominated under long invasion duration, particularly under high plant density. Random forest and linear regression analyses identified SOC, SOC/TN, and pH as key drivers of FR.

Together, our results demonstrate that restoration outcomes following *S. alterniflora* management depend on invasion history, with plant density regulating SOC sequestration primarily through microbial functional redundancy rather than gene abundance.

# Impact of Phenolic Additions on Microbial Properties of Peatland

**ABSTRACT**

Peatlands represent a critical global carbon reservoir, storing up to 1,000 Gt of carbon in the form of undecomposed organic matter. This immense storage capacity arises from a persistent imbalance in which the rate of organic matter decomposition is substantially lower than that of primary production. Understanding the mechanisms that suppress decomposition in these ecosystems is therefore of paramount importance.

A key mechanism underlying this imbalance is the waterlogged, anaerobic condition characteristic of peatlands, which severely limits oxygen availability. Freeman et al. (2001) proposed the Enzyme Latch Hypothesis (ELH) to explain how anaerobiosis stabilizes peat carbon. According to the ELH, oxygen limitation suppresses the activity of phenol oxidase, an enzyme responsible for degrading phenolic compounds. Phenolics, which are abundant in peatlands, are potent inhibitors of hydrolytic enzymes essential for organic matter decomposition. Consequently, under anaerobic conditions, phenolics accumulate and form an “enzyme latch” that constrains microbial activity and stabilizes large carbon stocks.

In this study, we investigated eight environmental conditions (e.g., water table depth, vegetation type, and peat excavation history) across three major experimental site types to examine general responses across peatlands in different states in Canada. Two phenolic materials—*Picea mariana* wood chips and aged roots derived from peat harrowing—were applied at a rate of 2 kg $m^{-2}$. Soil samples were collected and analyzed one year after application. Contrary to our hypothesis, phenolic additions increased the abundances of bacteria and Archaea, suggesting that these phenolic materials acted as carbon sources rather than inhibitory compounds for prokaryotic communities. In contrast, fungal abundances declined following phenolic additions on several occasions. We speculate that phenolic materials may selectively inhibit fungal proliferation in peatlands, thereby slowing the decomposition of recalcitrant carbon pools.

# Soil structure determines dissolved organic carbon release from peat soils

**ABSTRACT**

Preferential flow is widespread in peat soils but has been little studied, particularly in relation to dissolved organic carbon (DOC) transport. To investigate its occurrence, extent, and dominant pathways, undisturbed peat cores were collected from drained, rewetted, and natural peatlands in Mecklenburg-Western Pomerania, Germany, with two replicates per site. A multisegment percolation system (MSPS) with ten individual collection zones was used, and artificial rainfall (10 mm $day^{-1}$) was applied to each soil column for 40 days. The volume and DOC concentration of percolated water were measured to clearly distinguish preferential flow from matrix flow. Additionally, X-ray computed tomography (CT) was performed to characterize soil structure, macroporosity, and pore connectivity. Preferential flow accounted for over 90% of total DOC export, indicating it as the dominant transport pathway in peat soils. CT analyses revealed that air-filled porosity (AP) and maximum macropore length (ML) are the main parameters controlling macropore flow. These results demonstrate that preferential flow is prevalent in peat soils and plays a key role in DOC mobilization, highlighting the importance of pore connectivity in governing water and carbon dynamics in peatland ecosystems.

# Microbially Mediated Mechanisms of PFAS-Induced Soil Carbon Priming Effects in Mangrove Ecosystems

**Meiqi Zhao[1*], Huaihai Chen[1]**

[1] *School of Ecology, Sun Yat-sen University, Shenzhen, China*

*zhaomq27@mail2.sysu.edu.cn

**ABSTRACT**

Coastal wetlands, particularly mangrove ecosystems, store disproportionately large soil carbon (C) pools yet are increasingly exposed to per- and polyfluoroalkyl substances (PFAS) derived from urbanization and industrial activities. While PFAS toxicity has received growing attention, their capacity to alter soil organic matter (SOM) decomposition and carbon priming effects mediated by microbial processes remains poorly constrained, especially in coastal soils differing in carbon and nutrient status.

Here, we investigate how a legacy PFAS (perfluorooctane sulfonate, PFOS) and a short-chain replacement (perfluorobutane sulfonate, PFBS) regulate microbially driven C processing in a mangrove soil and an adjacent shrub soil from a rapidly urbanizing coastal region in South China. Soils were exposed to PFOS or PFBS across concentration gradients of 0, 10, and 100 mg $Kg^{-1}$ soil, with and without the direct addition of $^{13}C$-labeled glucose as a readily available carbon substrate. This design allows us to quantify PFAS-induced changes in total soil respiration and to partition $CO_2$ sources between native SOM and added substrate based on the isotopic composition of respired $CO_2$.

Our results reveal that PFAS exposure can significantly modify soil C mineralization rates and alter the coupling between microbial substrate utilization and SOM turnover, with contrasting responses between mangrove and shrub soils under substrate-amended conditions. To resolve the microbial mechanisms underlying these process-level responses, we integrate community composition analyses (16S rRNA and ITS amplicon sequencing), metagenomic functional profiling, and DNA-stable isotope probing to identify actively assimilating microbial populations and PFAS-sensitive carbon-use pathways.

By explicitly linking PFAS exposure to microbial carbon-use strategies and priming dynamics, this study provides mechanistic insights into the vulnerability of coastal wetland carbon stocks under emerging contaminant pressures, with implications for blue carbon conservation and climate-resilient management of contaminated coastal ecosystems.

**ABSTRACT**

Anthropogenic activities such as drainage and rewetting substantially modify carbon and nutrient dynamics as well as biodiversity in peatlands. Rewetting has been suggested as a potential strategy to restore peatland functions and mitigate carbon loss, though the results are not consistently as effective as envisioned. Here, we synthesize data from more than 200 peatlands across mid- and high-latitude regions—including natural, drained, and rewetted sites—to examine the influence of water table level on net carbon dioxide ($CO_2$) flux (i.e., net ecosystem production (NEP)) and methane ($CH_4$) emissions, plant biodiversity, and pore water quality. Our findings reveal that as the water table rises from –80 to 120 cm, $CO_2$ emissions decrease progressively, and CH4 emissions increase significantly. In shallow peatland lakes formed after rewetting, where the water table is at least 20 cm above the ground, the reductions in $CO_2$ emissions may be countered by elevated $CH_4$ emissions. This balance could lead to neutral net carbon radiative forcing (NEP and $CH_4$) over 300-year period with considerable uncertainty. The flooded 'rewetted' peatlands exhibit low species richness of peatland vegetation and higher concentrations of dissolved organic carbon, ammonium, and phosphate in pore water. This study further emphasizes that active rewetting strategies, such as maintaining water tables near the ground surface (–20 to 10 cm) and reintroducing peatland plants, can not only enhance carbon and nutrient sequestration but also promote plant biodiversity, as evidenced by the return of the abundance of peatland-specialist species.

**ABSTRACT**

Coastal ecosystems are widely recognized for the services they provide, especially coastal protection and carbon sequestration (Kauffman et al., 2020). The global average carbon sequestration rate reaches 174 g C $m^{-2}$ $y^{-1}$, and carbon storage can reach 937 t C $ha^{-1}$ (Alongi, 2014), and the value of these services has been estimated at US $194,000 $ha^{-1}$ $yr^{-1}$ (Costanza et al., 2014; Arnaud et al., 2023). However, despite the clear benefits that coastal ecosystems provide, the impacts of soil attributes, especially redox chemistry involving Fe, on carbon fluxes remain uncertain and unquantified. Soil carbon storage is strongly influenced by environmental variables such as nutrient availability, oscillations in tide, light, temperature, and salinity, which can be highly heterogeneous across space and time (Capooci, 2022; Seyfferth et al., 2020). This is especially important in such diverse lithoclimatic conditions as the ones observed along the Brazilian coastline (Ferreira et al., 2021, 2022, 2024), which encompasses approximately 10% of the world's total mangrove areas. In this sense, this work aimed to test machine learning approaches to predict total organic carbon concentration in contrasting coastal soils along the Brazilian coast. The dataset for this work represented three contrasting coastal ecosystems, mangroves, seagrass meadows, and hypersaline tidal flats, encompassing a wide spectrum of environmental conditions, vegetation types, and hydrological characteristics within coastal wetlands. A total of 455 soil samples were collected from the three studied ecosystems: 328 from mangroves, 75 from seagrass meadows, and 52 from HTF. The dataset comprised physicochemical data collected in field (pH, redox potential - Eh, and electric conductivity - EC) as well as soil parameters determined in the laboratory (total organic carbon - TOC, iron geochemical fractionation: exchangeable (EX), associated with carbonates (CA), associated with ferrhydrite (FR), associated with lepidocrocite (LP), associated with well-crystaline oxides (OX), associated with pyrite (PY) and total Fe concentration in the soils). Information about the collection points, such as latitude and seasons, was also added to the dataset. We used the Random Forest (RF) algorithm to model and predict Total Organic Carbon (TOC) based on a set of environmental and soil variables. All analyses were performed in R (version 4.4.2). Initial exploratory data analysis was conducted using the explore package, and variables deemed redundant or irrelevant were excluded. The dataset was cleaned by removing rows with missing values using na.omit(), and variable names were standardized with the janitor::clean_names() function. The RF model was implemented with the explore::explain_forest() function, with TOC as the response variable and the remaining variables as predictors. Model performance was evaluated using the Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and the coefficient of determination ($R^2$). These metrics were calculated by comparing the predicted TOC values against the observed values within the dataset, providing an assessment of prediction accuracy and model fit. The model explained approximately 58% of the variance in TOC (pseudo-$R^2$ = 0.5791), with a mean squared residual of 0.98. Among the most influential variables were ecosystem type, poorly crystalline iron (Fe_LP), latitude, and total iron content, indicating that ecological, physicochemical, geochemical, and spatial factors play key roles in shaping TOC in vegetated coastal soils in Brazil. The results showed a strong control of ecosystem type, latitude, and iron forms on total organic carbon (TOC) in soils accross Brazil coastline. By enabling TOC assessments in blue carbon (BC) ecosystems, this work can provide future guidance on modeling organic carbon in tropical BC ecosystems as well as contribute to Brazil's progress toward its nationally determined contribution (NDC) targets related to ecosystem sustainability and climate resilience.

# Iron Speciation as an Interpretive Framework for Pedochemical Variability in $CO_2$-Degassing Mofette Ecosystems

**Christian Dave R. Alonzo[1*], Michał Z. Cąplak,[1], and Tomasz Zaleski[1]**

[1] *Uniwersytet Rolniczy w Krakowie (Krakow, Poland)*

* cdave.alonzo@gmail.com

## ABSTRACT

Soils influenced by persistent $CO_2$ degassing structures called mofettes, represent complex geochemical environments where redox processes, iron transformations, and ionic chemistry interact across depth and space. However, the role of iron speciation as a lens for interpreting soil geochemical variabilities remains insufficiently understood in such environments. The study investigated the vertical and spatial distribution of iron speciation and its interaction to various soil properties across five mofette sites grounded on the hypothesis of whether the variability in soil properties can be systematically interpreted through which iron is transformed.

A total of 24 soil samples were analyzed for basic soil physical and chemical properties, and iron fractions including ammonium oxalate–extractable iron (amorphous iron or Feo), and pyrophosphate-extractable iron (organically-bound iron or Fep). ANOVA, multivariate techniques, correlation analyses, and linear regression analyses were applied to assess depth trends, site effects, and interrelationships among variables. The soil organic carbon (SOC) was observed to decline significantly with depth ($r \approx -0.50$, $p < 0.05$), while several variables exhibited no depth trends. Base cations, pH, EC, and iron indices showed strong site-specific variability ($p < 0.01$), indicating distinct site-specific pedochemical environments. Correlation analysis demonstrated strong positive association between Fep and SOC, in contrast Feo exhibited no significant associations with SOC.

Principal Component Analysis affirmed closer linkage between organically-complexed iron and SOC. PCA revealed that Fep loaded with SOC and Nitrogen along a dominant organic-associated axis, while Feo, EC, and exchangeable cations clustered along a separate geochemical axis. This highlighted a partial decoupling between redox-sensitive iron pools and SOC storage.

In general, the findings indicate that iron speciation provides a useful interpretive framework for understanding pedochemical variabilities among the studied soils surrounding mofettes, rather than acting as a single controlling mechanism for SOC accumulation. The results also emphasized the importance of accounting the spatial heterogeneity and site-specific geochemical conditions when assessing Fe interactions in redox-affected soils.

**ABSTRACT**

Globally, wetland restoration is increasingly being promoted as a nature-based solution or passive recovery for climate mitigation and biodiversity recovery (Schuster et al, 2025); however, evidence linking active human management actions to recovery of soil function at landscape scales often remains limited (Stirling et al, 2020). We assess long-term recovery of wetland soil moisture and surface condition following both passive and active hydrological restoration in degraded peat-forming wetlands in southern Australia, using a 38-year Landsat time series (1987–2025) and adjacent undisturbed wetlands as functional References sites.

In a wetland where grazing exclusion was implemented in approx. 2015 without hydrological engineering, we evaluate changes in surface wetness, organic matter exposure, and hydrological behaviour from trajectory analyses of: vegetation greenness (NDVI), moisture indices (NDMI), near-infrared reflectance (NIR), shortwave infrared reflectance (SWIR1/2), and derived wet-fraction metrics. Prior to fencing, the wetland treatment exhibited persistently lower NDMI, higher SWIR reflectance, reduced wet fraction, and greater interannual variability relative to the References wetland, consistent with drier, oxidised soil conditions under chronic grazing pressure. Following grazing exclusion, all indicators show a rapid and sustained shift toward the References state, with NDMI and wet fraction converging within 3-5 years and SWIR reflectance declining to levels indicative of darker, wetter, and more organic-like surfaces.

A second wetland provides independent evidence of active restoration effects following drain backfilling completed in May 2022. Paired-zone spectral analyses demonstrate a clear step-change in NDMI, increased NIR reflectance, and reduced SWIR reflectance within the re-wetted peaty wetland, contrasting with simultaneous drying trends in adjacent undisturbed peat areas. This divergence indicates localised re-establishment of saturated peat conditions attributable to drain infilling rather than regional climatic forcing.

Rainfall-normalised anomaly analyses across both wetlands demonstrates that post-restoration improvements cannot be attributed solely to climatic variability, and that rehabilitating wetlands demonstrate enhanced moisture retention and resilience. These results indicate functional recovery of wetland soil hydrology and surface organic matter condition under both passive and active management interventions. Our findings demonstrate the utility of multi-decadal remote sensing as an integrated proxy for wetland soil biogeochemical function and provide robust low-cost lines of evidence that grazing exclusion and drain backfilling can restore key soil-mediated ecosystem services-including soil biochemistry, carbon retention, moisture buffering, and climate resilience-under contemporary drying pressure.

## ABSTRACT

Arsenic (As) in paddy fields is a significant environmental and health concern. While previous research extensively investigated As dynamics in surface soil, the accumulation of As in the subsoil layer, particularly in an Fe-Mn accumulation layer, remains unexplored. This study aimed to illustrate the heterogeneity of As and its relationship with accumulated Fe-Mn forming geochemical barrier, as well as soil Eh, pH and microbial effects during the formation process.

In this study, paddy soils (Inceptisol) were sampled at three different depths (0-10, 10-20, and 20-30 cm). As-Fe-Mn concentrations were measured in soil solutions and ammonium oxalate (AO), dithionite-citrate-bicarbonate (DCB), and strong acid extractions. The results showed that DCB extractable As concentration in the 10-20 cm soil (278.3±2.8mg/kg) was over 30-fold higher than that in the 0-10 cm soil (8.5±6.8mg/kg), correlating with a higher Fe-Mn concentration. Spectroscopic analyses demonstrated that the distribution of As in soil particles is closely associated with Fe-Mn distribution and suggested possible mineral transformation. The Fe-Mn mineral distribution in soil pore water suggested that hydrodynamic processes played a significant role in the formation of potential As-adsorption Fe-Mn oxides. Adsorption experiments demonstrated that subsoils had a higher As binding and buffering capacity (1403 and 1243 mg/kg) than surface soil (891 and 167 mg/kg).

To clarify possible biogeochemical dynamics triggering this heterogeneous distribution in the vertical soil layer, we performed soil column experiments under flooded situations. From 5 cm, 10 cm, 15 cm and 20 cm depths of soil, we measured Eh and pH in situ and collected soil solutions and soil samples for elements and microbial analysis. During incubation, Eh generally decreased, although the 20 cm layer consistently maintained higher Eh than 5cm layer likely due to unsaturation. This Eh gradient affected soil solution As, Fe and Mn concentrations which were higher in the 5cm and 10 cm layer than 15 cm and 20 cm soil layer. This suggested a higher reduction rate in the surface layer, possible leaching to the subsurface layer and a refixation in the lower layer. The microbial analysis showed significant relationships among microbial communities and soil Eh, pH and soil depth, which resulted in corresponding changes in sequential extraction fractions of As, Fe and Mn elements. Overall, the pronounced vertical heterogeneity of arsenic distribution can be attributed to the combined effects of redox-driven mineral transformations, hydrological transport, and microbially mediated biogeochemical processes.

These findings provided additional evidence for Fe-Mn mineral bound As accumulation in lower soil layer and the possible mechanisms behind. Our experimental results suggested the potential for lower soil layers to retain arsenic by Fe-Mn oxides in limiting arsenic mobility, thereby alleviating the environmental risks associated with arsenic pollution.

# Coupled effects of human activities and river–Lake interactions evolution alter sources and fate of sedimentary organic carbon in a typical river–Lake system

**Shilan Wang[1], Zhongwu Li[1]*, Xiaodong Nie[1]**

[1] *College of Geographical Sciences, Hunan Normal University, Changsha, China*

* Email: lzw17002@hunnu.edu.cn.

**ABSTRACT**

Interconnected river–lake systems record sedimentary organic carbon (OCsed) dynamics and watershed environmental changes, providing valuable information for global carbon budgets and watershed management. However, owing to the evolving river–lake interactions under global change, monitoring OCsed is difficult, thereby impeding the understanding of OCsed transport and fate. This study provided new insights into the dynamical mechanisms of OCsed in a typical river–lake system consisting of Dongting Lake and its seven inlet/ outlet rivers (the three inlets of the Yangtze River and four tributaries) over the last century using stable isotope tracing and quantified the influences of climate change and human activities on OCsed. Results indicated that exogenous OC dominated the OCsed in the lake (58.2 %–89.0 %) and was lower in the west than in the east due to the differences in the material inputs and depositional conditions within the lake. Temporally, the distribution patterns of OCsed sources mainly responded to human activities in the basin rather than to climate change. Before 2005, the Yangtze River contributed the most OCsed (53.5 %–74.6 %), attributed to the high-intensity land use changes (path coefficient ($r\partial$): 0.48, p-value < 0.01) and agriculture-industry activities ($r\partial$: 0.44, p-value < 0.001) in the Yangtze River basin that increased soil erosion. After 2005, a large amount of Yangtze River OC was intercepted by the Three Gorges Dam, altering the OC exchange in the river–lake system and shifting OCsed dominance to the four tributaries (52.2 %–63.8 %). These findings highlight the active response of OCsed to the river–lake interaction evolution and anthropogenic control, providing critical information for regulating watershed management behavior under global change.

# Redox processes of particular organic matter in mediating carbon emissions in peatlands

**ABSTRACT**

Particulate organic matter (POM) has been proposed as an important reversible electron acceptor that can suppress methane ($CH_4$) emissions in peatlands. However, direct evidence explaining how the redox behavior of POM alters carbon mineralization pathways remains limited. In this study, we conducted a periodic redox-cycling experiment to monitor changes in the electron-accepting capacity of POM ($EAC_{POM}$) and to link these dynamics to carbon emissions in peatland soils. During anaerobic phases, POM respiration caused a lag time of methanogenic phase, effectively diverting carbon flow from $CH_4$ to $CO_2$ emissions. In contrast, aerobic phases were characterized by a pronounced pulse of $CO_2$ release. Follow-up experiments demonstrated that oxidation of reduced POM generated hydroxyl radicals, which strongly promoted oxidative transformations of organic matter. This process notably enhanced phenol oxidase activity and led to substantial abiotic $CO_2$ production during POM oxidation. Overall, our findings reveal a double-edged role of POM in peatland carbon cycling. While POM reduction can suppress $CH_4$ emissions under anoxic conditions, its re-oxidation stimulates organic matter decomposition, particularly lignin degradation, which potentially weakened the "enzymatic latch" in peatlands.

**ABSTRACT**

Crop residues represent as valuable reservoir of organic matter for sustaining soil health and fertility. Applying decomposition agents for straw degradation is a useful solution to avoid the adverse effect of traditional management which causes and increases the greenhouse gas emission and air pollution. However, the mechanism of applying the decomposition agent or solution on the soil environment is not fully studied yet. This study investigated the effects of application of a liquid soil activator (LSA) on soil microbial activity and straw decomposition level in 2 fields located in Germany and Serbia. The results showed that the application of LSA increased the abundance of several geniuses involved either directly or indirectly involved in straw degradation. The abundance of microbiota showed different trends in both locations. While in German filed, application of LSA increased the abundance of direct bacterial involved in straw degradation, in Serbia most of the changes belonged to direct funguses. The enhanced abundance of different microorganisms induced by LSA application led to a significant increase in straw degradation under both filed conditions. These findings provide new insights into the role of endogenous application of decomposition agents in straw residue management, highlighting their potential to improve soil health, fertility, and overall soil environment.

# Impacts of soil biostimulants on 'Valencia' sweet orange performance on Flatwoods and Ridge soils in Florida

**Duplicate Sambani[1*], Alisheikh Adem Atta[1], and Davie M Kadyampakeni[1]**

[1] *University of Florida, Soil, Water and Ecosystem Sciences Departments, Institute of Food and Agricultural Sciences, Citrus Research and Education Center, Lake Alfred, FL 33850, United States*

*d.sambani@ufl.edu /duesambani@gmail.com

**ABSTRACT**

Huanglongbing (HLB) disrupts citrus productivity by reducing fibrous roots early before disease progression, weakening nutrient and water uptake in citrus production. Soil-centered strategies that utilize soil biostimulants may restore the root-soil interface, enhance fruiting, and mitigate pathogen pressure. The objective of this study is to evaluate biostimulants [CitruSaver1(CS1), CitruSaver2 (CS2)], and beneficial microbes (BM) alone and combined (CS2+BM) on the performance of 'Valencia' [Citrus sinensis (L.) Osb.] across two Florida groves differing in soil characteristics and management practices: Wauchula (Flatwoods) and Fort Meade (Ridge). The study was laid in a randomized complete block design with five treatments replicated four times: CS1, CS2, CS2 + BM, BM, and Control. We summarized current harvest weight per plot, Quantitative Polymerase Chain Reaction qPCR cycle threshold Ct values (CLas), juice quality, and fruit drop counts. In Wauchula average yield, CS1 and CS2+BM slightly exceeded CS2 and the Control. In Fort Meade, fruit yields were lower overall, with CS1 highest, followed by CS2. CS2+BM was similar to BM. Wauchula showed slightly higher °Brix (9.94) than Fort Meade (9.53) with comparable ratios (13–13.5). Average fruit drop counts were similar (Wauchula 2.30; Fort Meade 2.05 per sampled unit). Wauchula demonstrated a more precise treatment separation, with CS2 and BM performing well in terms of yield. In contrast, Fort Meade responses were more variable, with CS2 showing higher yield but no clear advantage for BM in Ct values. In Wauchula, CS2 and CS2+BM yielded up to 8% higher fruit mass, indicating reduced pathogen load. Fort Meade responses were smaller but showed improved nutrient retention and stability of juice quality. Biostimulants can improve root-zone efficiency, nutrient-use balance, and soil carbon retention, supporting environmental quality in HLB-endemic citrus systems. Long-term adoption is expected to reduce chemical inputs, improve soil-water interactions, and mitigate nutrient runoff from Florida's citrus landscapes.

**ABSTRACT**

Preventing land degradation and restoring degraded and saline lands is vital for biodiversity conservation, ecosystem services, and human well-being, and is a crucial approach for ensuring food security and sustainable development. Given the detrimental effects of salinity and soil erosion, as well as the consequent soil–water losses, and considering limitations such as high costs, scarcity of raw materials, instability, temporariness, and the environmental drawbacks of commonly used amendments and stabilizers for erosion control, as well as the initial formation steps and the improvement of surface runoff components at the slope, the necessity arises to employ methods with practical, durable, and biological efficiency for controlling soil loss and generating surface runoff in highly saline and alkaline soils. Despite the approved role of biotechnological interventions in mitigating soil and water loss, soil cyanobacteria inoculation to reduce soil degradation in saline soils has not yet received attention. This study aims to evaluate the effect of direct inoculation of soil microorganisms using a surface broadcasting method on soil, through extraction, identification, selection of effective soil cyanobacteria for soil and water conservation, and purification and propagation of these cyanobacteria in bulk volume for planned deployment. Native cyanobacteria from the study area's soil microbial repository were identified, selected, purified, and cultured, and then inoculated on the plots in three replicates. Research findings showed that the volume of runoff produced under simulated rainfall with an intensity of 70 mm $h^{-1}$ for 30 min, after about 60 days of inoculation, in the soil treatment with low salinity and 10% slope, and in the soil treatment with high salinity and 5% slope, the inoculated cyanobacteria reduced soil loss by 60.54 and 32.83%, respectively, while runoff volumes were reduced by 7 and 16 times, with the reductions being statistically significant ($p<0.001$) compared to the control treatment. The results of this study represent a substantial step toward achieving a durable approach in research and management actions for erosion control and the improvement of surface runoff components, thereby preventing the salinization of saline soils and related areas, offering hope for the future of soil conservation.

**ABSTRACT**

Plants adapt to stress conditions by regulating root exudates, which sustain rhizospheric microbial growth and suppress soil-borne pathogens. Soil microbial communities are key regulators of ecosystem functions, driving carbon and nutrient cycling critical for plant productivity. Root exudates, particularly glucose, play a central role in shaping microbial community dynamics and rhizosphere biochemical processes. However, how successive wheat cultivation affects glucose exudation and its downstream effects on microbial activity remains unresolved. In this study, we hypothesized that continuous wheat cropping reduces glucose release, thereby diminishing microbial biomass, activity, and function. We employed optimized *in situ* glucose imaging in root windows installed in field-grown first (W1) and third (W3) wheat crops following break crops. This integrative approach combined spatial glucose mapping with measurements of microbial respiration, enzyme kinetics, and SWEET sugar transporter gene expression in root and leaf tissues. Glucose release hotspots declined by 17.7% in W3 compared to W1, with only 1.35% of the total soil surface showing detectable glucose release in W3. Concurrently, SWEET1a orthologue expression was significantly upregulated in W3, while microbial biomass in the W1 rhizosphere was nearly five times higher than in W3. Enzyme assays revealed significantly higher β-glucosidase $V_{max}$ values in W1, indicating stronger carbon acquisition potential. Gene expression analysis revealed significant upregulation of SWEET1a orthologous genes in W3 roots, suggesting increased demand for energy and carbon for nutrient uptake. In contrast, SWEET13 and SWEET2 orthologous genes were downregulated in W3, indicating shifts in resource allocation. These findings suggest that reduced glucose exudation and altered SWEET gene expression reflect adaptive plant strategies under continuous cultivation, possibly to limit opportunistic pathogens. This study provides novel insights into how continuous wheat cultivation reshapes rhizosphere interactions by altering root exudation, microbial dynamics, gene regulation, and enzyme activity. Moreover, it highlights the utility of *in situ* glucose imaging for advancing our understanding of plant–soil–microbe interactions in agroecosystems.

**ABSTRACT**

The Sahel is a vulnerable semi-arid environment, with degraded soils where the majority, subsistence farmers routinely face in-season drought and declining crop productivity. Our development of the Optimized Shrub-intercropping System (OSS) with 2 indigenous shrubs *Guiera senegalensis* and *Pilio reticulatum* at elevated densities (~1500) with annual incorporation of coppiced residue - addresses this challenge by increasing soil quality and microbial diversity, performing hydraulic lift (HL), and dramatically increasing yields (fig. 1). Recent field and growth chamber research of OSS will be presented that provides evidence for hydrological and microbiome mechanisms for these positive responses on pearl millet (*Pennisetum glaucum*). A simulated drought field study using deuterium ($D_2O$) as a tracer (applied to shrub roots at 1 m depth) detected a δD signal of > 300‰ increase over background levels in shrub-associated millet tissue; confirming HLed water was transferred to millet. Importantly the +OSS enabled millet to produce a harvestable yield in spite of the 41-day in-season drought, which did not occur in -OSS. Using mesocosms (hydrophobic 36 µm mesh allowing only mycorrhizal hyphae penetration) planted to millet, showed that millet in unturned mesocosms were labeled with $D_2O$ and had much greater tillering/plant biomass than turned microcosms, indicating a common mycorrhizal hyphal network (CMN) connected shrub roots with millet roots. Supporting the role of CMN was greater arbuscular mycorrhizal fungi (AMF) colonization in millet roots and FAME-AMF abundance in shrub over non-shrub soil. Another growth chamber study of early season drought was conducted to remove hydraulic lift as factor and isolate the effect of OSS on soil quality and the microbiome. Microbial metagenomic sequencing showed that shrubs enriched several plant-growth promoting taxa in millet rhizosphere soil (Fig. 2). These organisms have properties such as disease suppression, plant hormone production, and mobilization of nutrients (via hydrolytic enzyme or organic acids). We conclude that shrubs operate as a natural microbial repository that "inoculates" adjacent crop roots; directly reducing drought with CMN "bioirrigating" and by promoting *beneficial microorganisms that are known to improve plant growth and reduce water stress in crops*. Recent findings of pilot testing OSS in farmers' fields in Senegal will also be presented. OSS is appropriate for small holder farmers of the Sahel as the shrubs are a local resource, they are already familiar with.

## ABSTRACT

Revegetation strongly influences the dynamics of soil organic carbon (SOC) and microbial communities. While microbial communities are known to drive carbon (C) cycling, the specific traits responsible for C stabilization and mineralization during the revegetation of degraded karst ecosystems are not well understood. This study used a combination of metagenomic and instrumental methods to investigate variations in soil physicochemical properties, organic C fractions, C-cycle microbial community traits (diversity, life strategies, and co-occurrence patterns), and C-cycling (fixation and degradation) genes across four karst ecosystems representing a revegetation chronosequence encompassing cropland, grassland, shrubland, and primary forest. Our findings demonstrated that revegetation increased total SOC and recalcitrant OC (ROC) contents, while it decreased dissolved inorganic nitrogen (DIN) and reduced the ratio of labile OC (LOC) to SOC. This indicates enhanced C pool stabilization and storage, alongside reduced soil nutrient availability. These shifts favored the development of C-cycle microbial communities with low diversity and high proportions of K-strategists, which efficiently utilize recalcitrant C under oligotrophic conditions. Consequently, the increased dominance of K-strategists redirected microbial resource acquisition, manifested in a 29 % decrease in C-fixation gene abundances (rTCA, WL, and DC/4-HB pathways) and a 27 % decrease in genes degrading labile C compounds (starch, hemicellulose, cellulose, and chitin). Conversely, genes involved in degrading recalcitrant C compounds (pectin and lignin) increased by 19 %. Furthermore, the elevated proportion of K-strategists enhanced the complexity and stability of microbial taxonomic and functional networks, potentially strengthening community resilience and nutrient cycling efficiency. These results reveal a causal link between shifts in the soil C pool and nutrient availability during revegetation and the subsequent reshaping of C-cycling microbial communities. Such restructured communities, in turn, drive the expression of genes associated with C stabilization and mineralization, thereby impacting the soil C pool. This study provides mechanistic insights into microbial-mediated biochemical processes governing soil C decomposition and stabilization in karst ecosystems, offering critical guidance for ecological restoration in these degraded and fragile regions.

**ABSTRACT**

The root cell wall is the frontline defense against aluminium toxicity in acidic soil. How rhizosphere microbes affect responses ofthe root cell wall to aluminium stress has not been explored. A previous study showed that an aluminium-tolerant synthetic microbial community (SynCom) was capable of assisting rice growth and production in acidic soils. In this study, we proceeded to examine the association between microbial inoculation and cell wall composition and found that xyloglucan endotransglucosylase (XET) activity increased, leading to modifications in xyloglucan and reduced aluminium accumulation in the roots of an aluminium-sensitive rice mutant. Multiomics profiling revealed that XET activity is regulated by SynCom through the provision of a precursor of brassinosteroids, which activated the plant brassinosteroid pathway. Furthermore, SynCom inoculation promoted the growth of both indica cultivars and japonica cultivars rice plants in the field under aluminium stress by restoring aluminum-induced cell wall modifications. Our findings highlight a sustainable approach to utilizing acidic soils by inoculating SynCom to rescue XET activity and reduce aluminium accumulation in the cell wall (Fig.1).

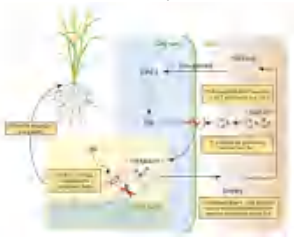

**Fig.1** A schematic model illustrating the effects of SynCom on rice root cell wall modification in acidic soils. (1) The activity ofthe XET enzyme in plants growing in acidic soils is inhibited, leading to the accumulation of aluminium (Al) within the cell wall, which consequently hinders the growth of roots. (2) SynCom releases MVA to enhance the synthesis of BR, including DWF1, in rice roots. BR then upregulates XET activity in the root cell wall, leading to the truncation of the XyG chain, and its components, such as glucan (G), can be released into the rhizosphere. (3) The microbiome may subsequently obtain carbon sources from the root cell wall and reduce aluminium binding to the root cell wall. (4) This process ultimately alleviates soil aluminium toxicity and promotes root cell expansion and growth.

# Methanotrophic activity as a driver of soil carbon cycling in agricultural soils

**A. Walkiewicz*, K. Jaromin-Gleń, and R. Mazur**

*Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland*

*E-mail a.walkiewicz@ipan.lublin.pl

## ABSTRACT

Methanotrophic bacteria are active in agricultural soils under different land uses. By oxidizing methane ($CH_4$) to carbon dioxide ($CO_2$) and water, they participate in the carbon (C) cycle. Soil methanotrophy helps lower atmospheric $CH_4$ levels via high-affinity methanotrophs, while also mitigating $CH_4$ emissions by oxidizing elevated methane concentrations within the soil profile before they reach the atmosphere (low-affinity methanotrophy). Through the oxidation of one of the key greenhouse gases, methanotrophs contribute to the mitigation of climate change.

Agricultural practices, alongside seasonal weather variations, strongly regulate soil $CH_4$ uptake. In arable fields, methanotrophic activity is often reduced or inhibited by regular nitrogen fertilization. On grasslands, excessive livestock grazing frequently increases soil compaction, reducing oxygen availability and lowering the capacity to oxidize $CH_4$. As a result, soils under pastures may periodically even emit $CH_4$, whereas mown grasslands typically act as a $CH_4$ sink. In this context, agroforestry systems represent a beneficial practice with the potential to improve soil health and enhance methanotrophic activity and C storage.

We conduct regular measurements of greenhouse gas emissions using the chamber method, combined with assessments of soil physicochemical parameters in pasture and arable fields, including the influence of trees. We will demonstrate how these parameters change seasonally and how they regulate atmospheric $CH_4$ uptake (high-affinity methanotrophy) depending on land use. The conducted research provides quantitative data that will be used for the validation and calibration of the MODASYS (Model for Decision-making in Agri-Environmental Systems) model, developed within the project and operating at the farm level.

Regular field measurements of soil methanotrophic activity provide valuable data on C cycling in agroecosystems, which is particularly important in the context of ongoing climate change and implementation of mitigation practices.

## ABSTRACT

Intensive potato farming heavily relies on mineral fertilizers, which can be detrimental to the environment. Microbial inoculants emerge as a sustainable alternative to such fertilizers due to their potential to improve nutrient availability and plant health. Nevertheless, their effect on the potato rhizosphere and tuberosphere requires further elucidation. A field experiment was conducted in Southeast Spain on potato using a randomized block design involving four fertilization treatments: conventional mineral fertilization (F100); 50% fertilization reduction (F50); and F50 combined with two distinct microbial inoculants (F50+BA, containing *Azospirillum, Bacillus*, and *Pseudomonas*; and F50+BAFU, containing *Azotobacter, Bacillus*, and non-mycorrhizal fungi). Soil samples from the bulk, rhizosphere, and tuberosphere were collected at four key growth stages: pre-planting, pre-inoculation, post-inoculation, and at harvest. Microbial community composition and diversity were assessed using sequencing data and estimated absolute abundance. The functional potential of the soil microbiome was evaluated by quantifying key genes involved in carbon and nitrogen biogeochemical cycles via quantitative PCR. In the post-inoculation stage, the estimated absolute abundance of potential pathogenic fungi such as *Neocosmospora*, *Botryotrichum*, and *Gibellulopsis* was significantly decreased in the F50+BAFU and F50+BA treatments compared to the F50 treatment, which showed the highest estimated absolute abundance values ($1.48\times10^5$, $1.20\times10^6$, and $6.87\times10^5$ copies $g^{-1}$ soil, respectively) ($p$-value < 0.05). Shannon diversity significantly varied across plant growth stages and soil compartments ($p$-value < 0.001), with the tuberosphere generally exhibiting the highest richness. Notably, during the post-inoculation period, diversity was significantly higher in the F50+BA treatment than in F100 ($p$-value < 0.05), indicating a positive effect of microbial inoculation under reduced fertilization. By normalizing functional gene abundance to total microbial biomass (gene/16S rRNA ratio) during the post-inoculation period, we observed not only a quantitative increase but also evidence of a treatment-driven functional enrichment, as in the F50+BAFU and F50+BA treatments, that significantly increased the abundances of key nitrogen cycling genes, such as *nifH* (0.09 and 0.06 copies $g^{-1}$ soil in April, respectively) and *nirK* (0.008 and 0.011 copies $g^{-1}$ soil in April, respectively), as well as gene GH7 (0.012 copies $g^{-1}$ soil in May), compared to the F100 and F50 treatments ($p$-value < 0.05). Microbial inoculants offer a promising strategy for reducing chemical fertilizer inputs in semi-arid potato cultivation by enhancing beneficial soil functions, temporarily promoting beneficial microbes, improving nitrogen cycling, and suppressing pathogens, thereby supporting a resilient crop microbiome.

**ABSTRACT**

*Phytophthora* blight caused by the destructive soil-borne oomycete pathogens is extremely difficult to control since it attacks the crops underground. Arbuscular mycorrhizal (AM) fungi could not only antagonize or inhibit soil-borne pathogen growth but also defend host against *Phytophthora* blight. However, due to the long-standing challenge in massive production of AM fungal inocula, the effective utilization of soil indigenous AM fungi has become a more desirable path to be explored. To this day, mycorrhiza helper (MH) bacteria as bioenhancers of AM fungi were rarely reported in combating soil-borne diseases. Therefore, a series of studies were conducted to screen MH streptomycetes strains for suppressing *Phytophthora* blight via greenhouse pot experiment, and to explore their specific and combined effects in inhibiting pathogen growth and benefiting AM symbiosis using plate confrontation test, non-targeted metabolomics and pot trials. Mycorrhizal colonization becoming one major factor influencing *Phytophthora* blight when AM fungus present, and *Streptomyces* tricolor (STr) and *S. tendae* (STe) isolated from the rhizosphere of a healthy individual in a *P. capsici*-infected field were screened as MH strains for combating pepper *Phytophthora* blight, while *Kitasatospora herbaricolor* (KHe) and *K. indigofera* (KIn) isolated from an acidic black soil were screened as MH strains for combating soybean *Phytophthora* blight. On one hand, only STr inhibited *P. capsici* growth, while STe which secreted the bioactive substance called 3'-methoxycoumestrol performed better in promoting the propagation and colonization of AM fungus. On the other hand, both KHe and KIn inhibited *P. sojae* growth, while KIn which secreted petroselinic acid and pinocembrin performed better than KHe in increasing AM fungal abundance and the colonization. Compared with any single inoculation, the combined inoculation of STr and STe or KHe and KIn changed the community structure and increased both abundance and colonization of soil indigenous AM fungi, and further decreased pathogen population and the blight severity, while further increased the fruit yield and total nutrient acquisitions. In addition, mycorrhizal colonization positively correlated to soil AM fungal abundance, diversity indices and the actinomycetes population. Taken together, the combined inoculation of STr+STe and KHe+KIn as synthetic microbiota (SynM) is valuable in the future to enhance AM symbiosis against *Phytophthora* blight.

## ABSTRACT

**Introduction**

Tea rhizosphere microbial communities are central to soil ecosystem services, driving nutrient cycling, organic matter decomposition, and plant stress resilience. This study aimed to determine how leguminous cover crops, specifically soybean (LC-S) and cowpea (LC-C), modulate the tea rhizosphere microbiome, enhance soil health, and improve tea quality, offering a sustainable alternative to monoculture tea cultivation.

**Materials and Methods**

This study was conducted at the "Zhongshanlin Tea Experimental Base Station" and the site featured a more than15 year established plantation of *Camellia sinensis* cv. "*Nanjing Yuhua*" tea. The topsoil layers (0–20 cm depth) in tea gardens are distinguished by a sandy loam texture. After two successive years of leguminous cover cropping, tea rhizosphere soil samples within the space of tea rows (i.e., monoculture tea rows, soybean and cowpea cover cropped tea rows) were obtained from tea plantations by extracting intact root-zone cores (20 $cm^2$ surface area × 30 cm depth) from three randomly selected locations or points in each plot. Rhizosphere soil was separated from the roots through a 10 min manual agitation in 1 L of sterile 0.9% *NaCl* solution. A two-year field experiment compared the effects of soybean and cowpea cover crops with conventional monoculture tea systems. High-throughput *16S rRNA* gene sequencing was employed for metagenomic, and metabolic pathway analyses to assess changes in rhizosphere microbial community structure, functional potential, and impacts on tea biochemical quality.

**Results**

Both legume cover treatments (LC-S, and LC-C) significantly restructured the rhizosphere microbiome compared to monoculture controls. *Acidobacteria*, *Proteobacteria*, and *Actinobacteria* were dominant phyla across all treatments. Key functional genera included *Chujaibacter* (regulating microbial circadian rhythms and soil homeostasis) and *Jatrophihabitans* (cytokinin biosynthesis, auxin response, siderophore production). LC-S uniquely enriched *Firmicutes*, *Mycobacterium*, *Bacillus*, and *Nitrospira*, and upregulated degradation and assimilation pathways (*PWY-7315*, *CENTFERM-PWY*) essential for carbohydrate and aromatic compound metabolism. While, LC-C exclusively enriched *Planctomycetes* and *Cyanobacteria*, and enhanced glycan biosynthesis/degradation pathways (*PWY-5744*, *FUCCAT-PWY*), facilitating glyoxylate assimilation and L-fucose degradation. Additionally, both legume cover crop treatments increased beneficial genera such as *Saccharimonadales*, *Leifsonia*, *Frankiaceae*, *Nocardia*, *Conexibacter*, and *Gordonia*, and elevated nitrogenase and glycoside hydrolase activities, optimizing nitrogen assimilation and nutrient cycling. Moreover, legume cover cropping enhanced the biosynthesis of key tea quality compounds, including theanine, polyphenols, catechins, and aromatic volatiles. LC-S primarily promoted aromatic metabolites and carbohydrates, while LC-C favored polyphenolic compounds like flavonoids. The combined incorporation of these two leguminous cover crops synergistically increased the accumulation of bioactive compounds and free amino acids, significantly improving tea's flavor complexity, aroma intensity, and antioxidant capacity.

**Conclusion**

Leguminous cover crops, particularly soybean and cowpea, effectively restructure rhizosphere microbial communities and enhance metabolic functions, creating a dynamic soil environment that supports both ecosystem services and tea quality improvements. This agro-ecological approach offers a sustainable, economically viable alternative to monoculture, advancing soil health, crop productivity, and the market value of tea.

# Global Change and Human Activity on Soil Microbial Community and Metabolism

**Huaihai Chen[1*], Jiayi Zhao[1], Jiaxin Li[1], and Xueying Wang[1]**

[1] *School of Ecology, Sun Yat-sen University, Shenzhen, China*

*chenhh68@mail.sysu.edu.cn

**ABSTRACT**

Global climate change, as projected by the IPCC to cause a 1.4–5.8°C global temperature rise by 2100 with even faster warming in ecologically fragile regions like the Qinghai-Tibet Plateau, coupled with increasing human-induced exogenous nutrient inputs, poses significant impacts on soil microbial communities and their regulation of biogeochemical cycles, key processes sustaining soil health, plant growth, and carbon sequestration. Soil microorganisms, which drive nitrogen and phosphorus cycling and mediate organic matter decomposition, are highly sensitive to environmental changes, making it critical to clarify their adaptive mechanisms across distinct vulnerable ecosystems. This study focused on three representative ecosystems (Qinghai-Tibetan Plateau alpine meadows, Tianshan glacier forefields, and Shenzhen mangroves) to explore how global change factors (temperature rise, nutrient addition, sea-level rise) shape microbial community structure, metabolic functions, and carbon cycling processes.

In the Qinghai-Tibet Plateau, a 4-year long-term N/P addition experiment at Haibei Station (3100 m altitude) showed that exogenous nutrients reduced plant species richness by favoring fast-growing grasses/sedges, shifted microbial communities toward eutrophic taxa (e.g., Proteobacteria), and altered metabolic priorities—promoting growth-related biosynthesis (e.g., amino acid metabolism) while inhibiting complex organic matter decomposition (e.g., lipid and aromatic compound metabolism), potentially impairing long-term soil carbon sequestration. For Tianshan glacier forefields spanning 10–120 years of succession, microbial functional succession drove carbon stabilization: autotrophic carbon fixation genes decreased significantly, while decomposition and respiration-related genes increased, with priming effects shifting from positive (young soils, nutrient limitation-induced microbial mining) to negative (mature soils, substrate-preferential utilization reducing organic matter loss). In Shenzhen mangroves, tidal gradients regulated microbial carbon use strategies: high/mid-intertidal zones (HT/MT) exhibited negative priming effects (favoring carbon sequestration) with distinct microbial communities (HT: Pseudomonadota; MT: Chloroflexi), while low-intertidal zones (LT) showed positive priming effects, suggesting future sea-level rise may reduce mangrove soil carbon sink potential.

Collectively, these findings reveal ecosystem-specific microbial adaptive mechanisms to global change, providing critical insights for predicting and mitigating the impacts of climate warming, nutrient enrichment, and sea-level rise on fragile ecosystem functions and carbon cycling.

**ABSTRACT**

Soil-borne diseases incited by fungal and bacterial pathogens persistently threaten global agricultural production security. Excessive long-term dependence on chemical control measures has resulted in a series of pressing issues, including environmental contamination, evolution of pathogen resistance, and food safety concerns. Consequently, the development of environmentally sustainable biocontrol strategies has emerged as a critical research focus in plant protection. Although the application of beneficial microorganisms and their metabolites demonstrates considerable promise, current biocontrol practices predominantly rely on single-strain formulations, such as *Trichoderma* spp. or *Bacillus subtilis*. These monospecific agents face practical limitations, including functional narrowness and poor colonization capacity, which severely constrain their field efficacy and potential for widespread adoption.

Therefore, this study proposes a novel ecological regulation strategy using microbial communities as holistic units. By screening and constructing stable microbial consortia with functional redundancy and synergistic antimicrobial capabilities, we aim to achieve efficient control of soil-borne diseases. The study selected eight different soil samples and utilized three culture media for continuous subculturing over nine generations, constructing a total of 120 serially passaged microbial consortia. From these, 600 derivative consortia were generated for screening antimicrobial functions. The results showed that approximately 20% of the consortia exhibited inhibitory activity against *Fusarium* spp., *Phytophthora* spp., and *Botrytis cinerea*, among which less than 5% demonstrated strong inhibition (inhibition intensity ≥ 80%). Systematic analysis of the stability of the antimicrobial function revealed dynamic evolutionary characteristics in the inhibitory capacity of the consortia: among the 120 serially passaged consortia, 22 were "fluctuating type" (with fluctuating inhibitory ability), 10 were "from presence to absence type," 7 were "from absence to presence type," while only 6 (5% of the total) were "sustained type" with stable inhibitory function. Further employing single-colony isolation and high-throughput community synthesis techniques, the key functional combinations within the "sustained type" consortia were analyzed and reconstructed. The study found that a synthetic community constructed with *Pantoea agglomerans* and *Serratia* sp. increased the inhibition efficiency against tomato gray mold by 7.3% compared to *Serratia* sp. alone. Mechanistic studies indicated that this synergistic effect originated from a 20% significant increase in siderophore secretion capacity under co-culture conditions, thereby effectively inhibiting pathogen growth through iron competition.

In summary, through the systematic research framework of "functional community discovery—key species analysis—synthetic community construction," this study lays a theoretical and resource foundation for building efficient, stable, and resilient synthetic microbial communities. It holds significant value for promoting the development of agricultural biocontrol technologies toward community-based and intelligent directions.

## ABSTRACT

Nitrous oxide ($N_2O$) is a potent greenhouse gas and a significant contributor to global warming. Agricultural soils represent the largest anthropogenic source of $N_2O$, releasing an estimated 2.7-4.8 Tg $N_2O$ annually into the atmosphere (Zhu et al., 2025). $N_2O$ is primarily produced in soils through microbial processes such as nitrification and denitrification. In denitrification, the nitrous oxide reductase (NosZ), which is encoded by the *nosZ* gene, catalyzes the reduction of $N_2O$ to dinitrogen ($N_2$), serving as the only known biological sink for $N_2O$ in soils (Chapuis-Lardy et al., 2007; Juhanson et al., 2017). The *nosZ* gene is generally recognized as being present in two major clades, *nosZ* I and *nosZ* II, which differ in their gene cluster composition, protein secretion pathways, enzymatic kinetics, taxonomic distribution, and co-occurrence with key genes involved in other denitrification pathways. In situ studies have suggested that the two *nosZ* clades may occupy distinct ecological niches within soil ecosystems (Jones et al., 2013; Liu et al., 2023). Soil oxygen ($O_2$) availability is a critical factor that directly influences the production and reduction of $N_2O$ (Qiu et al., 2024; Song et al., 2019; Wei et al., 2023). Compared to other denitrification genes, *nosZ* is particularly sensitive to $O_2$, with its expression being suppressed in the presence of oxygen. limited studies have investigated the effect of $O_2$ on *nosZ* I- and *nosZ* II-carrying microorganisms (Sennett et al., 2024), and the impact of $O_2$ on these two clades and the underlying mechanisms remain insufficiently explored.

In this study, $N_2O$-reducing microbial communities were enriched from fluvo-aquic soil through serial transfers with $N_2O$ as the electron acceptor under three different oxygen conditions: oxic, hypoxic, and anoxic. The microbial communities in all enrichment cultures were primarily dominated by Proteobacteria, followed by Firmicutes and Bacteroidota. Metagenomic and metatranscriptomic analyses revealed that, compared to *nosZ* I-carrying microbes, *nosZ* II-carrying microbes exhibited greater sensitivity to $O_2$. After assembling and de-redundantly processing the metagenomic data, 57 medium- or high-quality metagenome-assembled genomes (MAGs) were recovered, including 11 *nosZ* I-carrying MAGs and 10 *nosZ* II-carrying MAGs. Functional annotation showed that *nosZ* II-carrying MAGs generally lacked key genes related to reactive oxygen species (ROS) defense and genes encoding terminal oxidases. These findings were corroborated by the detection frequencies of these genes across the 3015 *nosZ* I-carrying bacterial genomes and 5237 *nosZ* II-carrying bacterial genomes in the GTDB database. Our results demonstrate that $O_2$ exerts selective pressure on the two *nosZ* clades due to their differing abilities to adapt to oxygen. This study highlights the crucial role of oxygen tolerance in shaping microbial community dynamics and $N_2O$ emission, with significant implications for accurately predicting $N_2O$ emissions from agricultural soils.

## ABSTRACT

Historically, lanthanides (Ln) were regarded primarily as cytotoxic agents. High concentrations of $Ce^{3+}$, for instance, destabilize the outer membrane of Escherichia coli by displacing essential $Ca^{2+}$ and $Mg^{2+}$ ions from lipopolysaccharides, increasing permeability and susceptibility to lysis. Consequently, microorganisms in Ln-rich environments have evolved distinct survival strategies, such as extracellular sequestration via surface phosphate groups and intracellular storage in acidocalcisome-like compartments to mitigate toxicity. However, recent discoveries have shifted this paradigm, establishing lanthanides as essential cofactors for specific methylotrophic bacteria. The discovery of XoxF, a pyrroloquinoline quinone (PQQ)-dependent methanol dehydrogenase (MDH), demonstrated that $Ln^{3+}$ can functionally replace $Ca^{2+}$ in active sites. This substitution leverages the higher charge density and Lewis acidity of lanthanides to enhance coordination flexibility and catalytic efficiency, a phenomenon strictly required for the growth of extremophiles like *Methylacidiphilum fumariolicum* SolV. Despite the comprehensive characterization of MDH, the broader landscape of lanthanide biochemistry remains largely unexplored. To investigate whether other enzymes exploit lanthanides, we performed a computational screen of metagenomic data derived from high-rare-earth mining environments. We focused on sequences containing the canonical calcium-binding EF-hand motif, identifying 534 candidate sequences. We employed AlphaFold2 for structural prediction, Foldseek for functional annotation, and Discovery Studio for molecular docking simulations to evaluate lanthanide binding affinity relative to calcium.Our analysis identified 94 distinct proteins, dominated by signal transduction factors (85%) and metabolic enzymes (8%). Docking results revealed five specific enzymes with a theoretically higher binding affinity for $Ln^{3+}$ than $Ca^{2+}$: phosphatidylserine decarboxylase precursor, transaldolase, glycerol-3-phosphate dehydrogenase, ATPase, and calcium-dependent protein kinase. Additionally, enzymes such as metallo-β-lactamase and $NH_3$-dependent $NAD^+$ synthetase exhibited affinities suggesting potential Ln-substitution via mass action effects in high-Ln backgrounds. These findings significantly expand the potential scope of lanthanide utilization in biological systems. Future work will focus on the spectroscopic characterization of these candidates to validate the impact of lanthanide binding on enzymatic activity and conformational stability.

# Beyond plant diversity: plant productivity responses to extreme drought are linked to arbuscular mycorrhizal fungal diversity

**ABSTRACT**

Plant and arbuscular mycorrhizal (AM) fungal diversity are both positively linked to ecosystem productivity across diverse ecosystems. However, given their high sensitivity to climate extremes such as extreme drought, the persistence and adaptability of these diversity-productivity relationships under rapid climate changes remain poorly understood. To address this, we established a grassland experiment at two sites with distinct natural plant and AM fungal communities, imposing two contrasting extreme drought regimes (intense and chronic), each exceeding a 20-year recurrence interval based on site-specific precipitation records. We show that AM fungal diversity consistently outperforms plant diversity in predicting plant aboveground/net primary productivity (ANPP/NPP), as well as compositional shifts in plant species productivity, despite pronounced drought sensitivity in both communities. Notably, enhanced drought resistance in plant productivity was primarily associated with the stability of AM fungal richness rather than plant richness, highlighting their mutual dependence under extreme drought. Structural equation modelling confirmed that AM fungal richness buffered drought effects on ANPP, NPP and plant richness, with stronger effects on ANPP and NPP than those of plant richness and soil properties. These results suggest that AM fungal diversity may play a greater role than plant diversity in buffering plant communities against climate extremes. While causality remains to be fully resolved, these findings shed light on the adaptive significance of this ancient symbiont in sustaining ecosystem functioning under rapid climate change.

## ABSTRACT

Phosphogypsum (PG), a by-product of phosphoric acid production, is a major industrial waste material (*Hanfeng et al,* 2025). Although it contains valuable nutrients, its agricultural use remains debated due to potential contamination risks. Nevertheless, interest is increasing in its use as a soil amendment, as PG may improve soil chemical properties and influence the soil microbiome, a key factor in soil health. Understanding the effects of PG on soil microbial communities is therefore essential for assessing its suitability for sustainable agriculture.

This study examined PG-induced changes in soil microbial biomass and community composition using phospholipid fatty acid (PLFA) analysis in two contrasting soils: an Arenosol (pH(KCl)=4.92) and a salt-affected, compacted Gleyic Chernozem (pH(KCl)=6.17). A two-year greenhouse pot experiment was conducted, where in the first year, PG was applied at 2 and 10 t $ha^{-1}$, with untreated controls. In the second year, pots were divided to assess either residual effects (no additional PG) or repeated applications (same doses re-applied) of PG. Spring wheat (*Triticum aestivum* L.) was grown in both years. Although the pot experiment covered a two-year period, the present study reports the results obtained in the second year.

Phosphogypsum increased total microbial biomass in both soils. In Chernozem, biomass was generally higher (220.9–301.7 nmol $g^{-1}$), with the lowest values in the control and the greatest increase in the repeated 2 t $ha^{-1}$ PG treatment. In Arenosol, biomass ranged from 157 to 231 nmol $g^{-1}$, with the lowest values in the control and the highest in the 10 t $ha^{-1}$ treatments under both residual and repeated PG addition.

Arbuscular mycorrhizal fungal biomass in Chernozem (10.7–49 nmol $g^{-1}$) increased significantly under all PG treatments, whereas Arenosol values (7.2–10.8 nmol $g^{-1}$) were lower and not significantly affected. Total fungal biomass showed no significant PG-induced change in either soil.

Gram-positive bacteria were more abundant in Arenosol (73.4–99.0 nmol $g^{-1}$) than in Chernozem (43.2–61.5 nmol $g^{-1}$) and showed slight, non-significant increases with PG. Gram-negative bacteria were less abundant in Arenosol (36.2–47.4 nmol $g^{-1}$) and more abundant in Chernozem (43.3–61.5 nmol $g^{-1}$), with no significant effects from PG.

Actinomycetes were more abundant in Chernozem (11.6–14.79 nmol $g^{-1}$) and were significantly increased by PG in the residual 10 t $ha^{-1}$ and repeated 2 t $ha^{-1}$ treatments, while Arenosol showed slightly lower values with no significant change under PG.

The fungal-to-bacterial ratio increased markedly in Chernozem (0.167–0.387 nmol $g^{-1}$) under PG treatments, indicating a shift towards a more fungi-dominated community, whereas Arenosol (0.10–0.17 nmol $g^{-1}$) remained unaffected.

Overall, PG enhanced microbial biomass and, in some cases, beneficial microbial groups, supporting its potential as a soil amendment, although responses varied between soils and microbial components.

**ABSTRACT**

The paddy-field herbicide Quinclorac (QNC) persists in soil and aquatic systems, accumulates along gradient-driven pathways, and inflicts phytotoxicity on succeeding crops while posing acute threats to aquatic organisms. An efficient and eco-friendly removal technology is therefore urgently needed. Microbial degradation is regarded as the most sustainable solution, however, current studies remain at the stage of strain isolation and phenotypic verification, and a genome-scale consensus on QNC-degradation pathways, key genes and regulatory networks is still lacking.

Here, a high-efficiency QNC-degrader, *Mycolicibacterium* sp. Qt1, was isolated from QNC-contaminated paddy soil and completely removed 50 mg/L QNC within 96 h, markedly reducing its ecotoxicological impact. Metabolite profiling and pathway reconstruction revealed four QNC-degradation routes and several novel intermediates. Machine-learning-driven multi-omics and protein-ligand docking systematically identified the genes and enzymes driving QNC transformation. On this basis, the first genome-scale metabolic model (iQt1) constrained solely by QNC cometabolism was constructed; it unbiasedly scanned genome-wide conditional-essentiality landscapes, pinpointed hidden metabolic nodes that become lethal in the presence of QNC, and quantified the energy/redox-electron competition between the catabolic pathway and central metabolism, thereby exposing the systemic bottleneck responsible for the gap between theoretical and observed degradation rates.

This study provides a panoramic, mechanistic understanding of microbial QNC degradation and offers computable targets and theoretical guidance for the precision bioremediation of Quinclorac-contaminated sites, while pushing the frontiers of environmental microbiology and systems biotechnology.

**ABSTRACT**

The mutualistic symbiosis between plants and their core microbiota plays a crucial role in maintaining plant health and enhancing disease resistance. However, the specific functions and mechanisms through which the phyllosphere microbial community confers protection against pathogen infection remain poorly understood. In this study, we collected 1,410 samples from multiple compartments (including bulk soil, rhizosphere, roots, stems, and seeds) of healthy and stalk rot diseased maize plants across a continental-scale transect spanning 3,317 kilometers in China. Amplicon and metagenomic data analyses revealed that stalk rot disease significantly disrupted the composition of the maize microbiota. Compared to other plant tissues, the integrity and function of the highly conserved stem microbiota were more severely compromised by the pathogen. Continental-scale sample analysis identified 14 bacterial and 26 fungal core taxa within the maize stem microbiota. Inoculation with a synthetic microbial community (SynCom) composed of six core bacterial and six core fungal strains demonstrated that these stem-endophytic microbes effectively alleviated pathogen infection. Strain removal experiments within the SynCom identified the fungus *Penicillium fructuariae-cellae* as a key contributor to disease resistance in the stem microbiota. *P. fructuariae-cellae* broadly inhibits multiple pathogenic fungi through the production of small molecular compounds. This study highlights the untapped potential of often-overlooked stem-endophytic core microbes in enhancing disease resistance and provides a promising strategy for mitigating globally prevalent stalk rot in maize.

**ABSTRACT**

Healthy soils with diverse and beneficial microbiomes are essential for sustainable agriculture and for protecting crops against soil-borne diseases. However, it remains unclear how plant genotypes generate soil microbial legacies and whether these legacies can be leveraged to enhance crop resilience across growing cycles. Using banana varieties differing in Fusarium wilt resistance, we combined soil conditioning, cross-inoculation, microbiome profiling, metabolite assays, and synthetic microbial community (SynCom) experiments to uncover the ecological and mechanistic basis of disease suppression. Soils conditioned by the highly resistant variety created a persistent beneficial legacy that improved the health of the susceptible variety, whereas soils conditioned by the susceptible variety promoted pathogen buildup. Bacterial communities were particularly responsive to legacy effects, while fungal communities were more strongly shaped by varietal identity. Resistant varieties selectively recruited microbial groups with strong pathogen-inhibitory potential, and their growth was stimulated by distinct root-derived metabolites. SynComs designed from these enriched microbial groups effectively reproduced the suppressive effects of resistant-variety microbiomes and significantly reduced pathogen abundance. Supplementation with metabolites characteristic of the resistant variety further enhanced SynCom performance. Together, our findings demonstrate that resistant crops can engineer beneficial soil microbial legacies through targeted recruitment of disease-suppressive microbiomes. This nature-based mechanism offers a promising path for improving soil health, reducing pathogen pressure, and supporting more sustainable and resilient agricultural systems.

# Long-term soil storage highlights the role of precipitation history in microbial dynamics and $CO_2$ emissions

**Kirill Bogdanov[1, 2*], Sergio E. Morales[1], and Timothy J. Clough[2]**

[1] *University of Otago, Department of Microbiology and Immunology, Dunedin, New Zealand*

**ABSTRACT**

Greenhouse gas emissions (GHG) challenge the modern world and future generations. One possible strategy for climate change mitigation is enhancing soil carbon (C) sequestration by promoting C uptake from the atmosphere and storing it in the form of soil organic matter to reduce increases in atmospheric $CO_2$ concentration. Agricultural soils can store C making them an important component of climate change mitigation strategies. The key to understanding C dynamics in soils is integrating the role of microbial communities since they control net C transformations. In this study, we assessed the potential link between soil organic C (SOC) and soil microbiomes in pasture soils in the South Island of New Zealand and the role of median annual precipitation (MAP) in controlling them.

A total of 48 soil samples were collected from 16 farms across the South Island of New Zealand, spanning a MAP gradient (500-5000 mm per year). Metagenomes and 16S/ITS rRNA profiles were generated from DNA extracted from fresh composite soil samples representing the top 0-10 cm, and for the same samples after air drying for one year. Soils were then used to measure $CO_2$ emissions and assess the Birch Effect after re-wetting.

Significant differences in fungal communities were observed in fresh soils, with strong grouping of sites based on MAP, where sites with < 1000 mm of rain a year clustered separately from higher rainfall areas, but similar clustering was absent for prokaryotes. However, both fungi and prokaryotes demonstrated strong clustering based on MAP after one year of drying. Furthermore, we observed higher $CO_2$ emissions from lower precipitation sites in response to water addition.

Our findings highlight how long-term soil storage provides better insight into microbial community assembly drivers. It suggests that caution with data interpretation is needed to disentangle the role of short-term disturbances (e.g. recent moisture changes) vs long term climactic and geologic drivers (e.g. historical precipitation patterns) of microbial community assembly patterns. The results also indicate that under future climate change scenarios, altered rainfall could lead to significant losses of SOC.

## ABSTRACT

Soil salinity is one of the fastest growing threats to global agriculture, with the FAO 2024 assessment reporting that about 10% of irrigated and rainfed croplands are already salt affected. Climate-driven aridification could expand the affected land surface to 24–32% in the coming decades, with the greatest impacts expected in arid and semi-arid regions. Among crops cultivated in these environments, okra is widely grown yet sensitive to salinity at all growth stages. Salinity suppresses plant growth and reduces soil microbial diversity, limiting key functions that support soil and plant health. While metagenomics offers valuable microbial community profiles, culture-dependent approaches remain necessary to obtain living cultures and evaluate their plant-beneficial traits, particularly for applications such as biopriming. This study aimed to characterize culturable bacteriomes from inland and coastal soils and identify plant growth-promoting bacteria (PGPB) candidate for okra biopriming under salinity. A total of 70 bacterial strains were obtained with serial dilution method from four locations using R2A and LB for inland soils (codes: NTR and FLD) or R2A with 1.5% NaCl and Marine Agar for coastal soils (codes: BEA and OKB). Relative abundance analysis based on 16S rRNA gene sequences showed a distinct genus composition between inland and coastal bacteriomes. *Bacillus* spp. was isolated consistently across all sites, whereas *Pseudomonas* spp. was the second most represented genus in coastal soils but rarely isolated inland. Several genera were site-specific, such as *Stenotrophomonas* in NTR and *Brucella* in OKB. Principal component analysis (PCoA) grouped inland and coastal communities separately, associating BEA with bacteria from genus *Microbacterium*, *Arthrobacter*, and *Metabacillus*, and FLD with genus of *Rossellomorea*, *Pantoea*, *Ralstonia*, and *Acinetobacter*. Functional potential was assessed through four PGP traits relevant to salinity: IAA production, EPS secretion, ACC-deaminase activity, and phosphate solubilization. Eleven strains produced IAA, seven showed ACC activity, thirteen solubilized phosphate, and fourteen secreted EPS. Nine multi-trait strains were subsequently tested for okra biopriming in a factorial completely randomized design using nine bacterial treatments and two salinity levels (0 and 150 mM NaCl) for 25 days, each contained 9 replications. Biopriming with these strains significantly improved okra biomass, particularly under salinity treatment. At 150 mM NaCl, *Rossellomorea marisflavi* FLD31 and *Ralstonia pickettii* FLD34 increased total dry mass from 96.96 mg in the control to 241.24 mg and 196.77 mg respectively. *Rossellomorea marisflavi*, though moderately halophilic, remains poorly studied in plant-microbe-soil interactions. These findings highlight the potential of underexplored soil bacteria to enhance crop performance under saline conditions and emphasize the importance of preserving soil biodiversity.

**ABSTRACT**

Soil microbes have closely evolved with plants, and enhance the root acquisition of soil nutrients. Some rhizosphere microbes offer other benefits to plants, such as improving plant's immunity to diseases and tolerance to environmental stresses. Annual crops requiring high-inputs are appear to be degrading soil health, exacerbating the dependence for more chemical inputs to maintain yields profitable. The microbiome rewilding hypothesis posits that plant health can be improved by reinstating the diverse (ancestral) microbes that were lost through domestication and industrialization. In the case of rewilding with soil microbes, this implies the loss that occurred through plant breeding for high-input or overuse of pesticides and fertilizers during the industrialization of agriculture. Evidence is mounting that degraded agriculture fields can be restored, and regain a highly functional soil, if microbiome wilding is implemented (Ramirez-Villacis et al. 2025). We tested the potential of wild soil microbiome inoculation with ancient pea species (e.g. *Pisum fulvum*), field pea cultivars (*P. sativum*); ancient wheat species (e.g. *T. monococcum*), and some old and modern wheat cultivars (*T. aestivum*). Diverse 'wild' rhizosphere soil was collected from native grasslands and pastures and used as a whole-soil community inoculum for growing plants in glasshouse trials. Preliminary results from these proof-of-concept experiments are discussed. For example, pea cultivars had about a 2.5 fold increase in nitrogen-fixing nodules, and tended to have less root rot (likely *Aphanomyces* or *Fusarium*) after growing with the 'wild' soil inoculum. Only under drought, and in ancient wheat were positive responses to the 'wild' soil inoculum found, in comparison to grown in sterile soil. Specifically, with ancient wheat, the 'wild' inoculum produced greater grain yield and improved tolerance to dry and nutrient-poor soil. A second set of experiments using diverse 'wild' soil communities (NatCom *sensu* Darriaut et al. 2025) is currently showing some promise to improve root growth and lower root rot in ancient and modern pea. Follow-up experiments with wheat and a greater domestication gradient are ongoing. More research on 'wild' rhizosphere microbiomes with common annual crops, could improve our understanding of the role of ancestral microbial associations, to improve sustainable agriculture. Harnessing and optimizing 'wild' soil consortia could help reduce the input costs of farmers, while simultaneously improving soil biodiversity and bolstering soil health.

**ABSTRACT**

Mangrove forests present a critically important coastal natural ecosystem, playing vital roles in carbon sequestration, biodiversity conservation, wave attenuation, water purification, etc. Despite this, the mechanisms of carbon sink formation in mangroves remain unclear, with a key knowledge gap lying in understanding the microbial communities that drive this process. This study investigated the diversity and composition of benthic autotrophs across varied coastal environments in Guangdong, China, including urban estuaries, industrial bays, mariculture areas, and mangrove coastlines. Using high-throughput sequencing of 16S and 18S rRNA genes, we characterized prokaryotic and eukaryotic autotrophic assemblages and evaluated how anthropogenic activities influence their structure. Results revealed that industrial heavy metals such as Cd and Zn, along with interactions with micro-eukaryotes (e.g., protists, metazoans, and parasites), significantly reshaped autotrophic community organization. Industrial pollution markedly reduced the abundance of both prokaryotic and eukaryotic autotrophs. In contrast, mangrove sediments promoted a distinctive community shift, enriching autotrophic taxa including sulfur-oxidizing bacteria, iron-oxidizing bacteria, and microalgae. This shift suggests a coupling of sulfur and iron cycling with carbon sequestration processes in mangrove ecosystems. Overall, these findings demonstrate that anthropogenic factors alter coastal sediment carbon sequestration capacity by restructuring autotrophic communities, with mangroves playing a mitigating and functionally enriching role.

## ABSTRACT

Global nitrogen (N) deposition deposition alters ecosystem nutrient stoichiometry. While N is essential nutrient for plant photosynthesis and calcium (Ca) is structural and regulatory substance in plants, the microbial mechanisms linking N:Ca ratios to plant-soil processes remain largely unexplored. We analyzed ten poplar plantations across 41°53′–48°14′N in Northeast China's Three-North Shelterbelt. We collected poplar leaf samples and soil samples from different soil layers to characterize the distribution of N:Ca ratio across all sites. We further examined correlations between N:Ca ratios and leaf nutrient contents, as well as soil physicochemical properties. Additionally, metagenomic sequencing was used to explore the characteristics and functional potentials of soil microbial communities in sites with distinct N:Ca ratios. The results indicated that soil N:Ca ratio ranged from 0.21 to 0.53 in the 0–20 cm layer and 0.16 to 0.57 in the 20–40 cm layer, increasing significantly along the latitudinal gradient ($p < 0.05$). Total nitrogen (TN), total carbon (TC), exchangeable calcium (ECa), altitude, and total potassium (TK) were identified as the top five key driving factors, cumulatively accounting for 96.1% of total variation. Regression analysis revealed that extremely significant positive correlations of soil N:Ca ratio with TC and TN, extremely significant negative correlation with TK, and a unimodal response to ECa ($p < 0.001$). Meanwhile, poplar leaf N and tissue Ca contents were strongly positively correlated with the N:Ca ratio, whereas leaf C and phosphorus (P) showed significant negative correlation ($p < 0.001$). In terms of soil microbial communities, elevated N:Ca ratio significantly reduced the α-diversity of both bacteria and fungi ($p < 0.05$). Bacterial communities exhibited significant separation across N:Ca ratio gradients, but fungal communities exhibited no significant separation. With respect to functional genes, the abundance of carbon cycle-related genes first increased and then decreased with increasing N:Ca ratio. In nitrogen metabolism, functional gene relative abundances differed by specific function. Additionally, the abundance of calcium signaling related genes significantly decreased with elevated N:Ca ratio. Structural Equation Modeling (SEM) verification confirmed that N:Ca ratio exerted negative regulatory effects on carbon cycling, nitrogen metabolism, and calcium signaling pathways ($p < 0.05$). As atmospheric N deposition intensifies, shifts in N:Ca balance may compromise plant resilience and productivity. By uncovering this overlooked nutrient interaction, our study provides a foundation for optimizing fertilization strategies in forestry to enhance resource efficiency and mitigate the effects of global N deposition.

# The impact of trees on soil microbial biomass and $CO_2$ emissions from fertilized soil

**K. Jaromin-Gleń, R. Mazur and A. Walkiewicz***

*Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland*

*E-mail a.walkiewicz@ipan.lublin.pl

**ABSTRACT**

Approximately 37% of the Earth's terrestrial surface is used for agricultural purposes, including arable land (33%) and grasslands (67%) [1]. Through microbial and root respiration, these systems consume oxygen and release carbon dioxide ($CO_2$), contributing to global greenhouse-gas emissions. Developing climate-resilient and environmentally sustainable agriculture therefore requires practices that enhance soil health and biodiversity, strengthen microbial functioning, and reduce atmospheric $CO_2$ release - such as maintenance and implementation of agroforestry systems and rational fertilization strategies.

In this context, our study examines how agricultural management and landscape structure shape soil microbiome activity and $CO_2$ emissions. The regular field measurements were carried out to generate quantitative data for validating and calibrating the MODASYS model (Model for Decision-making in Agri-Environmental Systems), under development for estimation of greenhouse-gas emissions at the farm scale. Soil $CO_2$ fluxes were determined using the dynamic chamber method with simultaneous soil condition testing and sampling for microbial biomass carbon (C) assessment using the Substrate-Induced Respiration (SIR) technique.

Results reveal pronounced spatial variability: fertilized plots distant from trees exhibited the highest $CO_2$ fluxes, whereas unfertilized zones near trees showed substantially lower emissions with seasonal changes both soil respiration and microbial biomass C. These patterns are consistent with recent empirical findings confirming that soil microbiomes respond strongly to fertilization regimes, organic amendments, and biogeochemical gradients [2, 3]. Seasonal reductions both in $CO_2$ fluxes and microbial biomass highlight temperature-driven constraints on microbial metabolism further modulated by the presence of trees.

By integrating microbiological indicators with field-scale gas measurements, this study demonstrates how soil microbial communities mediate C cycling under contrasting management conditions. The results reinforce the crucial role of diverse and functional soil microbiomes in supporting climate-resilient agriculture, restoring degraded soils, enhancing C sequestration, and stabilizing ecosystem processes essential for sustainable food production.

**ABSTRACT**

Reseeding the legume *Caragana korshinskii,* is an effective strategy to restore the vegetation in degraded desert steppe. Here, we explored the responses of soil environment and microbial communities to desert steppe degradation and *C. korshinskii* reseeding. A typical native-degraded-restored closed-loop system in desert steppe: the natural stage with native *C. korshinskii* (NC), vegetation degradation stage (bare soil) (BS), both vegetation and soil degradation stage (desertified soil) (DS), and restored stage with reseeding *C. korshinskii* aged eight years (RC). The results showed that, within this closed-loop system: 1) Compared to BS, soil degradation (DS) resulted in a 199% increase in sand content ($P < 0.05$), while no difference between RC and NC ($P > 0.05$), indicating restoration of soil texture. 2) The soil microbial structure of RC was similar to that of NC, but based on changes in abundance, it could be divided into communities that increased with the rise in soil sand content (UTC+SPP), decreased due to vegetation degradation and increased soil sand content (FOC+SEC) ($P < 0.05$), and unchanged (UC). 3) Microbial networks showed lower average degree and modularity after reseeding *C. korshinskii* compared to NC. In summary, eight years of vegetation restoration led to the recovery of soil texture and microbial community structure, but not community complexity and stability. The results emphasize the time lag for soil microbiome reconstruction after reseeding *C. korshinskii*, providing novel insight into plant-soil-microbial interactions during the restoration of degraded desert steppe.

Keywords: desert steppe degradation, legume reseeding, soil microbial diversity, soil microbial complexity and stability, soil texture

## ABSTRACT

Soil salinization and alkalization severely threaten global agricultural sustainability, affecting approximately 955 million hectares worldwide. Harnessing beneficial soil and plant-associated microbiomes represents a promising strategy for improving crop performance and rehabilitating degraded saline soils. Here, we investigated the diversity, functional potential, and plant growth–promoting mechanisms of endophytic and rhizospheric microbes associated with salt-adapted plants around the extreme saline–alkaline Yuncheng Salt Lake, China.

Using culture-dependent methods, we isolated 175 endophytic strains (4 phyla, 43 genera) and 121 rhizospheric strains (5 phyla, 39 genera). Amplicon-based sequencing revealed much broader diversity, with rhizosphere communities spanning 44 phyla and 108 classes. A high proportion of endophytic bacteria remained taxonomically unclassified, highlighting the substantial novelty of microbial resources in this extreme ecosystem. Functional screening showed that many isolates exhibited multiple plant growth–promoting (PGP) traits, including indole-3-acetic acid production, phosphate solubilization, siderophore and exopolysaccharide synthesis. Functional annotations further revealed widespread stress-adaptive features related to heat shock, UV resistance, oxidative stress defense, and osmotic regulation. Inoculation experiments under salt stress (12 g/kg NaCl) demonstrated that both individual endophytic strains (PG04, LC43, GM11) and a composite microbial consortium (CPDS) significantly enhanced wheat (*Triticum aestivum* L.) seedling growth. Compared with uninoculated controls, shoot height increased by 19.96–25.83% for single strains and by 33.24% for CPDS, while shoot biomass increased by 30.17–36.71% and 60.13%, respectively. CPDS showed the strongest effect, increasing mean shoot height to 167.07 mm and fresh seedling weight to 126.5 mg. Leaf chlorophyll content was significantly elevated by all inoculations, with CPDS and LC43 reaching 2.31 and 2.13 mg/g. Similar growth-promoting effects were observed following rhizospheric microbial inoculation, particularly with strain CUG-104, which markedly increased shoot height, root length, and fresh weight, and enhanced chlorophyll content, proline accumulation, and antioxidant enzyme activities (SOD and CAT).

Transcriptomic analysis of representative treatments (CUG-104 and CPDS) revealed distinct yet complementary mechanisms underlying microbial-mediated salt tolerance. Both treatments activated plant hormone signal transduction and starch and sucrose metabolism. CUG-104 preferentially enriched arginine and proline metabolism, fatty acid elongation, and glycerophospholipid metabolism, contributing to osmotic adjustment and membrane stability. In contrast, CPDS strongly enhanced photosynthesis, Calvin cycle carbon fixation, zeatin biosynthesis, protein processing in the endoplasmic reticulum, and reactive oxygen species detoxification, thereby promoting biomass accumulation and cellular homeostasis under saline stress.

Overall, microbes from salt-adapted plants employ synergistic and strain-specific strategies to enhance plant salt tolerance and growth. This study provides novel microbial resources and mechanistic insights for developing bio-inoculants to improve crop resilience and support sustainable saline soil rehabilitation.

# Tracing the dynamic life story of soil microbial hotspots

## ABSTRACT

Soil microhabitats are dynamic sites of microbial hotspots with intense biological activity that disproportionately drive organic matter (OM) turnover. Ecological transitions of microhabitats can alter their biological traits, and consequently, affect OM formation and decomposition. However, a mechanistic understanding of how microbial function and community assembly of microhabitats shift through ecological succession remains unclear. Since formation and decomposition of OM are largely oxidative processes, we used *in-situ* zymography of oxidative enzymes (peroxidases and phenol oxidases) to visualize their spatial activity as an indicator of OM turnover. Combined with planar optodes for $CO_2$ efflux, microscopic imaging to verify biopore reuse by new roots, and microbial analyses (PLFAs and substrate-induced growth respiration), we traced the life story of microbial hotspots from a maize rhizosphere to its root-detritusphere, then to bare biopores, and finally to biopores reused by lentil roots.

The maize rhizosphere was characterized by high $CO_2$ efflux hotspots (12.2%) derived from root and rhizomicrobial respiration, but low oxidative activity hotspots (0.31%), supporting the dominance of fast-growing, copiotrophic microorganisms such as Gram-negative bacteria. This pattern shifted dramatically in the root-detritusphere, where the oxidative hotspots increased 7-fold (to 2.25%), driven primarily by saprophytic fungi decomposing fresh necromass. At the same time, the concentrated input of labile carbon from decaying roots sustained a high abundance of Gram-negative bacteria, thereby maintaining microbial growth rate comparable to that in the maize rhizosphere. However, $CO_2$ efflux declined by 25% relative to the maize rhizosphere, indicating a shift from autotrophic to heterotrophic respiration. As decomposition of root residues progressed, the reduced availability of labile carbons likely constrained microbial growth in bare biopores, as reflected by lower oxidative activity and $CO_2$ efflux hotspots compared to the root-detritusphere. This pattern indicates constrained decomposition of recalcitrant residues, concurrent with a microbial community shift towards slow-growing Gram-positive bacteria and actinobacteria. Reoccupation by lentil roots revitalized hotspots, yielding the highest oxidative activity (3.15%) and $CO_2$ efflux (13.5%) hotspots, reactivating fast-growing communities via positive rhizosphere priming.

We conclude that microhabitat succession may affect OM formation and decomposition by shifting the balance between oxidative and respiratory decomposition through the restructuring microbial community and enzyme deployment in space and time. These findings underscore that management practices that promote root-derived inputs and biopore reuse, such as reduced tillage and crop rotation, can sustain microbial hotspots and enzymatic activity, thereby enhancing nutrient cycling while potentially stabilizing OM in carbon-limited microhabitats.

# The Regulatory Role of Rhizosphere Microorganisms in Tobacco Resistance to Black Shank Disease

**Liuying Wen[1*], Lirui Chen**

[1] *Key Laboratory for Tobacco Gene Resources, Tobacco Research Institute, Chinese Academy of Agricultural Sciences, Qingdao 266100, China*

*wenliuying@cass.cn

**ABSTRACT**

Plant roots assemble taxonomically and functionally diverse microbial consortia that constitute a "second genome" essential for host health. Yet, how plants exploit rhizosphere microbiota to enhance disease resistance remains insufficiently understood. Here, using the Solanaceae crop *Nicotiana tabacum*, we dissect how rhizosphere microbial communities modulate host immunity against black shank of tobacco (*Phytophthora nicotianae*). Susceptible (XHJ) and resistant (BH) cultivars were grown in soils differing in microbial complexity, followed by pathogen inoculation during the seedling stage. Integrated phenotyping, expression profiling of defense-related hormone pathways, and 16S rRNA–based microbial community analyses were performed.Plants grown in field soil exhibited markedly reduced disease severity compared with those in sterile soil, indicating a protective role of native microbiota. Root-split and soil-transplant assays further showed that pathogen-induced rhizosphere soil significantly suppressed disease symptoms in XHJ, demonstrating that pathogen challenge reshapes the rhizosphere microbiota toward a resistance-enhancing configuration. Community profiling revealed that both field soil and pathogen-induced rhizosphere soil possessed higher bacterial diversity and altered abundance of multiple taxa, most prominently *Methylobacterium*. Concomitantly, tobacco plants grown in these soils displayed enhanced activation of SA-, JA-, and ET-responsive defense genes—including *NtPR1a/c*, *NtPR1b*, and *NtACS2*—with *NtPR1b* showing the strongest induction, pointing to a microbiota-enhanced immune state. Together, our findings demonstrate that pathogen infection triggers a plant-mediated recruitment of beneficial rhizosphere microorganisms, which in turn strengthens host immunity. This work provides mechanistic insight and foundational evidence for leveraging microbiome assembly to improve plant disease resistance.

# Easily biodegradable organic materials serve as soil biostimulants to rapidly enhance soil aggregate stability by increasing fungal biomass

**Zheng Ma[1], Luyao Yang[1], Ruiting Guo[1], Longtao Tu[2], Xiong Qian[1], and Zhenlun Li[1*]**

*[1] Chongqing Key Laboratory of Interface Process and Soil Health, College of Resources and Environment, Southwest University. Chongqing 400716, China*

**ABSTRACT**

Soil microbial communities play a crucial role in the formation and stabilization of soil aggregates. The application of biostimulants that enhance the activity of native beneficial microorganisms offers a promising approach to rapidly improving soil structure in agriculture. However, this strategy remains underexplored and underutilized. In this study, we conducted a soil incubation experiment using two easily biodegradable and cost-effective carbon sources—kitchen waste hydrolysate and sugarcane molasses—as biostimulants. Our objective was to evaluate their impact on soil structure and fertility enhancement and to uncover the microbial mechanisms driving soil particle aggregation. The results demonstrated that both biostimulants: (1) rapidly increased the proportion of soil macro-aggregates and aggregate stability, while decreasing soil bulk density; (2) sustainably elevated soil dissolved organic carbon (DOC), sucrase (S-SC), and acid phosphatase (S-ACP) activities over 80 days; and (3) enhanced total soil biomass (bacteria, fungi, and protozoa) and soil biological extracellular polymeric substances (EPS) content. Both biostimulants significantly enriched putative beneficial microbial taxa that may enhance soil quality. Correlative analysis identified 16 small-molecule carbon sources (monosaccharides, disaccharides, short-chain fatty acids) in the biostimulants that facilitated soil aggregation by selectively recruiting native Gammaproteobacteria, Actinobacteria, and Microbotryomycetes. Random forest analysis revealed that DOC and fungal biomass were the primary determinants of aggregate stability. Partial least squares path modeling confirmed that biostimulants primarily improved soil structure and fertility by stimulating fungal activity. Fungi mediated the enhancement of soil aggregate stability through direct action or by producing EPS-proteins, while bacteria indirectly improved aggregate stability by producing EPS-polysaccharides. These findings provide theoretical and technical guidance for measures aimed at rapidly improving soil structure based on biostimulation methods, and hold significant implications for sustainable agricultural development.

**ABSTRACT**

(1) Background: This study compared the rhizosphere microbial communities of diploid, triploid, and tetraploid watermelons. We aimed to elucidate how ploidy shapes the micro-ecological environment, adaptation, seedless and resistance. The findings are expected to provide a theoretical basis for innovating watermelon breeding strategies and harnessing beneficial plant-microbe interactions.
(2) Methods: High-throughput sequencing technology was employed to analyze the community structure of rhizosphere bacteria and fungi associated with diploid, triploid, and tetraploid watermelons.
(3) Results: The alpha diversity of rhizosphere bacterial communities was significantly higher in triploid watermelons than in the diploid and tetraploid types. Functional prediction indicated that membrane transport, carbohydrate metabolism, and amino acid metabolism were the most abundant pathways in bacterial communities across all ploidy levels, with significant functional variations observed among them. Triploid watermelons also exhibited the highest rhizosphere fungal diversity. Community composition analysis revealed distinct dominant bacterial and fungal taxa associated with each ploidy level. Integrated analysis showed that the overall bacterial community structure was most strongly influenced by triploid watermelon roots. This may be linked to their unique genetic characteristics and the resulting pronounced effect on the root micro-ecological environment.
(4) Conclusions: This study reveals that ploidy level is a key factor shaping the rhizosphere microbiome in watermelons Triploid watermelons assemble a distinct microbial community through the specific selection for and against certain taxa. These insights offer a theoretical basis for optimizing cultivation practices to enhance yield and quality.

**ABSTRACT**

To investigate the relationship between the rhizosphere microbial community structure and lotus root texture, the biological properties, and the rhizosphere microbial composition of mealy (ML) and crunchy lotus (CL) varieties were all analyzed using traditional and high-throughput sequencing technologies. The results showed that the ML varieties exhibited significantly lower moisture but higher starch contents than those of CL. Meanwhile, the rhizosphere fungal richness of ML was also significantly higher than that of CL. Moreover, the relative abundances of bacterial phyla and genera, such as Nitrospirota, Bacteroidota, Proteobacteria, and *Bacillus*, alongside fungal phyla and genera, i.e., Ascomycota and *Emericellopsis*, were enriched in rhizosphere of ML compared to CL. Functional prediction also revealed that elevated nitrogen cycling, polysaccharide degradation and cellulose breakdown functions could be detected in ML, potentially driving starch accumulation and cell wall modification. These results suggest that rhizosphere microbial composition, particularly nitrogen-cycling bacteria and lignocellulose-degrading fungi, may contribute to texture formation between texture-differentiated lotus root varieties.

**ABSTRACT**

To explore the effects of different fertilizers on the value of peppermint essential oil and its mechanisms, apot experiment was conducted with five treatments: Organic Fertilizer (A), integrated organic-inorganic fertilizer (B), chemical fertilizer (C), no fertilization (D), and unplanted control soil (CK). The results showed that t the highest total terpenoid output (7.33 ± 0.72 mg $g^{-1}$ FW) and significantly increased menthol and isomenthol in treatment B compared to other treatments ($P$<0.05). In the root endosphere, bacterial diversity was highest under organic amendment (A) and lowest under chemical fertilizer (C). In contrast, fungal Shannon diversity was highest in C, followed by A ≈ D > B. Organic amendment enriched beneficial bacteria (e.g., Rhodococcus, Massilia) and fungi with suppressive functions (e.g., Chaetomium). Endosphere microbial networks exhibited higher diameter and clustering coefficients than rhizosphere networks, suggesting greater stability and resistance to disturbances. Integrated organic-inorganic fertilization optimized soil nutrient availability and enhanced microbiome functionality, leading to improved essential oil biosynthesis. Organic fertilization alone was most effective in maintaining endophytic bacterial diversity and beneficial functional groups. Fertilization regime had a stronger influence on endosphere than rhizosphere network stability. We recommend combined organic-inorganic fertilization as a preferred strategy for enhancing both biomass and essential oil production in peppermint.

**ABSTRACT**

Cucumber sex expression is a key agronomic trait determining yield, but whether its formations is related to rhizosphere soil microbes remains poorly understood. This study compared the soil microbial community structures in rhizosphere between gynoecious and monoecious cucumbers to identify potential associations. The results showed that bacterial genera including *Sphingomonas*, norank_f__*JG30-KF-CM45*, and norank_f__norank_o__*Saccharimonadales* were significantly enriched in the rhizosphere of the gynoecious cucumber. In contrast, norank_f__norank_o__norank_c__*KD4-96* and norank_f__norank_o__*Rokubacteriales* were significantly enriched in rhizosphere of the monoecious cucumbers. For fungi, genera such as *Aspergillus*, *Plectosphaerella*, and *Chaetomella* were enriched in rhizosphere of the gynoecious cucumbers. Conversely, *Trichoderma*, *Emericellopsis*, *Collariella*, and *Cordana* were significantly enriched in rhizosphere of the monoecious cucumbers. Functional prediction revealed that multiple nitrogen-cycling processes of bacterial communities, including nitrification, aerobic nitrite oxidation, nitrite ammonification, nitrate ammonification, aerobic ammonia oxidation, and arsenate respiration were detected in rhizosphere of the gynoecious cucumbers. By contrast, hydrocarbon degradation functions, particularly those for aromatic and aliphatic non-methane hydrocarbons were significantly enriched in rhizosphere of the monoecious cucumbers. Moreover, the rhizosphere of gynoecious cucumber harbored a higher abundance of saprotrophic and symbiotrophic fungi but a lower abundance of pathotrophic fungi compared to the monoecious cucumbers. These findings demonstrate that the composition and potential functions of the rhizosphere microbiome differ between gynoecious and monoecious cucumber, indicating that soil microbes in rhizosphere may play a role in the sex expression of cucumber varieties.

## ABSTRACT

Ozonated water ($O_3$), owing to its strong oxidizing and biocidal properties, has been proposed as a sustainable alternative to conventional plant-protection products. However, its effects on soil biological functioning and plant performance under biotic stress remain not fully understood. This study aims to evaluate the response of the soil–plant system to ozonated water irrigation, focusing on its effects on soil microbial processes, nutrient dynamics, plant growth, and its potential role in mitigating the biotic stress caused by tomato brown rugose fruit virus (*Tobamovirus frutctirugosum* - ToBRFV) and root-knot nematodes (*Meloidogyne incognita* Kofoid & White).

Greenhouse experiments were conducted using tomato (*Solanum lycopersicum* L.) under three irrigation regimes: tap water (control), ozonated water applied before transplanting (Pre $O_3$), and ozonated water applied after transplanting (Post $O_3$), in the presence or absence of ToBRFV infection. In parallel, trials on tomato (*Solanum lycopersicum* L.) and cucumber (*Cucumis sativus* L.) evaluated the effectiveness of ozonated water against *M. incognita*, comparing pre- and post-transplant applications.

Ozonated water significantly altered soil biological functioning. Both Pre $O_3$ and Post $O_3$ treatments reduced soil microbial biomass C and N, indicating a decline in soil biological fertility. The higher microbial respiration ($CO_2$) and increased metabolic quotient ($qCO_2$) suggesting oxidative stress and reduced microbial efficiency. Ozonated water also enhanced N transformations, promoting ammonification and nitrification, as reflected by higher soil $NO_3^-$ concentrations, particularly under Pre $O_3$ treatment. However, ozonated water did not mitigate the negative effects of ToBRFV infection on tomato plants; instead, pre-transplant ozone application further reduced biomass in virus-infected plants, indicating an amplification of stress under combined oxidative and viral pressure.

Conversely, ozonated water proved effective in reducing populations of *M. incognita*, especially when applied before transplanting. Pre $O_3$ treatments significantly decreased soil nematode density, root galling, and plant damage in both tomato and cucumber. This enhanced efficacy is likely due to the absence of host plants during pre-transplant application, which increases nematode exposure to ozone, impairing juvenile mobility and host root penetration.

Overall, ozonated water irrigation induced oxidative stress within the soil–plant system, negatively affecting microbial biomass and efficiency and failing to alleviate viral infection, while demonstrating promising nematicidal and nematostatic effects when applied before transplanting. These findings highlight the need for careful, context-specific application strategies to maximize the benefits of ozonated water while minimizing potential risks to soil biological health.

[3] *Institute of Earth System Sciences, Section Soil Science, Leibniz Universität Hannover, Herrenhäuser Str. 2, 30419, Hannover, Germany*

**ABSTRACT**

The sustainable intensification of agriculture requires systems that optimize both yield and ecosystem services. This study, part of the Horizon Europe funded project LEGUMINOSE, evaluates the multifunctionality of intercropping systems across varying pedo-climatic conditions in Europe. We analyzed 2,309 samples comprising bulk soil, rhizosphere, and roots from seven field trials to assess the impact of intercropping on nutrient cycling, greenhouse gas emissions, and soil microbial diversity.

Methodological approaches included physico-chemical profiling combined with microbial community analysis via qPCR and Next-Generation Sequencing (NGS). A major challenge identified was the strong influence of indigenous soil heterogeneity, specifically organic carbon (OC) variability, on microbial enzyme patterns, which necessitated the use of linear mixed-effects models to isolate treatment effects.

Our results indicate that while intercropping has a limited short-term impact on the Soil Organic Carbon (SOC) cycle, it acts as a strong driver of the Nitrogen (N) cycle, significantly enhancing nutrient turnover efficiency. At the biological level, intercropping functions as a filter, causing the distinct root microbial communities of cereals and legumes to converge when grown together. Furthermore, agronomic analysis revealed a Land Equivalent Ratio (LER) of 1.16, confirming that legume-based mixtures can achieve higher productivity than monocultures while simultaneously enhancing crop resilience and nutrient use efficiency. These findings suggest that legume-cereal intercropping is a viable strategy for stabilizing yields and mitigating environmental footprints in European agriculture.

# Harnessing Halophyte Microbiomes to Build Wheat Resilience under Extreme Coastal Salinity

**Mahdi Shahabirokni [1], Hassan Etesami [2], Alireza Raheb [2] , Dorota Krzyżanowska [3], Bahar S. Razavi[1]**

*[1] Department of Soil and Plant Microbiome, Institute of Phytopathology, Christian-Albrechts-University Kiel, 24118, Kiel, Germany*

*[2] Department of Soil Science, Faculty of Agriculture and Natural Resources, University of Tehran, Iran*

*[3] Laboratory of Plant Microbiology, University of Gdańsk*

**ABSTRACT**

Global warming and sea-level rise are accelerating soil salinization in coastal ecosystems, threatening food security, ecosystem stability, and soil carbon sequestration. Developing nature-based solutions that sustain soil and plant health under these conditions is therefore critical.

Halophytes, naturally adapted to saline environments, rely on tightly co-evolved microbial partners that support their survival under high salt stress. Here, we explored whether wild halophyte-associated microbial communities could be leveraged to enhance wheat tolerance to saline soil. A total of 510 bacterial isolates were obtained from the rhizosphere and endosphere of coastal halophytes along the Oman Sea and Baltic Sea. Rather than selecting microbes solely based on classical plant growth-promoting traits, we used plants themselves as biological filters. Salt-tolerant, non-antagonistic isolates were assembled into microbial consortia and inoculated into six wheat cultivars, grown in saline soil.

Plant responses varied strongly among cultivars and consortia. While some treatments markedly enhanced biomass (up to 228% in *Pishgam* and 127% in *Ofoq* with Consortium 3), others caused growth suppression (33% reduction in Arg with Consortium 7). Microbial community structure analysis revealed a shared core of 122 operational taxonomic units (OTUs) across treatments; however, β-diversity (UniFrac) analyses demonstrated pronounced genotype-specific microbial filtering. The salt-tolerant cultivar *Ofoq* maintained a rhizosphere microbiome closely resembling its uninoculated control (distance = 0.285), buffering negative effects, whereas the sensitive cultivar *Bam* showed a stronger microbial shift (distance = 0.401) associated with reduced growth. These patterns highlight the decisive role of root-exudate-mediated selection in shaping functional microbiomes.

Our findings demonstrate that the success of microbial inoculation under extreme salinity depends on genotype–microbiome compatibility, not inoculum composition alone. Harnessing native halophyte-associated microbes through plant-driven selection offers a promising, low-input strategy to enhance crop resilience, stabilize coastal soils, and reduce carbon losses under climate change.

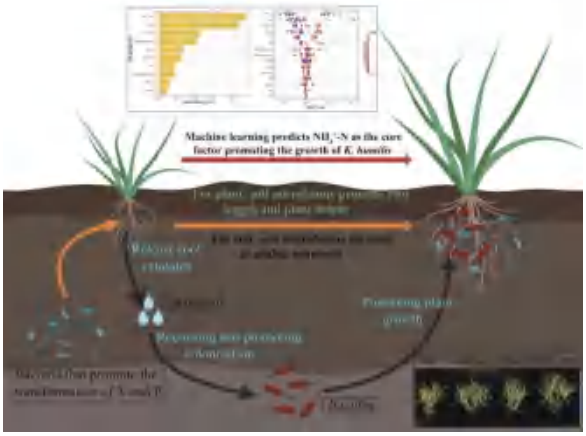
# Recovery Mechanism of Kobresia humilis in Alpine Meadows

**Junxi Li[1*], Hui Sun[1], Yongli Xie[2], Yujia Tang[1], Shuangchao Wang[1]**

[1] *School of Architecture and Environment, Sichuan University, Chengdu , China*

[2] *College of Agriculture and Animal Husbandry, Qinghai University, Xining , China*

*m15565114991@163.com



**ABSTRACT**

Alpine meadows, as crucial components of biodiversity and ecosystem services, are facing increasingly severe degradation issues, necessitating effective restoration strategies. This study investigated the recovery mechanism of *Kobresia humilis* (*K. humilis*), a group species in alpine meadows. By measuring the physiological activity, phenotype, soil nutrients, and rhizosphere microorganisms of *K. humilis* under varying degradation levels and enclosure durations, this study discovered that *K. humilis* resists grassland degradation by boosting its reactive oxygen species scavenging activity. Soil nutrients, which decline with grassland degradation, were restored after enclosure. Analysis of the rhizosphere microorganisms of *K. humilis* revealed that the microbial network in its rhizosphere becomes more complex and more unstable with grassland degradation. Microbial ecological functions, such as chemoheterotrophy, which decline with grassland degradation, were restored after enclosure.

Furthermore, across two annual samplings, a specific *Bacillus* species was consistently enriched in the rhizosphere of taller *K. humilis* plants, from which the representative strain D334 was isolated. By measuring the root exudates of *K. humilis* and correlating metabolomic and microbiomic data using Spearman correlation and the model-based integration of metabolite observations and species abundances 2 (MIMOSA2), we found that substances such as flavonoids were significantly positively correlated with *Bacillus* enrichment. In vitro experiments verified that *K. humilis* can recruit *Bacillus* by releasing baicalin and promote *Bacillus* growth by releasing riboflavin and sucrose.

To identify key drivers for *K. humilis* recovery, we integrated soil-plant data using machine learning: random forest and eXtreme Gradient Boosting models interpreted via SHapley Additive exPlanations (SHAP) analysis. Models consistently identified soil ammonium nitrogen ($NH_4^+$-N) as the primary factor promoting *K. humilis* phenotype. Ultimately, pot experiments showed that co-applying *Bacillus* and $NH_4^+$-N synergistically increased *K. humilis* plant height by 63.3%. Moreover, *Bacillus* promoted an increase in soil $NH_4^+$-N content. This provides a biological-chemical restoration method for the recovery of *K. humilis*.

# Establishing Genetic, Phylogenetic and Functional Mechanisms that Shape Acidobacteriota Diversity of Arctic Tundra and Boreal Forest Soils

**Max M. Häggblom**

*Department of Biochemistry and Microbiology, Rutgers University – New Brunswick, New Jersey, USA*

* haggblom@rutgers.edu

**ABSTRACT**

Increasing temperatures in Arctic tundra and boreal forest ecosystems are leading to higher microbial respiration rates of soil organic matter, resulting in the release of carbon dioxide and methane. To understand the effects of this microbial activity, it is important to better characterize the diverse microbial communities in these soil habitats. The *Acidobacteriota* are ubiquitous and abundant in tundra and boreal forest soils, however the genetic taxonomic and functional diversity within this bacterial phylum remain poorly known. Our aim is to refine the phylogenetic and functional diversity of the ubiquitous, but elusive, members of the *Acidobacteriota* phylum so we can link their diversity to different soil habitats and elucidate the mechanisms which shape their communities in soils. Bacteria excel at adapting to different environments, but the functional implications of community transitions need to be characterized. The overarching hypothesis is that resource partitioning, selective predation, and temporal separation of activity each contribute to the success of a particular bacterial strain/species. Laboratory- and field-based approaches are used to discern which species are successful and explain why, with a focus on sub-Arctic tundra and boreal forest soil habitats. From a set of long-term tundra and forest field sites we are collecting data on how the soil *Acidobacteriota* communities are selected across environmental gradients. The long-read capability of the Oxford Nanopore MinION is used to profile bacterial ribosomal RNA operons of soil communities and isolates in order to build a comprehensive rRNA operon sequence database of the *Acidobacteriota* with strain-level resolution. Assembled full *Acidobacteriota* genomes, multi-locus phylogenies, and annotated pangenome markers are utilized to differentiate *Acidobacteriota* species. By uncovering novel species and strains within the *Acidobacteriota* and improving the accuracy of their phylogenetic placements, we aim to enhance our understanding of this complex phylum and elucidate the mechanisms which shape microbial communities in soils.

## ABSTRACT

Sustainable management of crop rotation systems is critical for maintaining soil fertility, microbial diversity, and crop productivity in intensive agroecosystems. The Huang-Huai-Hai region, a major grain-producing area in China, predominantly employs a wheat-maize double-cropping system, often causing nutrient imbalances and soil degradation. Introducing legume rotations may improve soil quality and microbial functioning. Here, we investigated the effects of summer crop type (soybean vs. maize), location, ecological compartment (bulk vs. rhizosphere soil), and management practices (fertilization and straw returning) on soil bacterial communities using cross-regional field platforms established in 2017. Soil physicochemical properties, bacterial diversity, community composition, co-occurrence networks, and assembly mechanisms were analyzed.

Geographical location was the strongest environmental filter, explaining up to 34.15% of community variation, exceeding effects of ecological compartment and management. Crop type modulated responses to management: bacterial communities in maize were more sensitive to fertilization than in soybean. Community composition showed clear geographic differentiation: SZ and WS were enriched in *Sphingomonas* and *Lysobacter*, while YC was enriched in *Burkholderia*. CCA identified key drivers: clay content, soil water, and pH drove SZ/WS differentiation; sand content and $NH_4^+$-N drove XX/YC variation.

Network analysis revealed functional topological differences: soybean supported more complex (nodes/edges) and stable (higher clustering coefficient) networks; maize exhibited higher modularity and positive interaction proportion. Key ecological modules, enriched in nitrogen-cycling taxa (*Nitrospira*, *Nitrosospira*), were strongly influenced by management. Neutral model analysis indicated stochastic processes dominated community assembly (maize > soybean; bulk > rhizosphere), but rhizosphere conditions and fertilization increased deterministic selection.

Overall, regional soil background sets the foundational framework for bacterial community patterns, while crop type, via rhizosphere processes and interactions with management, regulates network stability and community assembly. Incorporating soybean into cereal rotations can enhance microbial network robustness and optimize community assembly, providing mechanistic insights for microbiome-informed sustainable intensification in agriculture.

# Microbial Hydrogen Cycling as a Potential Driver of Drought Resistance in Agricultural Soils

## ABSTRACT

Studies in natural and dryland ecosystems demonstrate that hydrogen-oxidizing microbes can survive prolonged drought by utilizing atmospheric $H_2$ to meet basal energetic demands. However, how hydrogen cycling operates in agricultural soils and whether these mechanisms are relevant for agroecosystems remain poorly characterized.

Here, we investigated soil $H_2$ cycling in a soybean agroecosystem which represent a well-established biological source of $H_2$ in soils. We quantified soil $H_2$ production and measured depth-resolved $H_2$ oxidation rates under field conditions, revealing pronounced vertical structuring of hydrogen oxidation within the agricultural soil profile. Notably, $H_2$ oxidation rates were consistently higher in upper soil layers, which are typically subject to greater environmental variability and resource limitation.

We further identified a significant positive linear relationship between soil moisture and $H_2$ oxidation rates within a moisture range (0.10–0.25 gravimetric water content), which is consistent with previous studies. This pattern indicates that soil moisture modulates $H_2$ oxidation capacity but does not solely determine it. Comparisons between agricultural and adjacent forest soils revealed distinct land-use–specific $H_2$ oxidation rates and differences in the abundance of high-affinity hydrogenase genes (*hhyL*).

Together, these findings suggest that biologically mediated $H_2$ inputs and depth-structured hydrogen oxidation contribute to microbial persistence and community stability in agricultural soils, consistent with survival mechanisms previously described in drought-prone ecosystems. We propose that $H_2$ cycling represents an underappreciated process linking microbial survival strategies to soil resilience in agriculture. Ongoing work will explore how $H_2$-driven microbial persistence interacts with crop systems, particularly leguminous crops such as soybean, to assess its potential role in agricultural drought resilience.

**ABSTRACT**

Endophytes are host-associated microbial communities that colonize intercellular and/or intracellular spaces, while arbuscular mycorrhizal fungi (AMF) are root-associated symbiotic fungi that form mutualistic relationships with plants. Both groups enhance plant performance through nutrient acquisition, stress tolerance, and growth promotion, while benefiting from plant-derived carbon. In this study, we investigated the dual partite interaction between AMF colonization and dark septate fungal endophytes (DSE: Thozetella neonivea, Leptodontidium orchidicola) on the growth and yield of soybean (Glycine max) grown in the field.

The DSEs were applied to seeds at three different dosages (low, medium, and high). All seeds were counter-coated with rhizobium bacteria, while the control treatment only had the rhizobium. We quantified AMF colonization based on the presence of arbuscules and documented the presence of other fungal structures (e.g., vesicles, fungal coils) using microscopy. AMF colonization levels were significantly higher in the DSE-inoculated treatments compared to the controls. This enhancement in AMF colonization correlated with increased plant growth (total dry biomass, root mass) and grain yield, with the medium DSE dosage producing the most pronounced effects compared to the control. However, a decline in plant performance was observed at the high dosage, suggesting a possible microbial imbalance.

Our results indicate that the inoculation of soybean seeds with the DSEs improved the naturally occurring AMF and plant growth, irrespective of the endophyte strain. This suggests a synergistic interaction between DSEs and AMF in the soybean rhizosphere. However, excessive DSE application may disrupt this balance, potentially altering the microbial network and negatively affecting AMF symbiosis and plant growth. DSE dosage is a critical factor influencing this dual symbiotic relationship. We conclude that targeted DSE inoculation can enhance AMF colonization, plant biomass, and yield in soybean, offering a promising strategy for sustainable crop improvement.

# Synergistic Soil Remediation and Microbial Network Reconstruction: Leguminous Cover Crops and Probiotics in Degraded Dry-Hot Valley Coffee Plantations

## ABSTRACT

Soil degradation poses a critical threat to agroecosystem sustainability in ecologically fragile dry-hot valleys, where intensive coffee cultivation has exacerbated soil erosion, nutrient depletion, and microenvironmental deterioration.As a promising eco-friendly remediation strategy, the combined application of leguminous cover crops and probiotics has shown great potential in reversing soil degradation, yet the underlying synergistic mechanisms governing soil physicochemical improvement and microbial community restructuring remain poorly elucidated, limiting its large-scale deployment.

To address this knowledge gap, a one-year field experiment was conducted in a degraded coffee plantation in the Jinsha River dry-hot valley, with three treatments established: monoculture of *Medicago sativa L.* inoculated with *Bacillus cereus* strain 4-8 (ZB1), mixed culture of *Medicago sativa L.* and *Vicia villosa var. glabrescens* inoculated with the same strain (ZB2), and a fallow control (ZCK).Comprehensive analyses were performed to assess the impacts of different treatments on soil chemical properties, key enzyme activities, bacterial community composition, and species co-occurrence networks.

The results demonstrated that the combined legume-probiotic treatments exerted a pronounced synergistic effect on soil remediation and reclamation: ZB1 treatment effectively optimized soil pH from weakly alkaline to neutral, while significantly increasing total nitrogen and potassium contents; both ZB1 and ZB2 treatments markedly elevated nitrate nitrogen levels, thereby enhancing nitrogen sequestration and mitigating nutrient leaching risks. Concurrently, the activities of soil enzymes involved in carbon, nitrogen, and phosphorus cycling were significantly upregulated, indicating the activation of microbial metabolic functions critical for soil nutrient transformation. At the microbial community level, the combined treatments drove a distinct shift in dominant bacterial phyla from Acidobacteria to Bacteroidetes, with a notable enrichment of beneficial taxa including *Xanthomonas* and *Rhodobacterium.* Redundancy analysis further identified total nitrogen as the pivotal edaphic factor driving bacterial community assembly, establishing a direct causal link between soil physicochemical remediation and microbial community restructuring.

This study provides the first field-scale empirical evidence for the cascading synergistic pathway underlying legume-probiotic mediated soil improvement, and proposes a practical, scalable remediation strategy for degraded dry-hot valley agroecosystems. The findings offer robust scientific support for advancing global efforts in soil degradation control and sustainable soil management, contributing to the realization of the "a shared future for soil and humanity" initiative.

*wsshen@nuist.edu.cn

**ABSTRACT**

The Taihu Lake region has experienced rapid land use intensification, characterized by conversions from natural wetlands (NW) to conventional rice-wheat rotation fields (RW) and further to greenhouse vegetable fields (GH), driven by economic interests. While such transformations are widespread, their combined effects on greenhouse gas (GHG) emissions and underlying soil microbial mechanisms remain poorly understood. This integrated study addresses these gaps through multi-faceted analyses of GHG fluxes, soil microbial communities, and nitrogen (N)-cycling functional genes across NW, RW, and GH sites. Two-year in-situ field experiments revealed significant GHG emission shifts: land use intensification reduced methane ($CH_4$) emissions (NW: 970.66 ± 100.09 kg C $ha^{-1}$; RW: 896.71 ± 300.44 kg C $ha^{-1}$; GH: 71.23 ± 63.62 kg C $ha^{-1}$) but markedly increased nitrous oxide ($N_2O$) emissions (NW: 3.35 ± 0.44 kg N $ha^{-1}$; RW: 14.38 ± 4.09 kg N $ha^{-1}$; GH: 81.62 ± 4.89 kg N $ha^{-1}$). Global warming potential followed the order RW > NW > GH, indicating intensified comprehensive greenhouse effects during NW→RW conversion and mitigation during RW→GH conversion. Microbial community analyses showed land use intensification directly altered bacterial and fungal compositions, with stronger impacts on bacteria. Bacterial communities correlated closely with soil $NO_3^-$-N, pH, and electrical conductivity, exhibiting decreased deterministic processes (opposite to fungi). Arable lands (RW/GH) displayed more complex microbial networks, and seasonal variations (notably summer) influenced microbial diversity and function, though less strongly than land use effects. Integrating quantitative PCR and metagenomics uncovered microbial mechanisms driving $N_2O$ emissions: intensification reshaped N-cycling microbial communities, depleting nitrogen fixation, dissimilatory nitrate reduction to ammonium, and anammox marker genes in GH soils. Denitrifying communities segregated similarly to total N-cycling assemblages, with increased network complexity but divergent stability. Critically, intensification amplified $N_2O$ emission potential by elevating Pseudomonadota harboring *nirK*/*norB* genes (and associated communities) while reducing *nosZ* (encoding $N_2O$ reductase) abundance—directly linking microbial functional imbalance to emission increases. Collectively, this study demonstrates that land use intensification in the Taihu Lake region drives GHG emission trade-offs (reduced $CH_4$ but amplified $N_2O$) and restructures soil microbial communities and N-cycling functions. These findings highlight the need to prioritize microbial functional balance (e.g., restoring *nosZ*-carrying taxa) in mitigation strategies, providing critical insights for sustainable land management in wetland-agricultural transition zones.

**ABSTRACT**

Soil biodiversity, essential for ecosystem functioning and plant resilience, is increasingly threatened by climate change and agricultural practices. While the impact of soil biodiversity loss on plants like legumes and grasses has been demonstrated, its effect on potatoes remains underexplored. This study addresses this gap by investigating how different microbial diversity gradients, including the presence of phages, influence potato growth and resilience under drought stress in a controlled climate chamber experiment. Our findings reveal that varying microbial diversity leads to distinct plant growth patterns, with low-diversity treatments suppressing plant recovery post-stress. Higher abundance of phages enhanced plant performance during drought stress, although no significant effect on recovery was observed. Notably, we demonstrate that soil microbial diversity significantly alters root exudate profiles, suggesting that interactions between root metabolites and the microbiome may regulate plant growth and responses to environmental disturbances. Furthermore, correlation analysis revealed a positive correlation between soil microbial diversity and plant productivity, particularly during the recovery period following drought stress, emphasising the critical role of the soil microbiome in supporting plant resilience. These findings underscore the importance of maintaining healthy soil microbial communities to enhance plant drought tolerance and sustain agricultural productivity in the face of climate change.

**ABSTRACT**

Anaerobic soil disinfestation (ASD) is a promising alternative to soil fumigation for suppression of strawberry black root rot complex pathogens, including pathogens in the *Fusarium oxysporum (Fo)* species complex. Soil treatment by ASD is facilitated by in-situ fermentation of organic soil amendments, which induces production of pathogen-suppressing reduced iron and manganese cations and volatile fatty acids (VFAs). However, little is known about how amendment composition influences *Fo* suppression and crop health via root-associated fungal communities in ASD. The influence of amendment composition on *Fo* suppression, crop health, and root-associated fungi was studied in strawberry pot trials in a greenhouse pot trial, using dried molasses, wheat bran, spent brewer's yeast, and Azolla meal amendments. Soil solution VFA and reduced metal concentrations, soil pH, and Fo inoculum viability were measured post-ASD. Plant biomass (as a proxy for crop health) was measured and roots sampled to determine endophytic colonization rates of beneficial mycorrhizae/endophytes by ITS2 amplicon sequencing. The influence of amendment type on VFA and reduced metal concentrations and *Fo* suppression was minimal due to low VFA and reduced metal concentrations owing to limited anaerobic conditions. However, some ASD amendments (i.e, molasses and wheat bran) were associated with enhanced plant health or abundance of key root-associated fungi (e.g., dried molasses and Serendipitaceae). Higher abundance of Trichoderma spp., members of the order Agaricales, and members of the family Serendipitaceae was positively associated with root and/or shoot biomass. Our results highlight the importance of ASD amendment properties and root-associated fungi in influencing crop health when ASD treatments do not provide adequate treatment effects through decomposition byproducts such as VFAs and reduced metals.

# Fungal community shifts govern microbial carbon use efficiency across an elevation gradient at Qinling mountain, China

**ABSTRACT**

Microbial carbon use efficiency (CUE) is a critical factor affecting soil organic carbon (SOC) dynamics. However, the relative importance of biotic and abiotic drivers of CUE variations remains debated, resulting in large uncertainties in SOC predictions. In this study, we combined field sampling with isotope labeling experiments to identify the driving factors of changes in microbial CUE along an elevation gradient (1,200–2, 400 m) of Qinling mountain. Our results demonstrated that higher elevations (2,000–2,400 m) resulted in greater microbial CUE, which partially aligned with the enhancement of SOC sequestration and the total SOC content change. The fungi-dominated cluster served as the directed CUE dynamics, while soil nutrients acted as the indirect factor affecting CUE by regulating the structure and interactions of the microbial community. Notably, the dominance of fungal taxa at higher elevations, shaped by substrate properties, promoted faster growth and stronger synergistic interactions within the microbial network, leading to higher CUE. These findings highlight the importance of integrating the taxonomic and functional traits of microbial communities to predict community-level CUE and SOC dynamics under global change.

## ABSTRACT

The black soil region of Northeast China, often termed the “giant panda of farmland” in China, is vital for national food security and agricultural sustainability. Intensive cultivation, however, has accelerated soil degradation, underscoring the urgent need to understand the microbial mechanisms that sustain its fertility. While black soil is known for high organic matter and nutrient content, the structural and functional links between its microbial communities and soil productivity remain unclear. Here, we conducted comparative metagenomic analyses of black soil alongside other major agricultural soils—fluvo- aquic, red, and saline- alkali soils—to systematically characterize the microbial features underpinning black soil fertility.

In the dryland black soil sampled from Lishu County in this study, Actinomycetota dominated at the phylum level, representing >64% of annotated genes. At the family level, marked enrichments were observed for Nocardioidaceae, Pseudonocardiaceae, Paraconexibacteraceae, and Sphingomonadaceae. The exceptional abundance of Nocardioidaceae (>18%) suggests a key role in decomposing complex organic matter. Functionally, KEGG annotation revealed elevated gene abundances linked to amino acid metabolism, carbohydrate metabolism, and energy metabolism, reflecting heightened organic matter transformation and energy flux. Black soil also showed superior gene representation in cofactor and vitamin metabolism, transport and catabolism, xenobiotics biodegradation, and lipid metabolism. Complementary eggNOG analysis further confirmed enhanced functional potential in carbon transport and metabolism, transcription, cell cycle control, cell division, lipid metabolism, secondary metabolite biosynthesis and transport, and iron ion transport/metabolism. Absolute quantification via SmartChip- based high- throughput qPCR validated these patterns, demonstrating substantially higher abundances of key functional genes involved in carbon (e.g., fumarate reductase), nitrogen (e.g., nitrogenase iron protein, nitrite reductase), and phosphorus (e.g., pyrroloquinoline- quinone synthase, alkaline phosphatase) cycling. Annotations against the Virulence Factor Database additionally revealed significantly higher abundances of genes related to exoenzymes, immune modulation, nutritional/metabolic factors, and stress survival in black soil. This suggests that the high- organic- matter, microbially active black- soil ecosystem selects for taxa with enhanced environmental adaptability and competitive traits.

Collectively, our findings identify distinct microbial taxa and functional gene repertoires that contribute to vigorous nutrient cycling and metabolic resilience in black soil. These insights provide a genomic foundation for developing microbial- based strategies to sustain and enhance the productivity and ecological health of this vital agricultural resource.

## ABSTRACT

Nitrification inhibitors can alleviate nitrogen loss by inhibiting nitrification. Research on biological nitrification inhibition (BNI), as an organic and environmentally friendly alternative, is gradually gaining a lot of attention for improving nitrogen use efficiency (NUE) and decreasing environmental pollution. Therefore, a deeper understanding of how biological inhibitors modulate soil nitrifiers and denitrifiers needs to be explored. A naturally nitrification-inhibiting plant, such as *Plantago lanceolata*, is an excellent model for assessing the inhibitory mechanisms of BNI. Six genotypes of *P. lanceolata* were planted as an intercropping species with maize in two different locations characterized by contrasting soil types. At BBCH 65 and 85 maize rhizosphere soil samples were collected for analysis of the activity of extracellular enzymes of the carbon (C), nitrogen (N) and phosphorus (P) cycle, to ensure that the suppression of nitrifiers by *P. lanceolata* exudates does not inhibit key functions of organic matter mineralization in soil. While ß-glucosidase (BG) and cellulase activity (CE) assess general hydrolytic microbial activities, leucine aminopeptidase (LAP) and acid phosphatase activity (AP) display nutrient-mineralizing activities. In addition, DNA and RNA were extracted and subjected to 16S rRNA gene sequencing to assess the effects of *P. lanceolata*–mediated BNI on the community composition and diversity of key nitrifiers and denitrifiers. Based on 16S rRNA gene sequencing and Tax4Fun analysis, we predicted functional genes involved in (de-)nitrification and assessed potential losses or gains of functional genes related to nitrification and denitrification. Subsequently, we went for qPCR of amoA to directly determine gene copy numbers depending on the Plantago genotypes.

We could demonstrate that P. lanceolate did not affect mineralizing enzyme activities in the maize rhizosphere and thus will not reduce mineral nutrient provision even under organic farming, where this is the kinetically limiting step controlling nutrient availability. Soil-specific effects on the microbiome exceed those of the P. lanceolate intercropping, diminishing genotype-specific effect on denitrifying and nitrifying communities across sites. This study provides molecular insights into the inhibitory processes in the rhizosphere that modulate the effectiveness of BNI. These findings pave the ground for sustainable strategies for a sustainable N-cycle management by intercropping.

**ABSTRACT**

The progressive restriction of peat extraction across Europe has intensified the need to identify sustainable alternatives for horticultural growing media that maintain biological functionality while reducing environmental impact. Peat has long been valued for its favorable physical properties; however, its non-renewable nature and role in carbon storage necessitate the development of peat-reduced or peat-free substrates. This study evaluates a range of alternative growing media and their mixtures with particular emphasis on microbial metabolic activity, functional diversity, and their role in soil carbon cycling.

Microbial community-level physiological profiling was conducted using Biolog™ EcoPlates to assess respiration activity, biomass production, and functional biodiversity in several growing media, including acidic peat, peat substrates, perlite, organic topsoil-based substrates, commercial biostimulants, and mixed formulations. Analyses were performed before plant cultivation to characterize the intrinsic biological potential of the substrates.

Functional indices such as Average Well Color Development (AWCD), Average Well Density Development (AWDD), and the effective number of substrates utilized (ENbs) were used to quantify microbial metabolic intensity and diversity.

Across all tested growing media, microbial metabolism was predominantly driven by nitrogen-containing carbon sources, particularly amines and amides, followed by amino acids and carbohydrates. This pattern indicates that nitrogen-rich substrates play a key role in supporting microbial activity and growth. Mixed substrates combining mineral components with organic matter exhibited high respiration rates, strong biomass production, and broad functional diversity, often comparable to conventional peat-based substrates. In contrast, perlite alone showed very low microbial activity and minimal biomass production, confirming its biologically inert character.

Functional biodiversity analyses demonstrated that substrates enriched with organic components and biostimulants supported metabolically versatile microbial communities capable of utilizing a broad spectrum of carbon sources. Polymer utilization remained consistently low across all substrates. Notably, the balance between respiration and biomass production indicated that certain peat-reduced mixtures effectively supported carbon transformation without inducing excessive microbial stress.

Overall, the results demonstrate that well-designed peat-reduced and peat-free growing media can sustain high microbial functionality. Microbial metabolic profiling is a valuable tool for evaluating peat substitutes and optimizing substrate composition, supporting the development of sustainable horticultural systems.

# Effects of inter-row management and cover crops on vineyard rhizosphere microbial communities

**Barnabás Kovács[1*], Zsolt Kotroczó[2], Péter Balling[1], Antal Kneip[1], László Matus[1], Péter Molnár[1], István Kiss[1] and Karl-Johan Fabó[1]**

## ABSTRACT

The microbial communities in vineyard rhizospheres have been the subject of considerable research, yet it remains unclear how floor management practices and cover crops affect their composition. Rhizosphere samples were collected from a long-term experimental vineyard designed to evaluate soil covering methods in erosion-prone areas (Figure). Our objective was to assess fungal diversity in vineyards differing only in floor management practices. To this end, we sampled two soil depths (10–30 cm (Shallow) and 30–50 cm (Deep)) in each vineyard. DNA was extracted using the Quick-DNA Fecal/Soil Microbe Kit following the manufacturer's instructions. Whole metagenome libraries were prepared and sequenced according to the Illumina protocol, with sequences analyzed using MEGAN6 and Kraken2 software.

Our results from this comparative long-term experiment on cover crops and tillage in an erosion-affected vineyard confirm previous literature findings: natural grass (dominated by *Lolium perenne* L.) acts as a significant water competitor for grapevines when used as cover crops. In summary, the Cover and Wheat treatments provided the best soil moisture retention, yielding the highest soil moisture values and grape water uptake. Next-generation metagenomic analyses revealed pathogenic strains comprising over 20% of the communities in three treatments Phacelia (Shallow), Wheat (Shallow), and Triticale (Shallow), whereas extremely low levels (<5%) were observed in Phacelia (Deep) and Cover (Deep). These findings can guide farmers in assessing risks associated with root disturbance (e.g., mechanical tillage in root zones), which may expose grapevines to soil-borne pathogenic fungi. The most pronounced soil disturbance occurred in the Wheat and Triticale treatments, resulting in higher pathogen ratios that warrant caution. Future evaluations of farming practices should incorporate this parameter when seeking sustainable alternatives.

**ABSTRACT**

In nature, conditions for tree growth are often harsh, and competition for nutrients and water in the soil is intense. To survive threatening conditions, plants form symbiotic relationships with different groups of fungi: arbuscular (AM) or ectomycorrhizal (ECM) symbiosis. The type of symbiosis that develops and which plants endure unfavorable conditions depend on limiting factors such as water and nutrients in their environment. In the Mediterranean, temperate, and boreal forests, trees establish both AM and ECM relationships, while in tropical regions, forests can be entirely dominated by AM. Within the eco2adapt joint project between the EU and China, we aim to determine how the mycorrhizal potential of forest plants and belowground diversity influence forest resilience to climate change. Since a plant's ability to survive largely depends on forming mycorrhizae with fungi that support them during drought or nutrient-limited conditions, we study root-associated mycobiome (RAM) communities across selected forests in Europe and China. Our focus is on linking the diversity and abundance of RAM to soil parameters, especially soil water and nutrient availability. To maximize ecological niche differences, in this contribution, we compare mixed alluvial forests in Serbia (co-dominated by ECM and AM hosts) with subtropical Moso bamboo (*Phyllostachys edulis*) forests in China (exclusively dominated by AM). Preliminary results from Chinese bamboo forests show that drought stress acts as a strong environmental filter, significantly reducing AM fungal diversity while promoting drought-tolerant genera such as *Glomus sp.* Despite a decrease in fungal diversity, the symbiotic infection rate in mature bamboo roots remains relatively stable, indicating a "core mycobiome" strategy that sustains water and nutrient uptake under stress. Preliminary findings from Serbian forests reveal marked seasonality in RAM diversity and structure, characterized by ECM dominance and the existence of a stable "core mycobiome". We aim to parameterize the soil environment that will favor specific plant/fungal communities (e.g., ECM versus AM trade-offs under water deficit) and thus enable monitoring of forest soil health, alongside the selection of forest management practices that will support forest survival in the future.

## ABSTRACT

Rhizospheric microorganisms constitute a central component of soil biodiversity and play a pivotal role in regulating plant performance and ecosystem functioning. Among them, plant growth–promoting rhizobacteria (PGPR) represent a key functional guild, capable of modulating plant physiology, nutrient acquisition, and stress responses. Their contribution is particularly relevant in the context of climate change, where increasing frequency of drought and soil degradation threatens crop productivity and soil health. Despite their proven potential, the effectiveness of PGPR in agroecosystems remains highly variable, largely due to the complex and dynamic nature of microbial interactions within the rhizosphere and their sensitivity to environmental and management-driven perturbations. Soil moisture regimes, plant developmental stage, and community-level microbial diversity profoundly influence the establishment, persistence, and functional expression of introduced strains. Consequently, understanding how environmental constraints and agronomic practices reshape rhizosphere microbiomes is essential for translating microbial inoculants into reliable tools for sustainable agriculture.

In this study, we tested whether the phenological timing of microbial isolation influences the functional outcomes of PGPR application. Three bacterial consortia were assembled from strains isolated at distinct phenological stages of spring wheat (*Triticum aestivum* L.), tillering , elongation and ripening stage, at Brackenhurst Farm (Nottingham, UK). All isolates were previously screened in vitro for key PGPR traits, including solubilization of phosphorus, potassium, and zinc, production of indole-3-acetic acid (IAA), ammonia, and siderophores. These consortia, representing temporally structured rhizosphere communities, were inoculated onto lettuce (*Lactuca sativa* L.) seedlings grown under well-watered and drought conditions. Plant performance was assessed through tissue traits (water content and dry matter), chlorophyll content (SPAD), and gas exchange (LI-COR) after 60 days from inoculation, while lettuce growth dynamics were monitored every 10 days using high-throughput phenotyping (PlantEye).

Under well-watered conditions, none of the consortia significantly altered dry matter, water content, or canopy architecture relative to the control, indicating that PGPR effects are muted when plants operate near their physiological optimum. In contrast, drought revealed strong strain-dependent physiological modulation.

Consortia assembled from rhizobacteria isolated during the elongation and ripening stages of wheat development significantly increased leaf chlorophyll content and reduced both transpiration and intercellular $CO_2$ concentration, while maintaining net photosynthetic rates. This coordinated response reflects a more efficient regulation of stomatal aperture, enabling plants to conserve water without compromising carbon assimilation, and thus represents a clear enhancement of intrinsic water-use efficiency under drought.These effects mirror mechanisms widely reported in PGPR literature, including ACC deaminase activity, hormonal modulation, and improved nutrient acquisition. Notably, whole-plant architectural traits derived from Phenospex scanning were not significantly altered by inoculation under drought, despite clear physiological benefits at the leaf level. This scale-dependent response suggests that PGPR primarily act as stress buffers, preserving photosynthetic function and delaying functional decline rather than driving rapid biomass accumulation.

Collectively, our results demonstrate that the temporal origin of rhizosphere bacteria encodes functional specialization relevant to plant stress adaptation, linking microbial succession in soil to ecosystem-level outcomes. PGPR isolated at different phenological stages of the host plant elicit distinct physiological strategies, underscoring the ecological significance of microbial turnover and niche differentiation within the soil microbiome. These findings align with emerging concepts in soil biodiversity and soil health, emphasizing that microbial function is shaped by dynamic community assembly rather than by isolated traits. Reframing inoculants as components of evolving soil microbiomes, whose adaptive history governs their functional expression, provides a new perspective for harnessing soil microbial diversity in climate-resilient agroecosystems. This temporal dimension of soil biodiversity offers a pathway for designing microbiome-based interventions that enhance plant resilience while maintaining the integrity and functional complexity of soil ecosystems.

## ABSTRACT

Urban greenspaces play a central role in safeguarding biodiversity and maintaining resilient cities, yet their influence on soil biotic homogenization remains unclear. We analyzed four contrasting greenspace types across major soil biota groups in 55 cities spanning a broad climatic gradient. Urban farms exhibited the highest soil biotic homogenization and pathogen prevalence. In contrast, golf courses and other structurally heterogeneous greenspaces showed low homogenization, with patterns comparable to natural ecosystems. Our results suggest that lower soil pH, higher tree cover, greater litter availability, and wetter environments may help reduce soil homogenization, and reveal that structural heterogeneity, rather than management intensity alone, determines urban soil biodiversity patterns.

## ABSTRACT

Agricultural soils rely on external nitrogen (N) fertilization to sustain crop productivity, which continuously activates ammonia-oxidizing microorganisms (AOMs). Although AOMs grow primarily via chemoautotrophic $CO_2$ fixation, their decay contributes to soil organic carbon (SOC) that can be respired as $CO_2$, leaving their net impact on soil carbon accumulation and neutrality unclear. This study employed two-phase microcosm incubation to examine how AOM cell proliferation and death affect SOC accumulation in long-term different fertilization black soils. During the 28-day incubation with $^{13}CO_2$ and urea (Phase I), net production of soil organic $^{13}C$ ($^{13}C$-SOC) showed no significant differences among treatments: unfertilized CK (continuous maize, 23.6 μg $g^{-1}$), chemically fertilized CC (continuous maize, 20.9 μg $g^{-1}$), CS (continuous soybean, 22.8 μg $g^{-1}$), and RCS (rotation maize-soybean, 25.0 μg $g^{-1}$). This $^{13}C$-SOC originated entirely from active ammonia-oxidizing bacteria (AOB) and archaea (AOA), with fertilized treatments showing significantly higher AOB: AOA protein-C ratios (CC: 4.48; CS: 5.88; RCS: 12.5) than CK (1.56). The mortality of active cells was further assessed (Phase II) by measuring AOM-related $^{13}C$-$CO_2$ mineralization, which was approximately twice as high in the CK compared with the fertilized treatments ($p < 0.05$) within 30 days. Moreover, we conducted a microcosm experiment using $^{13}C$-$CO_2$ and ammonium sulfate in a brown soil subjected to six long-term fertilization regimes (CK, N2, N4, M2, N2M2, N2P2). Single fertilizers (N2, N4, M2) showed the highest $CO_2$ fixation rates via ammonia oxidation (mean 13.1 μg $^{13}C$ $g^{-1}$), whereas manure treatments (M2, N2M2) emitted more $N_2O$ than inorganic fertilizers alone. The offset potential (warming equivalents of fixed $CO_2$ vs. $N_2O$) exceeded 70% in all treatments and topped 100% in N2 and N4. Notably, where AOA and AOB co-dominated (N2, N2M2), AOA-derived carbon contributed >97% of the newly fixed $^{13}C$-SOC. Long-term combined organic-inorganic fertilization (N2M2) shifted the active AOM community from AOB dominance (M2 alone) to AOA-AOB co-domination. We conclude that long-term urea application increases the AOB:AOA protein-C ratio and promotes ammonia oxidizer-derived SOC accumulation through their life cycles, ultimately supporting carbon neutrality. In contrast, ammonium sulfate application enhances the trade-off between $CO_2$ fixation and $N_2O$ emission, modulating the net greenhouse gas balance of AOM. These findings highlight the potential of optimized nitrogen fertilization to enhance carbon offset against $N_2O$ emissions in agricultural soils.

**ABSTRACT**

It is widely considered that conversion of natural landscapes to agriculture results in biotic homogenization. A recent study comparing soil biota of 27 paired natural steppe soil (NS) and agricultural soil (AS) sites across 900km in north-eastern China found that conversion to agriculture had increased spatial gradients in soil functional genes. Using the same shotgun metagenome samples, and bacterial amplicon data, we instead analyzed total observed variation at the between-site and within-site level. We found that land-use conversion from steppe to farmland diversified functional gene profiles both locally and spatially; it increased the abundances of functional genes related to labile carbon, but decreased those related to recalcitrant substrate mobilization (e.g., lignin), P cycling, and S cycling. Alpha-diversity of core functional genes was strongly related to multi-nutrient cycling in AS, suggesting a key relationship to soil fertility. From the perspective of community taxonomic composition, archaeal and fungal community variation was decreased in AS compared to NS at both within- and between-site scales. In contrast, the bacterial and metazoal community was homogenized only at the local scale. Total functional KEGG gene assemblage was homogenized in AS at both the local and regional scale, whereas "Y-A-S" strategies in bacteria were homogenized at the local scale but not the between-site scale. Overall, these results show a clear homogenizing effect of agriculture with respect to multiple aspects of soil taxonomic and functional diversity, though varying by scale. Certain abiotic soil properties showed homogenization in AS at within-site and between-site scales may explain this homogenization, and uniformity of plant cover in croplands likely contribute to the effect. These findings confirm and extend global-scale studies showing homogenization of soil biota in agricultural environments, revealing that effects extend to functional genes and the broad taxonomic spectrum of life – with potential loss of soil ecosystem resilience to environmental change resulting from agriculture.

# Challenges and opportunities in interpreting the complex microbial interactions in soil

**Xue-Xian Zhang***

*School of Biological Sciences, University of Auckland, Auckland 1010, New Zealand*

**Presenting & Corresponding author E-mail*: xxzhang1@gmail.com

**ABSTRACT**

A central challenge in contemporary soil microbiology is to bridge the gap between molecular mechanisms operating at the cellular level and population-level behaviors that emerge in complex soil environments. A key task in this endeavor is to elucidate the eco-evolutionary significance of the vast number of genetic variations that arise in nature. Understanding the environmental conditions under which such variants arise, persist, and gone is essential for correctly interpreting the biological and ecological functions of the corresponding genes.

I will briefly address issues in the so-called social microbiology, as well as the associated challenges and opportunities for enhancing our understanding of soil microbial diversity. Most importantly, I will take this opportunity to highlight key messages drawn from the contributed oral and poster presentations in this session.

## ABSTRACT

Global warming has intensified both the frequency and duration of drought events, posing severe threats to terrestrial ecosystems worldwide[1,2]. Drought limits soil water and nutrient availability[3], suppresses plant productivity[4], and disrupts carbon and nitrogen cycling[5]. Soil microorganisms, which drive these essential biogeochemical processes, are highly sensitive to water limitation[3,6]. However, while many studies have investigated microbial responses to short-term or pulse droughts[7-10], far less is known about how microbial diversity, community composition, and ecosystem functions change under sustained, long-term drought. Most previous research relies on snapshot or short-term experiments, which capture end-point effects but fail to reveal the temporal trajectories that govern microbial adaptation, community reassembly, and ecosystem resilience[7-10]. Understanding these time-resolved dynamics is critical for predicting how ecosystems will respond to progressive and persistent climate stress in the future[11].

To address this gap, we conducted a six-year field drought manipulation experiment in temperate grasslands. The experiment included a control and a drought treatment, in which ambient precipitation was continuously reduced by 50% using automated rainout shelters. Soil samples were collected annually from both drought and control plots to capture temporal trajectories rather than isolated responses.

Our results provides several important insights into the responses of belowground microbial communities to experimental drought. First, a six-year field drought treatment reduced microbial biodiversity and biomass across major kingdom-level soil microbiota, such as bacteria, fungi, and protists (**Fig. 1**). This cross-kingdom pattern of biodiversity decline has not been previously documented in drought-related literature, representing a significant advancement in understanding microbial responses to sustained climatic extremes. Second, long-term drought stress accelerates the temporal succession of soil microbial communities, driving both community compositions and networked communities toward higher divergence. Third, although stochastic processes initially dominated community assembly, their influence declined over time under drought, suggesting that drought acted as a strong deterministic filter (**Fig. 2**). Additionally, drought-driven shifts in community composition and succession down-regulated genes involved in biogeochemical cycling and altered ecosystem functioning (**Fig. 2**). These findings address a critical knowledge gap in understanding belowground responses to drought.

The above findings have important implications for predicting ecological consequences of climate change and for ecosystem management. First, prolonged drought can drive microbial communities to increasingly diverge from contemporary states, raising the likelihood of multiple alternative community configurations and reducing the predictability of future successional trajectories. Also, drought can weaken stochastic influences and strengthen deterministic constraints, allowing communities to converge toward less variable states. Consequently, future microbial community composition may become more constrained and predictable under persistent drought, though they may differ markedly from those observed today. In addition, drought functions as a strong environmental filter that reduces soil microbial biodiversity, which, together with rapid community turnover and declines in beneficial taxa, can substantially weaken ecosystem functions and services and increase ecosystem vulnerability under future drought conditions.

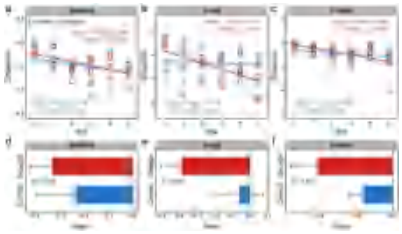

**Fig. 1. The drought effect on soil microbial biodiversity.** (**a**–**c**) Changes of soil microbial diversity over time based on the Shannon index under drought or control. **ABSTRACT**

Soil microorganisms acquire resources by producing extracellular enzymes to break down complex substrates; the depolymerised substrates are then taken up through membrane transporters. It has been widely theorised that some organisms do not produce extracellular enzymes but take up the shareable depolymerised resources, a behaviour often referred to as "cheating". However, genomic evidence for the cheating behaviour in natural soil communities is rare. Here we analyse glycoside hydrolase (GH) genes and sugar-specific ABC transporters in bacterial Metagenome-Assembled Genomes (MAGs) and use the gene count ratio as a cheating index to distinguish uptake-optimised "cheaters" from depolymerisation-optimised "producers". In an 18-month in situ litter-bag experiment in a Mediterranean grassland-shrubland ecosystem, early decomposition stages were dominated by MAGs representing cheaters with higher gene counts for transporters, but lower gene counts for hydrolytic enzymes, whereas later stages were dominated by producers with the opposite pattern. Metatranscriptomic data showed that fungi dominated early stages and encoded far more GH genes than bacteria, suggesting that early-stage cheater bacteria exploit products from fungi-driven depolymerisation. Extending this framework globally, analyses of 29,413 soil MAGs, 5,356 genomes of soil isolates, and 249,311 MAGs of environmental and host-associated bacteria revealed similar uptake-optimised cheater lineages. The cheating index was higher in MAGs from biomes with lower productivity and there was a clear phylogenetic signal. These findings advance our understanding of bacterial cheating as a widespread and enduring strategy in soils, underscoring its global prevalence and potential consequences for ecosystem functioning.

# Analysis of Soil Microbial Community Composition and Diversity Under Different Forest-Medicinal Plant Intercropping Patterns

**Shutong SANG [1], Wei Huang [1],Wendi LAN[1] Kaitai Yang[2], Baoling Chen [2], Fengqing Li [1*] Xingliang Chen[1*]**

**ABSTRACT**

ABSTRACT: *Pinus elliottii* Engelm. is a fast-growing evergreen arbor species native to the southeastern United States. Introduced into China in the 1930s, it has become one of the main afforestation tree species in the hilly areas of southern China. However, long-term monoculture plantations of this species can easily lead to soil nutrient depletion and microbial community imbalance, highlighting the need to improve stand quality and develop high-efficiency economic forests. 【Objective】 This study aimed to identify suitable intercropping patterns for understory medicinal plant in *Pinus elliottii* Engelm. forests, thereby providing a scientific basis for management decisions. 【Method】 Three intercropping patterns were tested: *P. elliottii-Ficus simplicissima-Spatholobus suberectus* (PHS), *P. elliottii-Alpinia oxyphylla-S. suberectus* (PAS), *P. elliottii-Amomum villosum-S. suberectus* (PSA), with a pure *P. elliottii* forest serving as control (CK). Soil nutrient dynamics and enzyme activities were determined, and rhizospheric microbial communities were analyzed using high-throughput sequencing. 【Result】 Under the same intercropping pattern, soil nutrients in (0, 20] cm layer were higher than those in the [20, 40) cm layer, except for total nitrogen (TN) under PSA pattern. In the (0, 20] cm layer, all three intercropping patterns significantly reduced amylase activity compared to CK ($p< 0.05$). The PHS pattern significantly increased acid phosphatase and urease activities while decreasing nitrate reductase activity ($p< 0.05$). In the PAS pattern, acid phosphatase, neutral protease, and urease activities were significantly enhanced, with urease activity significantly higher in (0, 20] cm than in the [20, 40) cm layer. High-throughput sequencing revealed interactions among intercropping patterns, soil properties, and microbial communities. Intercropping significantly affected the structure, composition, and diversity of both rhizosphere bacterial and fungal community. Molecular ecological network analysis indicated that the PHS pattern enhanced the stability and complexity of rhizosphere bacterial community. Redundancy analysis (RDA) identified organic carbon (SOC) and total nitrogen (TN) as key drivers of microbial variation. Random forest and LefSe analyses further identified key taxa, such as *Acidibacillus* and *Thermosporothrix*, as significantly associated with the intercropping effects. Different patterns may affect soil properties by increasing the relative abundances of specific taxa, thereby enhancing plant growth and stand quality. Functional prediction suggested that microorganisms may improve soil quality and promote plant growth by regulating gene responses in "Metabolism of terpenoids and polyketides" and "Urea Cycle" pathways, as well as by secreting enzymes such as ferredoxin hydrogenase and beta-mannosidase. 【Conclusion】 Different forest-medicinal plant intercropping patterns affect soil quality and enzyme activities, potentially via regulating microbial community diversity, the abundance of specific taxa abundance, functional gene response, and enzyme secretion.

# Wetland Age and Seasonality Drive the Succession of Active Methanotrophs in Constructed Wetlands

**ABSTRACT**

The Global Methane Pledge, endorsed by more than one hundred nations, highlights the urgent need to reduce $CH_4$ emissions to achieve the net-zero target by 2050. Wetlands function as effective carbon sinks but are also major natural sources of $CH_4$. Constructed wetlands (CWs) are increasingly utilized as nature-based solutions, yet the microbial mechanisms that regulate $CH_4$ oxidation, the primary sink for methane in soil, remain insufficiently characterized.

This study investigated how wetland age and seasonality influence $CH_4$ oxidizing communities in three CWs of different ages located in subtropical Taiwan. We used DNA-based stable isotope probing (DNA-SIP) combined with *pmoA* gene sequencing to identify potentially active methanotrophs during both summer and winter. We also analyzed key edaphic properties to comprehensively define the environmental drivers of community transitions.

Results showed that $CH_4$ oxidation potential was generally higher in winter but exhibited a functional decline as the wetlands aged. The SIP analysis revealed a clear shift in dominant active methanotrophic families, transitioning from *Methylocystaceae* in younger wetlands to *Methylomonadaceae* in older systems. Soil nutrients, salinity, and sulfate concentration were identified as important drivers structuring this ecological shift across wetlands of varying age.

These findings illustrate how wetland age and seasonality act as important drivers of compositional and functional succession within active methanotrophic communities. This mechanistic understanding provides crucial implications for optimizing CW design and management to enhance $CH_4$ oxidation potential, thereby strengthening their role in mitigating greenhouse gas emissions.

**ABSTRACT**

Salinity stress is a major constraint to global rice production. Plants employ two primary strategies to cope with stress: the 'do-it-self' (DIS) strategy reliant on intrinsic genetic capacity, and the 'outsourcing' strategy involving the recruitment of beneficial microbes. It remains unclear which strategy confers a greater advantage for stress resistance within the same species. To investigate this, we conducted a controlled greenhouse pot experiment comparing 18 rice varieties grown in saline-alkaline soil. By analysing root spatial architecture and plant growth parameters, we assessed the contribution of each strategy. We further employed amplicon sequencing, metagenomics, and ecological network analysis to characterize the associated rhizosphere microbiota. Results showed that 'outsourcing' plants exhibited superior growth under stress. Their root microbiome was enriched with core functional taxa, including *Hydrogenophaga, Brevundimonas*, *Ideonella*, *Aquimonas*, *Methylomonas*, and *Phenylobacterium*. Concurrently, the microbial networks in this group displayed greater topological complexity, with more nodes, edges, and keystone taxa, indicating enhanced stability. In contrast, the rhizosphere of "DIS" plants was enriched for bacteria such as *Paenisporosarcina* and *Porphyrobacter*, and their microbial networks featured a higher proportion of positive correlations and more positive interactions bridging the rhizosphere and endosphere compartments. Metagenomic functional analysis revealed a significant enrichment of genes involved in antioxidant response, synthesis of osmolytes, ion homeostasis, and membrane stability in the "outsourcing" group. Furthermore, the microbial genomes in this group contributed to ammonium accumulation, carbon fixation, and phosphorus solubilization. Our study, framed within the root economics space concept, demonstrates the critical role of the rhizosphere microbiome in crop stress resistance, identifies key taxa and their metabolic potential, and provides a theoretical foundation and candidate resources for developing microbial inoculants to enhance crop resilience.

**ABSTRACT**

Volcanic eruptions reset ecosystems to barren landscapes, initiating microbial colonisation that often relies on trace gases such as carbon monoxide (CO) for survival in nutrient-poor conditions. This study investigates CO metabolism in volcanic soils from these environments. Metagenomics and enrichment strategies targeting carboxydovores - bacteria capable of oxidising low-to-ambient CO concentrations - were employed to isolate two novel strains (Dawson et al., 2025). Whole-genome sequencing and CO consumption assays revealed distinct mechanisms regulating CO metabolism during transitions from heterotrophy to starvation, providing insight into microbial survival in extreme environments. Both strains contain *coxMSL* genes, which encode CO dehydrogenase responsible for CO oxidation, along with uncharacterised accessory genes. This work also explores the active microbes consuming CO in volcanic soils using stable isotope probing (SIP) with $^{13}CO$ as the substrate. SIP has shown that CO was primarily incorporated into Pseudomonadota. Further metagenome-assembled genomes from the heavy fractions show the presence of genes encoding for the CO dehydrogenase, responsible for the oxidation of CO. These findings emphasise the significance of CO metabolism in early soil formation and bacterial community establishment, presenting novel model strains to further investigate microbial adaptations in volcanic ecosystems.

**ABSTRACT**

The enhancement of soil multifunctionality (SMF) in medium- and low-fertility red soils is considered crucial for improving crops productivity and agriculture sustainable development in the southwestern plateau region, China. Rational intercropping plays an important role in enhancing crop yield and improving soil fertility in red soil. To study the effects of intercropping on soil multifunctionality, and to explore the relationship between soil multifunctionality and biodiversity effects under intercropping in red soil, a seven-year consecutive field experiment was conducted. Two planting patterns maize monoculture (MM) and maize//soybean intercropping (IM)-were compared under four phosphorus (P) fertilizer application gradients (0, 60, 90, and 120 kg $P_2O_5$ $ha^{-1}$). Changes in individual soil functions and SMF under intercropping system, The components of the biodiversity effect (BE), and their response to P application rate were systematically examined. The results showed that, compared to maize monoculture, SMF was significantly enhanced by maize//soybean intercropping across the four P gradients, with an average increase of 46.21%. The highest increase of 176% was observed at the P90 level. Specifically, the individual soil functions for nutrient cycling, production function, and water conservation were significantly enhanced by 58.12%, 56.04%, and 22.47%, respectively. Compared to the corresponding monoculture, maize//soybean intercropping significantly increased the biodiversity effects (BE), in which the net effect (NE) and complementarity effect (CE) of the intercropping BE were significantly increased with the rising of P levels, while the selection effect (SE) was reduced. The CE was identified as the primary factor driving the improvement in SMF. A highly significant positive correlation was observed between SMF and NE and CE. Key influencing factors were identified as soil available phosphorus (AP), soil microbial biomass phosphorus (MBP), soil ammonium nitrogen ($NH_4^+$-N), soil organic carbon (SOC), soil bulk density (BD), and soil microbial biomass carbon (MBC). In conclusion, maize//soybean intercropping offered significant advantages on low-fertility red soil in terms of increasing maize yield, enhancing soil multifunctionality, and strengthening biodiversity effects. The intercropping advantage was found to be optimal at P application rates of 60-90 kg $P_2O_5$ $ha^{-1}$, achieving a dual benefit of high crop yield and improved ecological service functions. Maize and soybean intercropping with optimizing fertilization in red soil is an effective practice both for improving soil quality and soil health, and promoting sustainable agricultural development.

**ABSTRACT**

Microbe is considered the engines that drive Earth's biogeochemical cycles, and play a pivotal role on greenhouse gas emission. However, it has been highly debated but rarely tested of eco-evolutionary mechanism underlying the production and reduction of greenhouse gas emission. In this presentation, I will take aerobic methane-oxidizing bacteria (MOB methanotrophs) as an example to show how novel MOB is generated and MOB community is maintained in an eco-evolutionary context. The focus will be niche differentiation vs extraordinary plasticity of MOB. The assembly of MOB community can be considered as a net result of long-term ecological and evolutionary adaptation to historical environmental variables. These variables could be largely predicted with time- and spatial-dependent patterns. The numerically dominant taxa are thus expected to have the highest physiology plasticity as environmental variables often fluctuate constantly and widely, but most importantly in a manner of being predictable. It thus implies the certain environmental factors could select for particular taxa, and microcosm experiment can inform global ecological problems. It is noteworthy that the generation and development of the individual microbial taxa cannot be achieved overnight and seems to be intractable under in situ field conditions. I would like to show how environmental factors can select particular methane oxidizers at ecosystem-level. The molecular evidence of MOB metabolisms will also be presented showing how ecosystem sustainability is supported by the population dynamics of microbial fecundity, survival, and mortality in complex soil.

*[3] Affiliation of the Z. Jia (State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences,Changchun, China)*

*E-mail Address of Presenting Author: zhangyifeng@iga.ac.cn

**ABSTRACT**

Given that microbial mediated input of cropresidues and their humification products may be more conducive to the transformation and sequestration of soil organic matter, this study aims to use $^{13}C^{15}N$ double labeling tracing technology in incubation experiments to quantify the differences in the fate and distribution of C and N from crop residues and their decomposition products under the mediation of different exogenous microorganisms in soil organic matter (SOM) and dissolved organic matter (DOM). The study utilized exogenous microorganisms including *T. reesei*, *T. harzianum*, *P. chrysosporium*, and *B. subtilis*, as well as a combination treatment of *T. harzianum*, *P. chrysosporium*, and *B. subtilis*. The study also reveals variation patterns of soil active organic carbon and humic carbon components. The main conclusions are as follows:

The addition of fungi was more favorable than bacteria in mediating the increase in soil SOM contribution of crop residues derived C and N. *Trichoderma* spp. treatments were more adept at mediating crop residues derived dissolved organic carbon, and fungi were more likely to stimulate soil production of dissolved nitrogen. Although the combination microbial treatment was most effective at translational immobilization of crop residues in SOM, the *T. reesei* treatment had the best ability to increase soil organic carbon content by mediating crop residues translational immobilization with the lowest depletion of SOM. Additionally, fungi were more effective than r-strategy microorganisms in increasing labile organic carbon and humic carbon fractions in soil.

Fungi mediated humification products was significantly better than bacterial and no microbe mediated for translational immobilization in soil, and fungal treatments contributed more to DOM and stimulated soil deriving dissolved nitrogen. The *T. reesei* treatment was most effective in immobilizing carbon and nitrogen derived from humification products. Fungi mediated humification products was superior to bacteria in boosting labile organic carbon and humic acid fractions. Combination treatments increased fulvic acid carbon and reduced PQ values early in the experiment, while fungal treatments increased fulvic acid carbon in later phases.

These conclusions provide a theoretical basis for microbial regulation of farmland management to improve SOM transformation and humification, offering practical guidance for agricultural production and soil carbon sequestration.

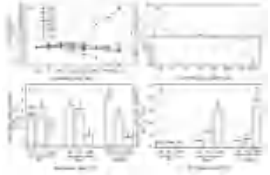
## ABSTRACT

Natural grasslands occupy ~40% of Earth's terrestrial surface and serve as the primary grazing areas for ruminant livestock. A single urination event from a sheep releases ~0.50 L of urine (Selbie et al., 2015), and daily urination frequency varies among individuals. Consequently, 70–95% of the nitrogen ingested by animals is returned to the soil via urine patches, which become hotspots of nitrogen transformation. Previous studies have focused on urine patches as strong sources of $N_2O$ emissions and on the microbial mechanisms driving ammonia oxidation (Schirmann et al., 2019; Zhu et al., 2021). However, this acute perturbation rapidly alters soil physico-chemical micro-environments and simultaneously affects the activity and community structure of soil methanotrophs. Systematic knowledge of the thresholds at which urine patches switch from methane absorption to emission is still lacking, especially regarding the response of soil methanotrophs to urine deposition. Elucidating these microbial mechanisms is therefore essential.
DNA-based surveys indicate that methanotrophic communities respond weakly to short-term environmental fluctuations (Nannipieri et al., 2019), making it difficult to capture instantaneous functional changes. RNA-Seq (transcriptome sequencing) is a recently developed deep-sequencing technology that detects global transcriptional activity at single-nucleotide resolution, enabling the identification of novel and rare transcripts, alternative splicing sites and coding-sequence SNPs (cSNPs), thereby providing high-resolution information on gene expression (Täumer et al., 2022). Consequently, the present study integrates *pmoA*-gene sequencing with transcriptome data to systematically unravel the microbial mechanisms driving methane oxidation beneath urine patches in natural grassland soils. Such knowledge will improve estimates of methane emissions and atmospheric concentration trends, supplying critical data for greenhouse-gas mitigation strategies.



**Materials and Methods**
The soil was collected from an ungrazed natural grassland on the Loess Plateau (37.12°N, 106.82°E), and fresh urine was obtained from Tan sheep, a locally common grazing breed (urine nitrogen concentration: 10.90 g N $L^{-1}$, equivalent to 545 kg N $ha^{-1}$). In the laboratory, a gradient incubation experiment was conducted with urine addition volumes of 0 (No urine, NU), 0.1 (Lowest urine, LU), 0.2 (Low urine, LU1), 0.3 (Field Urine, FU, representing the typical urine volume excreted by sheep in the field), 0.4 (Medium urine, MU), 0.5 (Medium-high urine, MHU), 0.7 (High urine, HU), and 1 mL (Ultra-high urine, UHU), with four biological replicates per treatment. Following the method described by Wang et al. (2022), the methane concentration in the headspace of the incubation bottles was determined y at 0 h, 2 h, and on Days 1, 3, 5, 7, 10, and 14 by gas chromatograph (GC-7890A, Wilmington, USA). The atmospheric methane oxidation potential (atmMOP) was characterized by calculating the methane oxidation rate based on the change in methane concentration between 0 h and Day 14.
Based on the results of methane oxidation potential, soil samples from the NU, FU, and UHU treatments were selected for analysis of methanotroph abundance and diversity. Total DNA of soil sample was extracted from 0.5 g fresh soil using the Mag-Bind® Soil DNA Kit (Omega Bio-tek, Norcross, GA, U.S.A.) according to the manufacturer's instructions. For the 16S rRNA and pmoA gene, the primers 515F/907R (Stubner, 2002) and A189F/mb661R (Costello and Lidstrom, 1999) were used to determine abundance of methanotrophs using real-time quantitative PCR (qPCR). The diversity of methanotrophs under urine influence was assessed by sequencing the *pmoA* gene (primers A189F/mb661R) on the Illumina MiSeq platform
Based on the methane oxidation trends and variations in methane oxidation potential across treatments, soil samples from the NU, FU, and UHU treatments incubated for 6 days (when methane concentration change was most pronounced) were selected for metatranscriptome sequencing, with four replicates per treatment. Total RNA was isolated with the RNeasy PowerSoil Total RNA Kit (Qiagen, Germany). Strand-specific mRNA libraries were prepared using the Illumina Stranded mRNA Prep, Ligation Kit (Illumina, USA) and sequenced on the NovaSeq 6000 S4 Reagent Kit v1.5 (300 cycles). Raw FASTQ files were quality-trimmed with fastp (https://github.com/OpenGene/fastp) (Chen et al., 2018). Clean reads were mapped to the Unigene set and expression values were calculated as RPKM (reads per kilobase of References per million mapped reads) with RSEM (http://deweylab.biostat.wisc.edu/rsem/).
Differences among urine-addition gradients at the same incubation time were tested by one-way ANOVA. Statistical comparisons of soil physicochemical properties and measured values of 16S rRNA and *pmoA* gene abundances were performed using one-way ANOVA, with means compared by Duncan's post-hoc test. Pearson correlation among atmospheric methane oxidation potential, soil physicochemical properties, and methanotroph abundance was estimated using R software.

**Results and Discussion**
***Effect of urine addition on methane oxidation trend and methane oxidation potential***
Methane concentrations exhibited distinct trends across the urine-addition gradient. In NU treatment, $CH_4$ was completely oxidized, whereas the UHU treatment switched from a $CH_4$ sink to a pronounced source after Day 5 (Fig.1A). The atmMOP of UN was 0.11±0.001 ng g_1 h_1 (dry weight soil, *d.w.s.*). Treatments with LU1, LU2, FU and MU, soil also oxidized $CH_4$, although at lower rates. In contrast, treatments with MUH, HU and UHU showed progressively increasing net $CH_4$ release with higher urine volumes (Fig.1B). Treatment with the FU, soils acted as a weak atmospheric $CH_4$ sink, consistent with observations from Nandi County, Kenya (Tully et al., 2017) and a desert steppe in Inner Mongolia (Jiang et al., 2012). Studies reporting $CH_4$-uptake inhibition (Wu et al., 2020) align with our UHU treatment (Fig.1).
***Effect of urine addition on methanotroph abundance***
Based on the methane oxidation potential observed across the urine addition gradient, the NU, FU, and UHU treatments were selected for subsequent analysis. Urine amendment significantly influenced the abundances of total bacteria and methanotrophs in contrasting patterns (Fig.1C,D). Specifically, urine addition decreased *pmoA*-based methanotroph abundance, with this reduction becoming progressively more pronounced among treatments after 7 days of incubation. By Day 7 and Day 14, methanotroph abundance in the UHU treatment was significantly lower compared to both the NU and FU treatments (Fig.1C). Conversely, quantification of 16S rRNA genes indicated that urine addition, particularly under the UHU treatment, led to a significant increase in total bacterial abundance. Although total bacterial abundance remained unaffected by the urine gradient at 2 hours post-incubation, the UHU treatment showed significantly elevated bacterial abundance relative to the NU and FU treatments by Day 7 and Day 14 (Fig.1D).
Methanotroph abundance can respond to environmental changes more rapidly than shifts in methanotroph diversity (Zheng et al., 2012), a pattern consistent with our observations. Methanotroph abundance declined with time and urine dose (Fig.1C), reflecting the transition from a $CH_4$ sink to a $CH_4$ source. Total bacterial abundance increased with incubation time and urine dose (Fig.1D), likely because urine addition progressively altered soil pH, $NH_4^+$-N and TC (Fig.2A). Following urine addition, both soil pH and $NH_4^+$-N concentration increased sharply, showing significant negative correlations with atmMOP (Fig.2A). This suppression may be attributed not only to osmotic stress induced by urine salts under elevated pH conditions, which nonspecifically inhibits methanotroph activity, but also to the conversion of $NH_4^+$ to ammonia ($NH_3$). Due to their similar molecular structures, $NH_3$ competes with $CH_4$ for the active site of methane monooxygenase, leading to competitive or non-competitive inhibition of methane oxidation (Gulledge et al., 1998). In addition, $NH_4^+$-N and TC provided nutrients for the growth of other microorganisms, resulting in an increase in total bacterial abundance. The increased relative abundance of the phylum Firmicutes supports this inference (Fig.2B).
***Impact of urine addition on methanotroph composition***
High-throughput sequencing of the *pmoA* gene revealed that, along the urine-addition gradient, the methanotroph community was dominated by USCγ (USCγ + JR3), accounting for 94.97–99.87% of all *pmoA* reads. Notably, the UNU treatment showed a significant increase of the relative abundance of *Methylocaldum* on Day14, reaching 4.13%, far higher than other treatments (Fig.3). Therefore, it can be concluded that the changes in community composition are caused by a significant decrease in the relative abundance of USCγ (Wang et al., 2022).
**Gene expression underlying methane oxidation and methanogenesis in response to urine addition**
After six days of incubation, metatranscriptome data (RPKM) fully revealed the gene expression profiles related to methane oxidation and methanogenesis under NU, FU, and UHU treatments (Fig.4). In the NU, transcripts of aerobic methane oxidation—*pmoCAB*, *xoxF*, *fae* and *fdh*—were abundant. Nearly all known aerobic methanotrophs possess the pMMO-encoded *pmoA* gene (Murrell et al., 2010); Accordingly, significantly higher expression levels of *pmoA* and *XoxF* transcripts were detected in the NU compared to the FU and UHU treatments, with no methanogenic genes detected. This gene expression profile confirms the dominance of aerobic oxidation, explaining the net soil $CH_4$ uptake under these conditions (Fig. 4A). Furthermore, the atmMOP under the NU treatment is consistent with and extends our previous regional findings, wherein soil factors (soil moisture and nitrogen) were shown to govern the atmMOP by directly or indirectly regulating methanotroph abundance (Wang et al., 2022).
At the FU treatment, the high expression of *hdrD* (involved in sulfate-coupled anaerobic methane oxidation) (Alperin et al., 1985) along with *pmoA* and *xoxF* transcripts indicates concurrent aerobic and anaerobic methane oxidation. Detection of *Mer* and *ackA* transcripts also suggests active hydrogenotrophic and aceticlastic methanogenesis (Fig. 4B). Nevertheless, the soil remained a net methane sink, as methane oxidation exceeded methanogenesis. This can be explained by urine-induced micro-zone differentiation: aerobic methane oxidation continued at the oxygenated patch edges, while strictly anaerobic zones (e.g., patch centers or soil aggregates) favored anaerobic methane oxidation and methanogenesis (Sexstone et al., 1985). Overall, methane oxidation—integrating both aerobic and anaerobic pathways—slightly surpassed methane production, thereby sustaining the soil's methane-sink function (Le Mer and Roger, 2001).
In contrast, the treatment of UHU showed elevated $CH_4$ concentrations. *pmoA* and *xoxF* transcripts were absent, and only the methylotrophic methanogenesis genes *mtmB* and *mtrC* were expressed (Fig.4C). *mtmB* encodes a trimethylamine-inducible methyltransferase characteristic of novel Euryarchaeota methanogens, and both *mtmB* and *mtrC* are also present in the proposed methanogenic pathway of Verstraetearchaeota (Vanwonterghem et al., 2016). With increased urine application, the urine patch rapidly establishes an anaerobic microenvironment. Concurrently, ammonium ($NH_4^+$) generated from urea hydrolysis competitively inhibits methane monooxygenase activity (Isobe et al., 2020). Moreover, urine contains small organic molecules—including methanol, methylamines, and acetate—that act as direct substrates for methylotrophic and aceticlastic methanogens, enabling rapid methane production. Enhanced expression and activity of key methanogenic enzymes encoded by genes such as *mtmB* and *mtrC*, further drive methanogenesis, ultimately shifting the soil from a methane sink to a net methane source (Bueno de Mesquita et al., 2023).
**Conclusion**
Compared with NU, the FU treatment reduced atmospheric $CH_4$ oxidation capacity by 80.74%, yet the soil still functioned as a weak $CH_4$ sink. In contrast, the UHU treatment shifted the soil from a sink to a source. These outcomes were primarily driven by changes in methanotroph abundance and differential expression of key genes regulating $CH_4$ oxidation and emission. In the FU treatment, net $CH_4$ uptake occurred because the combined methane oxidation flux (aerobic+anaerobic methane oxidation) exceeded the concurrent methane production flux (hydrogenotrophic and aceticlastic methanogenesis). In the UHU treatment, methylotrophic methanogenesis was strongly stimulated while $CH_4$ oxidation was nearly completely suppressed, resulting in net $CH_4$ emission.

**ABSTRACT**

In response to the slow increase in soil organic matter in the black soil farmland of Northeast China, a field positioning experiment was conducted on black soil farmland in Xing'an League Ulanhot, Inner Mongolia. A split-plot design was adopted, with two straw incorporation depths 0–20 cm (Q) and 0–40 cm (S)) as the main plots and four straw input amounts 0 (CK), 1/3 (JG1), 2/3 (JG2), and full amount (JG3)) as the subplots, to analyze the effects of straw return methods on soil microbial community composition. The results showed that: (1) Compared with CK, all treatments significantly increased the contents of SOM, AK, AP, and TN, and these values increased with the straw return amount. Meanwhile, soil pH and $NH_4^+$-N content were significantly reduced, with soil pH gradually decreasing as the application rate increased. The shallow incorporation treatment performed better than the deep incorporation treatment. (2) In terms of microbial community, under shallow incorporation, the abundances of Proteobacteria and Basidiomycota increased with the application rate, while the abundance of Ascomycota decreased. Compared with deep incorporation, shallow incorporation increased the abundances of Actinobacteria and Chloroflexi but decreased the abundance of Proteobacteria. (3) Regarding microbial diversity, the microbial Chao1 index initially increased and then decreased with increasing application rate, while the Simpson index increased with the application rate. (4) Random forest analysis revealed that soil pH was the key environmental factor influencing bacterial diversity, while fungal diversity was mainly affected by soil SOM. In summary, different straw return methods can help improve basic soil physicochemical properties and enhance microbial diversity, promoting a shift from K-strategists to fast-responding r-strategists. In practical production, shallow incorporation with full straw return is recommended, providing a theoretical basis for microbial organic carbon sequestration, conservation, and sustainable development of black soil farmland.

# Tropical rubber plantations' expansion alters multiple ecosystem functions and C storage

**Ashutosh Kumar Singh [a] *, Wenjie Liu [a],**

*Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Menglun, Yunnan 666303, China.*

**ABSTRACT**

The global demand for natural rubber has driven substantial expansion of rubber plantations since the last century, with over 2 million hectares established in the most recent decade. Southeast Asia remains the primary region for rubber cultivation, often at the expense of other land uses. While rubber farming has raised farmers' incomes, it has also altered local habitat ecology and ecosystem functions. Yet studies on the impact of rubber plantations on ecosystem functions are limited, and a comprehensive synthesis is lacking. To address this gap, we conducted an inclusive review of the ecosystem functions of rubber plantations, focusing on soil carbon storage, aboveground biomass (AGB) and belowground biomass (BGB), litter production and decomposition, respiration, and biodiversity (plants, animals, soil fauna, and microbes). We compared ecosystem functions in monoculture rubber plantations with those in forests, as forest conversion to RP is common in the tropics, and most rubber plantation studies use forests as References ecosystems. Our findings indicate that rubber plantations generally exhibit lower ecosystem functions than forests. The adverse effects on several components of ecosystem function are pronounced. AGB, BGB, and plant diversity show declines exceeding 55% and these impacts persist across plantation ages.

# Cobamide Auxotrophy and Unexpected Cobamide Synthesis Potential in Organohalide-respiring Dehalococcoidia

**Yiru Cui[1*], Xiuying Li[1], Jingjing Wang[1], Huijuan Jin[1], and Jun Yan[1]**

[1] *Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, Liaoning 110016, China*

**ABSTRACT**

Cobamides (Cbas) are structurally diverse, vitamin $B_{12}$ family enzyme cofactors that fulfill essential microbial metabolisms such as methanogenesis and organohalide respiration. The best-studied cobamide is cobalamin (Cbl), which carries 5,6-dimethylbenzimidazole (DMB) as the lower ligand. Because *de novo* Cba biosynthesis is restricted to a subset of bacteria and archaea, environmental Cba pools in soils and sediments are largely governed by microbial cross-feeding, salvage, and remodeling. Such community-level cofactor supply is particularly important for organohalide-respiring bacteria (OHRB), which reply on specific Cbas to enable the catalysis of carbon-halogen bond-cleaving reductive dehalogenase (RDases). In contaminated vadose-zone and aquifers, OHRB can form reactive biobarriers at the groundwater-soil interface to detoxify chlorinated contaminants and reduce their upward migration flux from groundwater into overlying soils. Yet, how Cba bioavailability constrains OHRB activity remains poorly understood. Here, we demonstrate the strict dependence on external Cbl supply to sustain *Dehalogenimonas etheniformans*, an organohalide-respiring lineage affiliated with the class *Dehalococcoidia*. Substitution of the lower ligand with a DMB analogue compromised, and in some cases completely inactivated *D. etheniformans*, suggesting pronounced cofactor selectivity that can translate into ineffective biobarrier performance *in situ*. Notably, 5-hydroxybenzimidazolyl-cobamide ([5-OHBza]Cba) did not sustain *D. etheniformans culture*, but the ability of *D. etheniformans* to respire a chlorinated ethene (e.g., tetrachloroethene) into non-toxic ethene was fully restored with the addition of DMB. This phenotype aligns with genomic predictions, suggesting that *D. etheniformans* uses CbiZ-mediated remodeling pathway to convert an unusable cobamide into Cbl. By analyzing available genomes across the class *Dehalococcoidia*, we further show that *Dehalogenimonas formicexedens* and *Dehalogenimonas* sp. strain W encode nearly the full set of genes for *de novo* corrin ring biosynthesis. Remarkably, *D. formicexedens* is, to our knowledge, the only formally named non-*Bacillota* bacterium identified to harbor a complete *bza* gene set for DMB biosynthesis. The Cba-related genes in *D. formicexedens* are partitioned into three loci, corrin ring synthesis, cobinamide salvage, and DMB synthesis, each positioned directly downstream of a Cbl riboswitch, implying coordinated regulation and potential to produce Cbl *de novo* from glutamate. Collectively, our results correlate Cba structural feature (i.e., lower base) with the ecological control of soil and subsurface microbiomes as well as the effectiveness of natural attenuation of chlorinated solvents at contaminated sites. Through targeted-manipulation of indigenous Cba/DMB producers, it is possible to maintain robust dechlorination activity and limit the upward flux of chlorinated contaminants from groundwater into soils. : soil microbiome

## ABSTRACT

Banana *Fusarium* wilt (Panama disease), caused by the soil-borne pathogen *Fusarium oxysporum* f. sp. *cubense* tropical race 4 (*Foc*TR4), is a devastating disease that threatens global banana production. This study combined eight years of field trials with complementary pot experiments, multi-omics analyses, and functional validation to systematically investigate the mechanisms through which pepper-banana and eggplant-banana rotations—together with the incorporation of rotation crop residues—shape the soil core microbiome, enhance microbial diversity, enrich antagonistic taxa, and suppress *Fusarium* wilt.

We found that pepper and eggplant rotations selected nine rotation-specific core antagonistic microorganisms through soil legacy effects. Pepper rotation enriched eight of these taxa, while eggplant rotation enriched one.

These core antagonistic communities stably persisted into the subsequent banana cropping season, reducing the disease incidence from 53% in monoculture control to 31% (pepper rotation) and 28% (eggplant rotation), respectively (Figure 1). Integrating traditional culture-based methods with high-throughput sequencing identified *Bacillus* and *Pseudomonas* as core functional taxa enriched under rotation. Metabolite extracts and volatile organic compounds from these taxa strongly inhibited *Foc*TR4 growth.

Figure 1 Conceptual model showing the targeted enrichment of crop-unique antagonistic core microbiota by distinct rotation systems for wilt disease suppression in banana (Hong et al., 2023, *New Phytologist*).

Further experiments involving residue incorporation demonstrated that adding pepper and eggplant residues significantly increased soil available phosphorus. Beyond enhancing microbial diversity, residue amendment enriched antagonistic taxa such as OTU180 (*Rhizomicrobium*) and OTU187 (*Gp4*) by remodeling the rhizosphere, contributing to a functional microbial defense barrier that reduced disease incidence below 20% in follow-up pot trials. Structural equation modeling identified available phosphorus as a critical mediator linking residue incorporation to pathogen suppression, operating indirectly through increased abundance of core antagonistic microbes (Figure 2).

Figure 2 The model diagram revealed a potential mechanism by which incorporating pepper and eggplant residues into the field suppresses soil-borne pathogens (Hong et al., 2025, *Applied Soil Ecology*).

This work provides the first systematic analysis of the assembly and functional dynamics of core antagonistic communities in rotation systems, and demonstrates that residue-driven enhancement of soil microbial diversity can further boost the disease-suppressive capacity of rotations. Key innovations include: (1) a framework for identifying rotation-specific core antagonistic microbiomes and characterizing the temporal persistence and spatial stability of their legacy effects; and (2) elucidation of a novel phosphorus-mediated pathway, through which residue-microbe interactions enhance disease suppression by increasing microbial diversity. The proposed integrated model of "rotation screening—residue enhancement—microbiome regulation" provides a practical framework for sustainable, disease-resilient cropping systems.

**ABSTRACT**

Saline–alkali soils in arid and semi-arid regions severely constrain plant growth and soil microbial functioning, but the mechanisms underlying rhizosphere bacterial community assembly driven by different plant life remain unclear. Here, we investigated four representative halophytes in desert saline–alkali habitats of Manas County, Xinjiang, China, including two annual herbs (*Halogeton glomeratus* and *Suaeda glauca*) and two perennial shrubs (*Haloxylon ammodendron* and *Krascheninnikovia ceratoides*). Rhizosphere soils were analyzed for physicochemical properties (pH, electrical conductivity (EC), soil organic carbon (SOC), total nitrogen (TN), total phosphorus (TP), total potassium (TK)) and bacterial communities using 16S rRNA high-throughput sequencing. The results showed that (1) perennial shrubs exhibited significantly higher SOC and TN contents, as well as higher bacterial α-diversity (ACE, Chao1, Shannon) and lower Simpson indices, than annual herbs ($P < 0.05$), indicating more diverse and stable rhizosphere bacterial assemblages. Community composition profiling revealed perennial shrubs more consistent and structured microbial communities, annual herbs exhibit greater heterogeneity in their rhizosphere microbiomes. (2) Redundancy analysis (RDA) and correlation heatmaps identified SOC, TN, and pH as the dominant environmental drivers of rhizosphere bacterial diversity and community composition, with taxon-specific responses of major phyla (e.g., *Actinobacteriota*, *Proteobacteria*, *Chloroflexi*, *Gemmatimonadota*, *Firmicutes*, *Acidobacteriota*) to nutrient status and pH in saline–alkali soils. (3) Piecewise structural equation modeling (SEM) further revealed that perennial and annual plant life forms influence rhizosphere bacterial diversity and structure via both direct and indirect pathways. The direct effect (standardized effect=0.99) was predominant in shaping bacterial diversity, while plant life forms mainly affected bacterial community structure through indirect effects (standardized effect = 0.34) mediated by soil physicochemical properties, particularly TN, SOC, and pH. These findings highlight that plants shape their rhizosphere microbiota through direct selective recruitment and indirect modification of soil physicochemical properties. Our results enhance understanding of plant functional type-soil-microbe interactions in saline–alkali ecosystems and emphasize the ecological value of perennial shrubs for microbial-mediated restoration and sustainable management of saline–alkali lands.

## ABSTRACT

Frequent drying-wetting cycles significantly affect soil microbial diversity and community structure, thereby mediating soil carbon cycling. Through three cycles of dry-wet experiments, this study combined continuous $CO_2$ monitoring, organic carbon spectroscopy, multi-omics analysis, single-cell Raman-$D_2O$ labeling, and microfluidic cultivation to demonstrate that repeated dry-wet alternations inhibit microbial metabolic activity and simplify interspecies interaction networks by reducing the proportion of labile carbon, while preserving the stability of the core soil microbial community. The results show that with increasing frequency of dry-wet cycles, cumulative soil $CO_2$ emissions and single-cell Raman CDR values exhibit a stepwise decrease, which is associated with a decline in labile carbon fractions and an increase in recalcitrant components. The microbial community displays high resilience (core taxa shared between DNA and RNA sequencing account for >70%), with cooperative interactions representing the dominant relationship pattern. DNA-based co-occurrence network parameters decreased with more frequent dry-wet cycles, whereas RNA-based network parameters first decreased and then increased, with positive correlations prevailing throughout. Raman-$D_2O$ labeling coupled with cultivation consistently identified Actinobacteria, Firmicutes, and Proteobacteria as the core functional microorganisms. This study reveals that repeated dry-wet stress enriches metabolically conservative taxa and reduces interaction complexity in response to the shift of organic carbon toward recalcitrant forms. By innovatively integrating multi-scale techniques, the research elucidates the synergistic mechanisms linking "microbes-substrates-functions," offering theoretical support for predicting soil microbial stability under climate change.

# Widespread presence of extraordinary high-affinity of atmospheric methane oxidation by conventional methanotrophs in paddy soils across China

**Yan Zheng[1], Yuanfeng Cai[1], Zhongjun Jia[1,2*]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, PR China*

[2] *Northeast Institute of Geography and Agroecology, Chinese Academy of Science, Changchun 130102, PR China*

*E-mail Address of Presenting Author: jia@issas.ac.cn

**ABSTRACT**

Wetland systems are known methane ($CH_4$) sources. However, flooded rice fields are periodically drained. The paddy soils can absorb atmospheric $CH_4$ during the dry seasons due to high-affinity methane-oxidizing bacteria (methanotroph). Atmospheric $CH_4$ uptake can be induced during the low-affinity oxidation of high-concentration $CH_4$ in paddy soils. Multiple interacting factors control atmospheric $CH_4$ uptake in soil ecosystems. Broader biogeographical data are required to refine our understanding of the biotic and abiotic factors related to atmospheric $CH_4$ uptake in paddy soils. Thus, here, we aimed to assess the high-affinity $CH_4$ oxidation activity and explored the community composition of active atmospheric methanotrophs in nine geographically distinct Chinese paddy soils. Our findings demonstrated that high-affinity oxidation of 1.86 parts per million by volume (ppmv) $CH_4$ was quickly induced after 10,000 ppmv high-concentration $CH_4$ consumption by conventional methanotrophs. The ratios of 16S rRNA to rRNA genes (rDNA) for type II methanotrophs were higher than those for type I methanotrophs in all acid-neutral soils (excluding the alkaline soil) with high-affinity $CH_4$ oxidation activity. Both the 16S rRNA:rDNA ratios of type II methanotrophs and the abundance of $^{13}C$-labeled type II methanotrophs positively correlated with high-affinity $CH_4$ oxidation activity. Soil abiotic factors can regulate methanotrophic community composition and atmospheric $CH_4$ uptake in paddy soils. High-affinity methane oxidation activity, as well as the abundance of type II methanotroph, negatively correlated with soil pH, while they positively correlated with soil nutrient availability (soil organic carbon, total nitrogen, and ammonium-nitrogen). Our results indicate the importance of type II methanotrophs and abiotic factors in atmospheric $CH_4$ uptake in paddy soils. Our findings offer a broader biogeographical perspective on atmospheric $CH_4$ uptake in paddy soils. This provides evidence that periodically drained paddy fields can serve as the dry-season $CH_4$ sink. This study is anticipated to help in determining and devising greenhouse gas mitigation strategies through effective farm management in paddy fields.

# Decoding Deep Soil Microbial Response Dynamics to Afforestation in Semiarid Regions: Biotic-Abiotic Trade-offs Under Land-Use Transition

**Rongrong Zheng[1], Guangyao Gao[1*]**

[1] *State Key Laboratory of Urban and Regional Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China*

*E-mail: gygao@rcees.ac.cn

**ABSTRACT**

Vegetation restoration is critical for improving the ecological environment and curbing land degradation. However, in semi-arid regions, long-term restoration projects have improved ecosystems at the expense of triggering persistent water deficits and substantial organic carbon loss in deep soils (>1 m). Critical knowledge gaps remain regarding how biotic (vegetation type, biomass) and abiotic factors (soil moisture, physicochemical properties) collectively regulate deep soil microbiomes under sustained restoration. We investigates bacterial and fungal community along vertical profile (0-500 cm depth) in abandoned grasslands (GL), shrublands (SL), and 20 and 40-year *Robinia pseudoacacia* plantations (RP20, RP40) on China's Loess Plateau. Our results showed that during the afforestation process, soil bacteria exhibited greater variability across soil layers, with bacterial abundance in the middle and deep layers decreasing by 9.95% and 8.40%, respectively, compared to the top layer. In contrast, fungi demonstrated stronger process heterogeneity. Fungal communities began to shift during the SL stage, showing opposing trends between the top-middle layers and the deep layer. Fungal communities in the top and middle layers reached lowest point in the SL before increasing, whereas those in the deep layers peaked at 86.58% in the SL and then decline. Afforestation exerted negative effects on deep-soil (300-500 cm) factors. Microbial communities adapted through a coordinated dual-path mechanism: exhibiting negative feedback to SWC ($\beta$ = -0.40,$\beta$ = -0.53) and positive feedback to TN ($\beta$ = 0.25) and SOC ($\beta$ = 0.67), which facilitated the enrichment of drought-tolerant taxa and the adaptation of functional groups. This synergistic response served as a key buffer against afforestation, guarding the stability of deep soil microbial communities. These results underscore the importance of incorporating vegetation and soil depth in future studies, with particular focus on deep soil ecosystems, to inform tailored restoration practices.

**ABSTRACT**

The diverse microbial communities perform central roles in global biogeochemistry, yet only a small share of this diversity is actively growing. Microbial growth is a core life-history trait, virtually representing reliable performance of integrated physiological responses to environmental change. It is, however, unknown whether microbial growth rate and associated strategies differ fundamentally across biomes and environments, or how growth dictates the fate of assimilated carbon and soil organic carbon (SOC) accumulation and soil functions. Here, drawing on evidence from plot, regional and global scales in different biomes, we highlight the importance of microbial growth in driving SOC cycling and soil functions. We hypothesize that ecosystem-specific nature and environmental shifts decouple microbial growth from respiration by altering metabolism, function and viability, resulting an imbalance between carbon use efficiency (CUE) and SOC cycling, with profound consequences for carbon stocks in soil. Using long-term monitoring biodiversity platforms, we determined the ecology of soil microbial responses to above-belowground biodiversity changes, by quantifying microbial growth and functional traits. We explored how interactions between plant diversity, microbial communities, and soil properties impact carbon allocation toward growth, respiration, or extracellular enzyme production. Our findings reveal that realized growth rates manifest differently across biomes, for instance, higher maintenance respiration in alpine and polar regions results in lower CUE at low growth rates. Furthermore, regional observations indicate that the quantity of microbial-derived carbon depends more strongly on biomass size and total growth rates than on plant inputs or CUE. Specifically, belowground diversity and physiological traits drive a higher microbial contribution to SOC in temperate forests (dominated by K-strategists) than in temperate grasslands. Ultimately, we demonstrate that microbial growth is the primary 'volume control' for the microbial carbon pump, consequently, enhancing microbial growth is likely more effective than targeting CUE alone for soil carbon management. As such, microbial growth plays a core role in running global biogeochemistry and ecosystem functions.

# Elucidating Soil Microbial Community Activity Through Sipros-and-Aerith-Assisted Proteomic and Metabolomic Stable Isotope Probing

**Yi Xiong[1*], Zhongjun Jia[2]**

[1] *the University of Oklahoma, Norman, the United States*

[2] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, China*

* superxyz@vip.qq.com

**ABSTRACT**

Understanding the activity of specific microorganisms within the complex soil ecosystem requires tools that can trace substrate metabolism into newly synthesized proteins and metabolites. To address this, we present an integrated approach using the upgraded Sipros algorithm for proteomic stable isotope probing (SIP) and the new Aerith package for isotopic visualization, designed to elucidate soil microbial community function.

Sipros[1] enables sensitive identification of $^{13}C$-labeled proteins and accurate quantification of their isotopic enrichment from soil samples. Benchmarked against other tools using labeled *E. coli* standards, Sipros demonstrated superior performance, offering more identifications with greater accuracy, especially at ≥5 atom% $^{13}C$, and a computational speed over 20 times faster than its predecessor. When applied to soil communities, Sipros successfully traced $^{13}C$ from labeled methanol and plant exudates to the active microbial populations assimilating them.

Complementing this quantitative analysis, the Aerith[2] R package allows for the simulation, visualization, and critical validation of isotopic patterns in labeled peptides and metabolites detected in SIP experiments. Aerith uses efficient algorithms to model isotopic distributions, providing a vital interface for researchers to manually inspect and confirm the spectral signatures of labeling within complex environmental samples.

Together, Sipros and Aerith form a powerful suite that enhances the resolution and reliability of SIP for soil microbial ecology. This combined approach—pairing high-throughput, sensitive protein-SIP analysis with robust tools for spectral visualization—provides a more complete framework for deciphering the metabolic activity that drives soil biogeochemical processes.

# Microbial interactions drive microbial succession during soil formation

**Kazuo Isobe[1*], Yaping Liu[1], and Bao Zhihua[2]**

**ABSTRACT**

Microbial communities underpin soil formation and ecosystem functioning, yet how microbial succession is initiated and progresses during soil formation remains poorly resolved. Soil development typically unfolds over decades to centuries, limiting direct observation of successional dynamics and the biotic mechanisms that drive them. In particular, it remains unclear whether and how changes in microbial interactions link soil-formation gradients to shifts in microbial diversity, community composition, and ecosystem functions under natural field conditions.

To address this gap, we combined a natural, continuous soil-formation gradient with dynamic inference of time-lagged, state-dependent microbial interactions to test whether interaction rewiring drives microbial succession. We leveraged a shrub-associated soil gradient in a desert region of China, where soil properties, plant inputs, and microbial communities vary smoothly from sandy soils to organic-matter-enriched soils under broadly similar climate, vegetation, and parent material. Spatial position along the gradient can therefore serve as an ordered proxy for successional progression.

Using this framework, quantitative amplicon sequencing revealed strong increases in bacterial and fungal abundance and richness toward more developed soils, accompanied by continuous compositional turnover along the gradient. Community composition shifted from stress-tolerant pioneer taxa to diverse heterotrophic and plant-associated taxa. Adaptive taxa identified from community ordination exhibited clear spatial partitioning into early-, mid-, and late-stage groups that differed in taxonomy, functional traits, and associations with roots and litter.

To link microbial succession to biotic interactions, we applied empirical dynamic modeling to infer state-dependent interactions while accounting for environmental variation. Microbial interaction networks became progressively denser along the gradient, and mean interaction strength per link showed a non-linear pattern consistent with compositional turnover. Importantly, interaction intensity aligned with successional position: taxa adaptive to a given stage exhibited the strongest interactions where they dominated in abundance, demonstrating a tight coupling between interaction networks and taxon dominance during succession.

These community-level changes coincided with enhanced soil functions. Soil carbon mineralization rates and enzymatic activities increased toward later stages, carbon limitation was progressively relaxed, and microbial functional efficiency increased during soil development.

Together, our results provide field-scale evidence that rewiring of microbial interaction networks drives microbial succession and functional transformation during soil formation. This study highlights microbial interactions as a key, dynamic mechanism underlying soil ecosystem development and offers new insights for managing soil functional trajectories.

# Soil Bacterial Diversity at the Molecular Level: Origins, Consequences, and Implications

**ABSTRACT**

A central challenge in contemporary microbiology is to bridge the gap between molecular mechanisms operating at the cellular level and population-level behaviors that emerge under complex environments such as soils. A key task in this endeavor is to elucidate the evolutionary significance of the vast number of genetic mutants that arise in nature. Understanding the environmental conditions under which such mutants emerge, as well as their subsequent evolutionary fate, is essential for correctly interpreting the biological and ecological functions of the corresponding genes. We will integrate recent findings from our laboratory to explore the origins, functional consequences, and evolutionary implications of spontaneous mutations in genes involved in siderophore biosynthesis and histidine catabolism. Using *Pseudomonas fluorescens* as a model system, and combining experimental evolution, genomics, and molecular genetics, we dissect genotype–phenotype–environment interactions at the molecular, individual, and population levels.

Siderophore (pyoverdine, Pvd) secretion by *Pseudomonas* species represents a major model system for studying microbial cooperation. Because extracellular siderophores can be taken up by neighboring cells, they are considered public goods, with producing cells viewed as cooperators and non-producing cells as cheaters. However, through analyses of spontaneous siderophore-deficient mutants arising during experimental evolution under well-defined laboratory conditions, we demonstrate that the regulatory architecture of the wild-type strain is maladaptive for growth in closed environments. Consequently, cooperation and cheating alone are insufficient to explain the emergence of siderophore non-producing mutants.

In addition, with the widespread application of genome sequencing, environmental isolates (wild-type strains) are frequently found to harbor mutations in key metabolic genes encoding degradative enzymes, raising questions about their adaptive capacity. A representative example is the histidine utilization pathway in the plant pathogen *Pseudomonas syringae*, where mutations—including nonsense mutations in *hut* genes for histidine utilization—are commonly observed. We will discuss the evolutionary routes and environmental conditions under which mutants may regain the ability to utilize histidine.

**ABSTRACT**

Synergistic remediation of desertification and carbon sequestration in extreme environments remains poorly understood, especially under low-temperature and drought constraints. To fill this gap, we isolated three indigenous functional microbial strains (assigned No. 56, 86, 111) from the Loess Plateau and Mu Us Sandy Land, and acclimated them to the distinct extreme environments of three target desertified regions (Zhongwei, Jingbian, Mangya): Strain 56 (highly drought- and temperature-difference-tolerant phosphorus-solubilizing microorganisms, PBSMs) for Zhongwei; Strain 86 (mild saline-alkali-tolerant *Chitinophaga lutea*) for Jingbian; and Strain 111 (cold-tolerant *Pseudomonas mandelii* CBs-1, synthesizing poly-β-hydroxybutyrate, PHB, to adapt to low-temperature arid conditions) for Mangya. Five experimental treatments with three replicates were set for in-situ field trials (commencing in November 2025 across the three extreme environments): blank control (CK), three single-strain treatments (Strain 56 alone, Strain 86 alone, Strain 111 alone), and one core treatment (mixed culture of the three strains + biochar). The results showed that Zhongwei desert formed stable biological crusts within 1 month, with >30% higher water retention and 25% higher survival of native *Artemisia ordosica* and *Hippophae rhamnoides*; Jingbian observed 60% inhibition of *Fusarium*, 15% lower salinization, and 40% higher vegetation growth; Mangya desert maintained >80% *Pseudomonas mandelii* survival (-5~25℃) with 6-month sand fixation and 35% higher cold-tolerant vegetation survival. All regions showed improved microbial diversity and stable microecosystems. Notably, the formation of biological crusts and stable microecosystems also lays a solid foundation for enhancing soil carbon sequestration potential in desertified areas. The technology is scalable, eco-friendly (no chemical residues), and cost-controllable (local raw material rate >90%). Our findings verify the adaptability and effectiveness of this region-specific microbial technology. Future efforts will optimize microbial community ratios and carrier functions, realize intelligent screening via machine learning, and promote application in more desertified regions, providing solid support for northwest China's desertification control and ecological security barrier construction.

# Microbial CHON Assimilation and Stoichiometric Strategies in Natural and Agricultural Black Soils Revealed by Multi-Isotope Tracing

**Zeyu Cheng**[1*]

[1] *Northeast Institute of Geography and Agroecology,Chinese Academy of Sciences, Changchun, Jilin*

* chengzeyu@iga.ac.cn

**ABSTRACT**

Intensive agricultural practices can profoundly reshape soil microbial activity and ecosystem functioning, yet their impacts on microbial elemental coupling across carbon (C), hydrogen (H), oxygen (O), and nitrogen (N) remain poorly quantified. How long-term land use influences microbial CHON assimilation strategies is still unclear. Here, we applied a multi-isotope tracing approach to compare microbial metabolic activity and stoichiometry between natural and agricultural black soils.

Soils were incubated under controlled laboratory conditions with a factorial design combining water tracers ($^2H_2O$ or $H_2{}^{18}O$) and substrate additions ($^{13}$C-glucose and $^{15}$N-$NH_4Cl$). Treatments included water-only controls, single-element labeling, and combined C–N labeling, allowing simultaneous quantification of microbial growth, substrate assimilation, and elemental coupling. Incorporation of $^{13}$C, $^2$H, $^{18}$O, and $^{15}$N into soil organic matter was determined as atom percent excess, and net CHON incorporation was used to calculate microbial stoichiometric ratios. Soil $CO_2$ production was measured to assess respiratory responses, and microbial community dynamics were further evaluated using DNA and RNA-based sequencing.

Glucose addition markedly stimulated microbial $^{13}$C incorporation and $CO_2$ emission in both soils, whereas water-only treatments showed minimal isotopic enrichment. Agricultural soils exhibited higher C assimilation and respiration rates than natural soils, indicating a more rapid metabolic response to labile substrates. In contrast, natural soils showed lower C incorporation but more constrained CHON stoichiometric shifts. Combined C and N additions further altered elemental coupling, resulting in distinct C:N, C:H, and C:O ratios between soil types.

Our results demonstrate that long-term agricultural management alters microbial CHON assimilation strategies by promoting rapid carbon uptake and respiratory activity at the expense of balanced elemental allocation. This study highlights the value of multi-element isotope approaches for linking microbial metabolism, stoichiometry, and soil resilience under intensive land use.

**ABSTRACT**

Soil microorganisms constitute the largest portion of Earth's biodiversity, yet their responses to multiple concurrent environmental stressors remain poorly resolved at large spatial scales. Through an extensive cross-ecosystem field survey, we examined how the number of environmental stressors exceeding relevant stressor thresholds shapes soil microbial community structure, genomic traits, and ecological strategies. We show that as the number of high stressors increases, the diversity and abundance of rare microbial taxa decline. In contrast, unknown taxa and genes become progressively enriched. Metagenome-assembled genomes from common taxa reveal exhibit resistance or positive responsiveness to multiple stressors. These resistant common taxa display reduced genomic potential for core cellular processes but enhanced capabilities for environmental sensing, genetic regulation, and metabolic versatility. Furthermore, the number of stressors, more than their average intensity, was the dominant predictor of shifts in microbial traits linked to growth inhibition and stress adaptation. Our findings demonstrate that multi-stressor environments drive soil microbial communities toward increasingly unknown and stress-adapted lineages while diminishing rare biodiversity, with implications for ecosystem functioning under global change.

# Summer drought impacts micropredator abundance and microbial foodweb structure in a rewetted fen peatland

**Die Hu[1], Haitao Wang[1,2*], Verena Groß[1], Anna M. Burns[1], Tim Urich[1]**

[1]Institute of Microbiology, University of Greifswald, 17489 Greifswald, Germany

[2]Grassland and Forage Sciences, University of Rostock, 18059 Rostock, Germany

**ABSTRACT**

Summer drought significantly affects soil microbiome diversity and functioning, and metabolic interactions in wetland ecosystems. However, drought effects on the microbial food web in wetlands is much less understood.

We investigated the dynamics of bacterivorous microorganisms and prey bacteria (PBac) in a rewetted fen peatland before, during and after summer drought, using 16S rRNA and 18S rRNA gene amplicon sequencing and quantitative metatranscriptomics. Based on SSU rRNA transcripts and genes, we screened for bacterivores including bacterivorous bacteria (BBac), protists (BPro), and nematodes (BNem), as well as those with a host-dependent lifestyle including Ca. *Patescibacteria* and DPANN archaea (PD). In addition, bacteriophage transcripts were enumerated.

The summer drought led to a higher diversity of BPro and BBac in the fen as compared to pre-drought months and was accompanied by decrease in water levels and an increase in redox potential. The SSU rRNA transcripts abundances for all bacterivores (with the exception of PD) increased during drought, reaching a peak in October. Notably, the transcript abundance of all bacterivores remained above the pre-drought level after the end of drought, suggesting a long-lasting impact of summer drought on bacterivore dynamics. This became more evident when assessing the bacterivore-to-prey bacteria ratios, with the ratios of BBac-, BPro-, and BNem-to-PBac increasing by more than two-fold compared to the pre-drought ratio.

This study provides a holistic view of diversity and composition of bacterivores in a fen soil microbiomes, including PD and bacteriophages, and revealed a long-lasting impact of summer drought on bacterivore and food web dynamics. The strong responses of these bacterivores may lead to changes in ecosystem functioning through modulated trophic interactions in a changing climate.

# Effects of Disturbance Intensity on Soil Microbial Diversity, Composition, and Network Complexity in Coastal Georgia, USA

**Tiehang Wu[1*], Angelly Bartolomei[1], Mylette Gordon[1], and Demetria Parham[1]**

[1] *Department of Biology, Georgia Southern University, Statesboro, Georgia, 30458, USA*

*E-mail Address of Presenting Author: twu@georgiasouthern.edu

**ABSTRACT**

Soil microbial diversity and community composition are strongly influenced by anthropogenic activities and environmental conditions, which in turn regulate ecosystem functions. Disturbance intensity often reshapes microbial community structure and co-occurrence networks, thereby affecting ecosystem resilience and functionality. In this study, we investigated the diversity, community composition, and network complexity of soil bacterial, fungal, and eukaryotic (including fungal) communities across a disturbance gradient encompassing cropland, transition, and forest soils at three locations in the coastal region of Georgia, USA. Illumina high-throughput DNA sequencing targeting the 16S rRNA (Klindworth *et al.*, 2013, bacteria), ITS region (White *et al.*, 1990, fungi only), and 18S rRNA (Stoeck *et al.*, 2010, eukaryotes including fungi, same as below) genes was used to characterize microbial communities and their co-occurrence networks. Our results indicated that soil bacterial community structures differed significantly among disturbance intensities ($p = 0.01$) but not among locations ($p = 0.09$), suggesting that bacterial taxa are more widely distributed at the local scale. In contrast, fungal and eukaryotic community structures varied significantly both across disturbance intensities ($p = 0.02$ for fungi, and $p = 0.01$ for eukaryotes) as well as three different locations ($p = 0.01$ for fungi, and $p = 0.03$ for eukaryotes), indicating more localized or endemic distributions. Network analysis revealed that bacterial network complexity declined with increasing disturbance intensity, as shown by a reduction in node connectivity (degree) from 890 in forest soils to 593 in cropland soils. Compared with less-disturbed forest soils, agricultural practices significantly decreased soil bacterial richness and Shannon diversity. Whereas the network complexity of fungi and other eukaryotes remained relatively stable across increasing disturbance intensities. The richness and Shannon diversity of soil fungi and other eukaryotes were significantly higher in forest soils than in crop soils. Soil microbial communities are strongly shaped by disturbance intensity. Proteobacteria dominate in highly disturbed crop soils, whereas transitional and forest soils have lower abundances. Forest soils are enriched in Basidiomycota fungi, while Tubulinea, a major grouping of Amoebozoa, are most abundant in crop soils and least abundant in forest soils. The important role of Tubulinea in predating soil bacteria may be closely linked to the lower bacterial diversity and diminished network complexity observed in crop soils. Overall, these findings indicate that varying disturbance intensities substantially alter soil microbial diversity, community composition, and co-occurrence network complexity, potentially affecting ecosystem stability and resilience in coastal soils of Georgia, USA.

**ABSTRACT**

Soil microorganisms are vital components of wetland ecosystems, and their responses to long-term remain nitrogen (N) enrichment remains unclear. To investigate their evolutionary trajectory during sustained N enrichment, a synergistic treatment combining N input with vegetation removal for 11 years (CK: 0 g N $m^{-2}$ $yr^{-1}$; N1: 6 g N $m^{-2}$ $yr^{-1}$; N2: 12 g N $m^{-2}$ $yr^{-1}$; N3: 24 g N $m^{-2}$ $yr^{-1}$; CKW: vegetation removal treatment; N3W: 24 g N $m^{-2}$ $yr^{-1}$ and vegetation removal treatment). The microbial community traits were analyzed using 16S rRNA and ITS sequencing technologies. The results showed that both soil fungal and bacterial communities significantly increased deterministic processes under both low N input (N1) and high N input with vegetation removal (N3W) treatments. Deterministic processes dominated in fungal communities under both treatments, deterministic processes in bacterial communities only emerged under both treatments.This not only indicates that fungal communities are more strongly influenced by environmental factors, but also demonstrates that deterministic processes are enhanced under both scenarios: low nitrogen input alone and high nitrogen input with vegetation removal. Mantel tests revealed that the increase in deterministic processes was significantly positively correlated with soil TN content, while fungi exhibited a significant positive correlation with soil MBC content. Compared to community assembly processes, soil microbial phylogenetic diversity exhibited lesser susceptibility to N input. Both fungal and bacterial phylogenetic α-diversity showed no significant changes under N input treatments, with significant alterations occurring under the synergistic effect of vegetation removal and high N input when compared with the CKW treatment. Under the N3W treatment, fungal phylogenetic α-diversity increased significantly, while bacterial diversity decreased. Correlation analysis revealed that fungal phylogenetic α-diversity positively correlated with soil $NO_3^-$-N and C:N ratios, but negatively correlated with soil pH, TP, and MBC; bacterial diversity was positively correlated with soil pH and MBC, but negatively correlated with soil $NH_4^+$-N and $NO_3^-$-N. Moreover, microbial phylogenetic β-diversity followed the same trend as α-diversity. Fungal phylogenetic β-diversity were primarily influenced by $NH_4^+$-N, pH, and C:P ratios, whereas bacterial phylogenetic β-diversity were mainly affected by soil MBC and pH. This study elucidates the distinct community assembly mechanisms and phylogenetic diversity patterns of fungal and bacterial communities in wetland soils under N enrichment, providing theoretical framework for predicting microbial evolutionary mechanisms in N enrichment wetland ecosystems.

**ABSTRACT**

To determine the scientific understanding of both mineralogy and geochemistry, in addition to establishing the pH values of healing clays, twenty (20) clay-like materials, which are believed to be used as therapeutic agents for treating various ailments, were procured. The samples were sourced from in situ field materials, stockpile materials brought up from 4 metres below ground level for processing, and finished clay products that originated from the study area and are sold in markets. All 20 samples, each weighing 100 grams, were sent to the ALS geochemical laboratory for multi-elemental analysis using Inductively Coupled Plasma-Mass Spectrometry (ICP-MS). X-ray Diffraction (XRD) technique was used on four in situ clay materials to analyze the mineralogical composition. To establish the pH and EC values of the healing clays, 8 clay materials from different locations, each weighing 10 grams, were analyzed using JENWAY 350 pH meter and Hanna Instrument, respectively. The findings from the XRD Qualitative Analytical technique identified Quartz, Muscovite and Kaolinite as the predominant minerals in the analyzed clay samples. Rutile and Anatase were also revealed in some of the samples, although in trace amounts. The pH values of all samples ranged from 7.43 to 8.60, indicating an alkaline environment. The EC values of the clay samples fell below 2.0 dS/m, indicating non-saline conditions according to FAO guidelines, and are far lower than the threshold for saline materials (≥4 dS/m). From the geochemical analysis, most of the elements found in the clay sampled media showed depletion of macro, micro and toxic elements, which can be attributed to their low EC values. The implication is that the clay consumed by the practitioners would be harmless, as it lacks deleterious constituents and possesses alkaline properties that neutralize the acidic conditions within the stomach. It is evident that ingesting clay to alleviate stomach discomfort caused by excessive acid secretion that causes heartburn or ulcers seems to be justifiable because of the alkaline nature of the sampled clays. However, caution should be exercised when considering its use as a wholesale product due to potential variations in mineralogy and associated narratives. To add to this, the abundance of quartz in the clay samples poses a potential threat to human dental enamel upon ingestion. Thus, it is imperative that mineralogical and geochemical analyses be conducted prior to the consumption of clay as a medicinal product.

## ABSTRACT

The toxic effect of active aluminum (Al) on crops is a primary manifestation of soil acidification damage. During soil acidification, exchangeable $H^+$ is transformed into exchangeable $Al^{3+}$, though the detailed mechanism remains unclear. This study investigated the mobilization of Al during soil acidification, focusing on the roles of surface hydroxyl groups and the Al coordination environment in phyllosilicate minerals and acid dryland soils. Traditional electrochemical methods were combined with modern spectroscopic techniques to elucidate the underlying mechanisms. Surface hydroxyl groups of montmorillonite were removed by high-temperature treatment (Fig. 1). After high-temperature treatment, dehydroxylation reduced mineral crystallinity, layer spacing, pH, and cation exchange capacity (CEC). Al mobilization experiments at constant pH, conducted using an automatic potentiometric titrator, revealed that the removal of surface hydroxyl groups inhibited Al mobilization, with the inhibitory effect strengthening as treatment temperature increased up to the complete dehydroxylation point (Fig. 2). This indicated that protonation of surface hydroxyl groups played a critical role in releasing mineral solid phase Al. Furthermore, four phyllosilicate minerals with differing Al coordination nature were studied. $^{27}Al$ magic-angle spinning solid-state nuclear magnetic resonance (MAS-NMR) spectra showed kaolinite contained only octahedral Al ($Al^{VI}$), phlogopite and illite contained only tetrahedral Al ($Al^{IV}$), and vermiculite contained both. At pH < 5.1, the amount of Al released followed the order: illite > vermiculite > phlogopite > kaolinite, correlating with the CEC and tetrahedral Al content of the minerals. Al mobilization kinetics at constant pH, well-described by the Elovich equation, showed the release rate was generally higher in minerals containing $Al^{IV}$ (e.g., illite, phlogopite) than in kaolinite (only $Al^{VI}$), and increased with decreasing pH. The experimental results of vermiculite acidification with different HCl concentrations showed that the intensity of the $Al^{IV}$ peak in the $^{27}Al$ MAS-NMR spectra gradually decreased, while the intensity of the $Al^{VI}$ peak gradually increased with rising HCl concentration (Fig. 3). This further demonstrated that $Al^{IV}$ was more readily mobilized than $Al^{VI}$. These findings were corroborated by studies on two Oxisols at different ages and four zonal soils. The 10-kilo-annum Oxisol, which contained detectable $Al^{IV}$, released more Al during acidification than the 1330-kilo-annum Oxisol, which contained only $Al^{VI}$. The Al release amount across zonal soils was consistent with their relative $Al^{IV}$ content. This confirmed that $Al^{IV}$ was more readily mobilized than $Al^{VI}$ during soil acidification.

* matsuki.rina.24p@st.kyoto-u.ac.jp

## ABSTRACT

Secondary clay minerals play crucial roles in controlling soil physicochemical properties, and their abundances are governed by the soil-forming factors, especially parent material, climate, and time. Despite studies on single drivers of secondary mineral abundances, cross-regional, multifactor analyses are lacking, partly due to their highly complex interactions. We propose that soil solution properties (e.g., pH and $H_4SiO_4$ activity) and weathering indices (e.g., total reserve base, TRB), which reflect the influence of parent material, climate and time, could link these factors with secondary minerals and be effectively used to predict their abundances.

We identified key variables for predicting mineral abundances, including kaolinite, gibbsite, vermiculite+mica, and acid ammonium oxalate extractable Si ($Si_o$; a proxy for allophane and imogolite) using regression Random Forest (RF) and correlation analyses. Then, based on the identified variable set, we tested a hypothesized model using structural equation modeling (SEM). The model incorporated both direct effects from soil-forming factors and indirect pathways. The primary indirect pathway was modeled as a hierarchical cascade: Climate/Parent Material (Layer 1) → Weathering Indices (Layer 2) → Soil Solution Properties (Layer 3) → Secondary Mineral Abundance (Layer 4). The analysis used subsurface soil samples (mostly 30–60 cm depth) from 213 sites covering temperatures of 7.0–26.9°C, precipitation of 720–4301 mm, and parent materials encompassing igneous and sedimentary rocks. Predictor variables representing soil-forming factors included the following: mean annual temperature (MAT), precipitation (MAP), and excess precipitation (EP) as climatic factors; $Al_2O_3$ + $Fe_2O_3$ and parent material type (binary: sedimentary = 1, igneous = 0) as parent material factors; slope and aspect as topographic factors; and total and aboveground potential net primary productivity (TNPP, ANPP) as biological factors. Although weathering indices are influenced by parent material, they were considered proxy variables reflecting the time factor.

After examining multicollinearity and performing variable selection via RF and correlation analyses, variables showing strong influence (e.g., correlation coefficient > 0.3) were selected for SEM: for kaolinite and gibbsite, MAT, parent material type, TRB, and $H_4SiO_4$ activity; and for vermiculite+mica and $Si_o$, MAT, EP, parent material type, TRB, and pH. The $R^2$ values ($p < 0.05$) for the generated models were 0.48 (kaolinite), 0.32 (gibbsite), 0.61 (vermiculite+mica), and 0.47 ($Si_o$). In all models, the dominant indirect effects via soil solution properties or weathering indices were substantial, accounting for 34–100% of the total effect. Collectively, pH, TRB, and $H_4SiO_4$ activity capture the key pathways connecting soil-forming factors to secondary mineral abundances.

# Models of rock weathering in soil environments based on rock fractal geometry

**ABSTRACT**

The aim of the present research is the study of the solid rock weathering and following transformation into clayey material in the soil environments. The objects are represented by the shallow and mature soils that are derived from and underlain by the highly sensitive to weathering rocks (ultramafic and mafic). The studied soils have formed in the cold environments of the Polar Urals and the Central Siberian Plateau. The mineralogical compositions of rocks and soils were determined on randomly oriented powder specimens and textured specimens of the soil fine size fractions using XRD. The thin sections of rock fragments from the soils were studied by optical microscopy. The specific surface area and the pore size distribution in the rock fragments were determined by low-temperature nitrogen adsorption. The mesostructure data (structural parameters in the range 2–100 nm) and fractal properties of the rocks were investigated by the small angle neutron scattering (SANS) method.

Based on SANS data the ultramafic rock can be seen as a mass fractal structure. The fractal nature of the rock helps to explain the fact that rock transformation into clayey material occurs throughout all sample volume. That leads to appearance of smectite, which was not identified in the rock itself, in the soil profile of Haplic Cryosols (Reductaquic). The rock weathering is fast enough to retain a sufficient amount of smectite, due to continuous supply of new portions of this unstable in the soil horizons mineral.

The studied mafic rock can be imagined as a surface fractal structure that means the phase boundary (hard rock / pore space) is characterized by fractal structure. The rock fragments from the bottom to the upper horizons became more dispersed but smoother. In the fine earth smectite conserves in the inherited aggregates, in which this unstable mineral is protected against dissolution in acidic Entic Podzols.

Thus, two models of the solid rock weathering and transformation into clayey material in the soil environments were shown based on the fractal nature of the studied rocks. That reveals the key role of nanoscale processes based on soil mineralogy in understanding the macro level of rock weathering and pedogenesis.

**ABSTRACT**

The aim of this research is the study of clay mineralogy of the soils formed under cold continental climate in a broad landscape range of (i) the Kolyma Lowland (the Alazeya River Basin): coastal marsh (Gleyic Tidalic Fluvisols), alas meadows on the plain composed of the ice complex deposits (Stagnic Gleysols), and typical northern taiga (Histic Cryosols; (ii) middle taiga in the Central Yakutian Plain (Cambic Cryosols); (iii) middle taiga in the Lena (Prilenskoe) Plateau (Entic Podzols and Cryosols); and (iv) southern taiga in the Lena–Angara Plateau (Calcaric Chromic or Calcaric Rhodic Luvisols and Calcaric Albic Rhodic Luvisols). The mineralogical compositions of rocks and soils were determined on textured specimens of the soil fine size (<0.001 mm) fractions using XRD. The thin sections of soils were studied by ADF U300-P polarizing microscope (Chaina) in plane-polarized light (PPL), cross-polarized light (XPL).

Based on findings of XRD data the soil mineral associations and mineral phase distribution in the soils profiles are affected by inheritance of minerals from the parent substrates and their sensitivity to weathering in acidic environment. The soils of the Alazeya River Basin are characterized by occurrence of (i) vermiculite in the acidic soil horizons of the alas meadow and zonal northern taiga landscapes and (ii) iron hydroxide (lepidocrocite) in the profile of the marsh meadow soils as a result of pedogenesis. Cambic Cryosols (pale soil) of the Central Yakutian Plain are weakly differentiated, their mineral association inherited from loesslike loams differ from that of European Russia due to higher proportion of chlorite.

Despite differences in the particle-size distribution and mineralogical composition, the studied soils formed on the eluvium of Mesozoic noncalcareous sediments of the Lena Plateau are characterized by the high proportion of kaolinite among clay minerals. The illite–chlorite association of clay minerals with a predominance of dioctahedral minerals occurs in the soils on the red colored calcareous Cambrian substrate of the Lena-Angara Plateau. These soils are characterized by the vertical homogeneity of the parent material that was confirmed by the same Coarse/Fine related distribution and similar shape of large grains in thin sections of soil. Micromorphological studies of soils have shown occurrence of the texturally differentiated pedofeatures in the most humid conditions that increase along with higher altitudes. At lower altitudes, the signs of clay illuviation are less pronounced, though they can be traced in the profiles.

# Contributions to the Study of Geophagic Clays in Africa

**Georges-Ivo E. Ekosse**

*Africa Clays and Clay Minerals Research Group and Research and Innovation, University of Venda, Thohoyandou, South Africa*

ekosseg@gmail.com

**ABSTRACT**

Geophagia is the deliberate ingestion of clayey soils and materials; the subject is very wide, multi-, trans-, and inter-disciplined. It is a practice that may likely persist and so making geophagic clays safer for human ingestion has been one of the goals behind its research. The scope of this presentation is limited to the characterisation of geophagic clays from selected countries in Africa including Botswana, Cameroon, Democratic Republic of Congo, Eswatini, Nigeria, and South Africa. Questionnaires were administered to geophagists (individuals who practice geophagia) to understand the types of geophagic clayey materials consumed. The characterisation of the geophagic materials concentrated on their physicochemical and chemical properties and understanding the relationship between the postulated reasons for ingestion of the geophagic clays and these properties. Studies on the mineralogical and chemical compositions of geophagic clays from different regions of South Africa, and different countries indicate huge variations in the properties of the clays ingested as shown in Ekosse and Ngole (2012), Ekosse et. al., (2011), and Ngole and Ekosse (2012), Variations in geophagic materials were also identified and discussed appropriately with specific References to geophagic clays from different countries (Ngole-Jeme and Ekosse, 2015). Though geophagic clays could be sources of nutrient supplement (Ngole and Ekosse (2012), they could have loads of geohelminths which could lead to human geohelminth infection (Sumbele et. al., 2013).

# Mineralogical and Geochemical Contributions to the Study of Clays and Clay Minerals in Africa

**Georges-Ivo E. Ekosse**

*Africa Clays and Clay Minerals Research Group and University of Venda, Thohoyandou, South Africa*

Email: ekosseg@gmail.com

**ABSTRACT**

Africa is endowed with vast deposits and occurrences of both primary and secondary Clays and Clay Minerals of which their geochemical and mineralogical properties are related to their geneses. Clays and Clay Minerals are widely used in many conventional, traditional and emerging applications; and do contribute to national economies in the continent. Of major economic importance is kaolin that find usage in many applications due to influences from its geochemical and mineralogical compositions and properties. With increasing continental population in Africa, demands for food security, augmented industrialization, improved urbanization, and technological advancement hinging on the Fourth Industrial Revolution (4IR) will continue to be on the rise. There is thus the need for better exploration and exploitation of known and unknown Clays and Clay Mineral Resources of the continent for the benefit of its inhabitants. This presentation, which focuses on mineralogy and geochemistry, is part of research efforts conducted on Clays and Clay Minerals in five countries in Africa over the last twenty-five years by the author. Studies covered mainly kaolin, and to a lesser extent talc, illite, and smectite. The kaolin deposits could be primary (hydrothermal, residual or mixed hydrothermal and residual) or secondary (Ekosse, 2010); and kaolinite formed by mineral alteration of feldspar and muscovite contained in rocks such as granite and rhyolite as indicated in equations 1 and 2.

$2KAl_3Si_3O_{10}(OH)_2 + 2H^+ + 3H_2O = 3Al_2Si2O_5(OH)_4 + 2K^+$ (1)

$2AlSi_3O_8 + 2H^+ = 9H_2O = Al_2Si_2O_5(OH)_4 + 2K^+ + 4H_4SiO_4$ (2)

Extensive fieldwork covering Botswana, Cameroon, Eswatini, Gabon, Ghana, Nigeria, and South Africa was conducted by visiting selected formations, deposits, and occurrences that had argillaceous rocks and sediments, and studying soils next to abandoned manganese mine, human settlements and clayey materials from volcanic cones. X-ray powder diffraction analysis was employed for the identification and characterization of mineral phases present in the samples. Flame photometry, X-ray Fluorescence Spectrometry, Laser Ablation – Inductively Coupled Plasma – Mass Spectrometry, Fourier Transform Infrared Spectrophotometry, Thermogravimetric Analysis and Differential Scanning Calorimetry analytical techniques were applied in mineralogically and chemically characterizing the samples. The research findings, published in different scientific outlets, are discussed from an integrated perspective.

## ABSTRACT

The stability of soil clay minerals in the soil environment remains unclear. The present study aims to elucidate chemical structural information of soil clay minerals including isomorphic substitution and detect weathering-induced structural changes of them in a soil profile. For the purpose, the authors investigated the clay minerals at a single-particle level using electron probe microanalyzer (EPMA).

To validate the accuracy of the EPMA method, six standard clays obtained from the Clay Science Society of Japan (Miyawaki et al., 2010) were investigated. These standard clays were analyzed untreated and after Cs-saturation treatment. For detecting structural changes due to weathering, soil clay fractions (< 2 μm) were separated from soil samples collected from A, Bw1, Bw2, BC, and C horizons from a Cambisol (Inceptisol) profile in Fukuoka, Japan (Mori et al., 2023). The soil clay fractions were subjected to dithionite-citrate-bicarbonate treatment, hot citrate treatment, and Cs-saturation treatments, sequentially. Those clay samples were embedded in epoxy resin, polished, carbon-coated, and analyzed with EPMA (JEOL JXA-8530F). The chemical formulas were normalized based on the information of mineral species identified by powder X-ray diffraction analysis (Mori et al., 2023). Non-exchangeable K was defined as K remained after the Cs-saturation treatment.

The analysis of standard clays revealed that the EPMA method successfully collected target mineral data from impure samples, yielding accurate structural information. In the analysis of soil clays, it was clarified that beidellite was the predominant clay mineral with an averaged chemical formula of $[K_{0.35}, Na_{0.06}, Ca_{0.03}, Mg_{0.06} (Si_{3.67}, Al_{0.33})(Al_{1.65}, Fe^{III}_{0.01}, Fe^{II}_{0.22}, Mg_{0.08}, Ti_{0.04}) O_{10}(OH)_2]$. Although the soil profile has developed horizons with soil formation, the chemical structure of the beidellite showed no statistically significant differences in the frequency and type of isomorphic substitution among horizons, remaining constant throughout the soil profile. Furthermore, non-exchangeable K accounted for approximately 25% of the total interlayer charge, and this value was also consistent across all horizons. These results suggest that beidellite is highly stable in the acidic weathering environment, and that isomorphic substitution within its tetrahedral sheet leads to strong interlayer fixation of K, similar to illite. Further research is needed to elucidate the structural changes in clay minerals during weathering and enhance our understanding of weathering processes.

# Crystallinity–solubility relationship of phytoliths derived from different gramineous plants: validation using X-ray diffraction analysis

**Akihito Fukuoka[1*], Junta Yanai[1] and Atsushi Nakao[1]**

[1] *Graduate School of Life and Environmental Sciences, Kyoto Prefectural University, Kyoto, Japan*

*s825631048@kpu.ac.jp

**ABSTRACT**

Silicon (Si), a beneficial element for gramineous plants, is the second most abundant element in soils. Plant available Si in soil primarily originates from soil minerals, however, phytoliths, plant-derived hydrated amorphous silica, have recently attracted attention as an important alternative source of available Si. The solubility of phytoliths varies among plant species; but the underlying factors governing this variability remain unclear even though it directly affects the Si-supplying potential. Therefore, based on the hypothesis that differences in crystallinity determine phytolith solubility, we investigated phytoliths extracted from different species and organs of gramineous plants to clarify the physicochemical factors determining their solubility.

Phytoliths were prepared from the culms, branches, and leaves of moso bamboo (*Phyllostachys pubescens*), the straw and husks of rice (*Oryza sativa*) and the stems and leaves of sugarcane (*Saccharum officinarum*) using a wet digestion method. The crystallinity of the prepared phytoliths was evaluated using the References intensity ratio (RIR) method based on X-ray diffraction (XRD) analysis. The phytolith (200 mg) was mixed with 50 mg of corundum ($\alpha$-$Al_2O_3$) as an internal standard for RIR measurements. Also, amorphous silica and sea sand were used as external $SiO_2$ standards representing 100% opal-A and $\alpha$-quartz, respectively. The opal-A phase (i.e., amorphousness) and $\alpha$-$SiO_2$ phase (i.e., crystallinity) were calculated from the ratios of the RIRs of the phytolith opal-A peak ($2\theta = 22.1°$) and $\alpha$-quartz peak ($2\theta = 26.6°$) to that of amorphous silica and sea sand, respectively. The solubilities of the phytoliths and the external $SiO_2$ standards were determined via 0.2-M NaOH extraction.

The contents of the opal-A and $\alpha$-quartz phases in the phytoliths were on average 85.3% and 4.8%, respectively across different organs and species, with a negative correlation ($p < 0.01$). The opal-A phase increased from the proximal to distal parts of the plants. The initial Si dissolution rate and maximum Si dissolution amount of the phytoliths were on average 138 g Si $kg^{-1}$ $h^{-1}$ and 343 g Si $kg^{-1}$, respectively. Both parameters exhibited an increasing trend from the proximal to distal parts. The initial dissolution rate exhibited a positive correlation with the opal-A phase ($p < 0.01$), whereas the maximum dissolution amount exhibited a negative correlation with the $\alpha$-quartz phase ($p < 0.01$) (Fig. 1). These results indicate that differences in tissue developmental stage across plant organs control phytolith crystallinity, i.e., the relative abundance of opal-A and $\alpha$-quartz. This composition, in turn, strongly controls phytolith solubility, specifically the dissolution rate and capacity, respectively. In conclusion, these findings quantitatively elucidate the mechanism controlling Si supply from phytolith, thereby enabling a more precise estimation of Si supply from gramineous plant based on developmental stage.

# Mineralogical Composition of Bulk and Clay Fractions in Mongolian Soils: Insights from X-Ray Diffraction Across Arid to Forest-Steppe Gradients

**Undrakh-Od Baatar[123], Franz Ottner[2], and Karl Stahr[1]**

[1] *Institute of Soil Science and Land Evaluation (Hohenheim University, Stuttgart, Germany)*

[2] *Institute of Applied Geology (University of Natural Resources and Life Sciences, Vienna, Austria)*

[3]*Central Asian Soil Science Society (Ulaanbaatar, Mongolia)*

*undrakhod.baatar@gmail.com

**ABSTRACT**

Mongolia's diverse landscapes span forest-steppe, steppe, semi-desert, and Gobi Desert zones, featuring soils influenced by aridic to sub-humid climates, varied parent materials (basalt, sandstone, slate, fluvial/alluvial sediments, dune sands, lake/playa deposits), and pedogenic processes including salinization, sodification, calcification, gypsification, clay illuviation, and redoximorphism. These result in prevalent References Soil Groups such as Solonchaks, Solonetz, Gypsisols, Calcisols, Luvisols, Cambisols, Arenosols, Andosols, and Phaeozems (WRB classification).

This study examines bulk and clay mineralogy via X-ray diffraction (XRD) on selected Mongolian soil profiles from northern forest-steppe (P-series: e.g., P1 Leptic Phaeozem vitric, P2 Vitric Andosol, P3 Sodic Cambisol protocalcic) and southern/southeastern arid/semi-arid regions (X-series: e.g., X1 Gleyic calcic Solonchak sodic, X5 Hypogypsic calcic Gypsisol sodic, X7 Vertic Solonetz takyric, X8 Vertic luvic Calcisol sodic yermic, X9 Calcic Solonetz endoskeletic). Field descriptions document high pH (often 8.5–10.4), elevated carbonates (up to >50% in calcic/petrocalcic horizons), gypsum accumulations (e.g., By, Byk horizons in X5, X6), clay cutans (Btn horizons in X3, X4, X7, X8, P14), vertic features, and gleyic/sulfidic properties in depressions.

The mineral assemblages reflect lithology, aridic moisture regimes, sodium/carbonate accumulation, illuviation, and redox conditions. These findings underscore mineralogical controls on cation exchange, water retention, aggregation, and vulnerability to salinization/sodification in Mongolia's dryland ecosystems, informing sustainable management amid climate change and pastoral pressures.

# A Novel Rainfall-Based Model for Forecasting Soil Moisture Content

**Daniel B. Gu**[1]

[1] *Hamilton High School, Chandler, Arizona, USA*

*gu.daniel303@gmail.com

**ABSTRACT**

Growing concerns regarding current methods addressing restrictions in data accessibility and real-world reproduction reinforce the motivation to develop more accurate simulation methods, especially in agricultural sectors. This study utilizes established modeling techniques like the Monte Carlo simulation as well as graphical analysis to account for rainfall unpredictability and foresee volumetric moisture content (VMC) values. This research includes 4 rainfall events measured in Cedar Rapids, Iowa, chosen for its periodic, steady rainfall throughout the year 2025. Key materials used to design the model includes Microsoft Excel spreadsheet as well as publicly available data, primarily from Iowa Environmental Mesonet and United States Geological Survey's National Map tool. Through the utilization of a 5-step process involving the collection of rainfall and soil data, a 4th-degree polynomial regression, application of the Monte Carlo Simulation, and then both exponential decay formula and VMC formula, the compilation and transformation of raw rainfall data aim towards simulating real-world conditions. The Monte Carlo simulation was chosen for its ability to simulate randomness, reflecting the uncertainty in nature. Relative error for one specific data set ranged from -0.873% to +0.695% between the real and simulated values; in addition, the RMSE relative to the values comes extremely close to 0, reaching 0.000344, indicating a superb fit alongside the R^2 of 0.995 for the simulated rainfall intensity. However, the model does stray away from extremely precise values when faced with unexpected surges in rain since the fit for data set 2 saw a R^2 of 0.374, the resultant VMC values are overestimated, seeing high error percentages of 3.91%. With due time, the model may correctly encapsulate and consider numerous natural parameters (e.g. temperature, atmospheric pressure, wind speed) and display a spatial diagram. But the current model can act as the basis to culture the realm of irrigation and agriculture, potentially resolving the current lack of data and uncertainty posed by changing climates.

## ABSTRACT

Ecotones are transitional zones between two ecosystems, and their sensitivity and fragility make them ideal settings for investigating how community-level interactions respond to global change and anthropogenic disturbance. To address the wide range of ecological problems caused by soil degradation, China has implemented a series of ecological restoration programs since the 1970s, achieving substantial success. However, excessive vegetation restoration has consumed excessive soil moisture, potentially disrupting the fragile ecological balance of the farming-pastoral ecotone of northern China. Therefore, accurately analyzing and predicting trends in soil moisture dynamics under different vegetation utilization types will help to achieve the sustainable development of its ecological environment.

We designed this study to combine the in-situ experiment and the macro-scale regional sampling survey. For the in-situ experiment, we measured soil moisture in grassland (*Stipa bungeana*, etc.), shrubland (*Caragana korshinskii*), and woodland (*Populus simonii*) on steep slopes (with gradient larger than 30°) between 2021 and 2022, and used the Hydrus-1D model to simulate 0–500 cm soil moisture dynamics as affected by vegetation types. We set up different scenarios of vegetation replacement and cover reduction to assess the long-term effects of vegetation management on soil moisture over a 50-year period. Our results revealed significant variations in soil moisture dynamics among vegetation types, with the highest soil moisture observed in woodland and the lowest in shrubland. Notably, a dried soil layer extending beyond 500 cm was observed across all vegetation types. Results from Hydrus-1D modeling indicated that although woodland currently retains more soil moisture than grassland, this pattern will reverse after 21 years. Decreased vegetation cover, irrespective of vegetation type, would lead to soil moisture accumulation. Converting shrubland to grassland would increase soil moisture in the 0–500 cm depth, whereas the impact of converting woodland to grassland depends on vegetation coverage.

In parallel, we conducted a three-round field campaign from 30 July to 25 September 2023, sampling more than 200 sites across the provinces encompassed by the farming-pastoral ecotone of northern China. Soil samples were collected beneath cropland, grassland and woodland, and key physical and chemical properties were measured. We are currently using the aforementioned data and flux data to calibrate vegetation parameters in a biogeochemical model. The findings will provide both theoretical support and practical guidance for the scientific management and sustainable development of ecotone ecosystems.

## ABSTRACT

Soil aggregates serve as the physical foundation for critical ecosystem services in riparian zones, and their stability is intricately linked to the root functional traits during ecological rehabilitation. Flooding, a common stressor in these ecosystems, has great potential to alter plant communities and their functional traits, yet the role of these traits in aggregate turnover and stabilization remains poorly understood. To bridge this knowledge gap, we conducted a thorough investigation into the soil aggregate turnover in a typical riparian zone of the Three-Gorges Reservoir. We closely tracked water level fluctuations and their impacts on vegetation, using undisturbed soil sampling and sieving techniques to assess aggregate size distribution dynamics. Additionally, we employed on-site plant quadrat surveys, minirhizotron observations, and lab analysis of above- and below-ground traits to assess the changes and relative contributions of plant functional traits to aggregate stability. Controlled indoor experiments further explored the mechanisms by which root functional traits influence soil aggregate formation and stability. Our findings revealed that soil aggregate stability decreased significantly with the increasing flooding intensity, but not in a linear fashion. Oxides played a crucial role in aggregate stability under intense flooding, while organic carbon dominated under milder conditions. We observed significant variations in above- and below-ground biomass with flooding intensity, and species diversity had contrasting effects on small macro-aggregate formation. Perennial herbs with fibrous root systems were essential for soil aggregate stability under intense flooding, while plant diversity was critical under milder conditions. Root volume density mediated the effects of plant diversity on riparian soil stability. This study highlights the complex interactions between flooding, plant functional traits, and soil aggregate stability in riparian zones. Root exudate stoichiometry governs soil aggregation through temporally differentiated microbial pathways, with fungi providing sustained structural stabilization while bacteria contributing stage-specific functional reinforcement. Understanding these dynamics is crucial for effective management and restoration of these vulnerable ecosystems. This research will also enhance our understanding of soil aggregate turnover in extreme environmental contexts and the role of vegetation in promoting aggregate formation and stabilization within the soil-plant system.

# Evapotranspiration varies across different landscape units, influenced by hillslope position, soil properties and vegetation: An example from the Qinghai-Tibet Plateau

**Yurova Alla[1*], Dobrokhotov Alexey[2], Yang Fei[3]**

[1] *State Key Laboratory of Cryospheric Science and Frozen Soil Engineering, Northwest Institute of Eco-environment and Resources CAS, Lanzhou, China*

**ABSTRACT**

When mapping soil types based on their spatial arrangement within the landscape, geomorphological features of hillslopes emerge as a key factor. Unlike conventional pedology, hydropedology not only considers these geomorphological predictors but also aims to describe the characteristic hydrological processes for different landscape positions. A critical focus is on soils with differing water regimes, particularly those affected by lateral water redistribution.

In this study, we utilized evapotranspiration as a hydrological variable to assess land-atmosphere interactions in two areas within the Qinghai-Tibet Plateau. We modeled evapotranspiration at a high resolution through satellite remote sensing of surface temperatures combined with the METRIC simulation algorithm for the period 1990 - 2021. To connect evapotranspiration with landscape positions, we employed the LUMP tool, which incorporated geomorphological and vegetation data for clustering. This approach enabled us to identify five representative hillslope types characteristic of the study regions.

For each representative hillslope and each terrestrial unit (comprising representative soil-vegetation columns at a given landscape position), we gathered time series of simulated evapotranspiration. Our findings revealed that soil properties and vegetation significantly affect surface energy exchange processes. Specifically, alpine meadow and wet meadow soils located at the foothills exhibited the highest rates of evapotranspiration (e.g. 0.5 mm h-1 at noon in July), while alpine steppe soils on steep slopes demonstrated the lowest rates (e.g. 0.1 mm h-1 at noon in July).

Vegetation disturbances (assessed through vegetation indexes) had the most considerable impact on the functioning of the alpine steppe soils and were least detrimental to wet meadow soils. Presumably soil properties are instrumental in maintaining stable evapotranspiration rates that correspond to climatic precipitation levels. It can be hypothesized that the mattic horizon proved to be more resilient to disturbances in high moisture conditions compared to low moisture regimes. Furthermore, with vegetation restoration, wet meadows exhibited the quickest rates of evapotranspiration recovery.

Evapotranspiration plays a crucial role in the moisture recycling process that stabilizes the regional water cycle by returning water vaporized from land back as precipitation. Practice of avoiding disturbance at dry areas and wet meadow prioritization in restoration can be useful considering both implementation success and opportunity values.

# Identifying spatiotemporal patterns of hillslope subsurface flow in an alpine critical zone on the Qinghai–Tibetan Plateau based on three-year, high-resolution field observations

**Guangrong Hu[1], Xiaoyan Li[1*], Xiaofan Yang[1], Fangzhong Shi[1]**

[1] *Faculty of Geographical Science, Beijing Normal University, Beijing, China*

hugr@bnu.edu.cn

**ABSTRACT**

The spatial heterogeneity and temporal variability of hillslope subsurface flow (SSF) generation are poorly understood in the alpine critical zone (CZ). Owing to the limitations of observation technology bottlenecks and harsh environments, existing studies lack a holistic and process-based understanding of SSF generation, particularly for the deep CZ and annual freeze–thaw cycle. This study improves the conventional trenching observation scheme and is the first to have successfully monitored SSF processes from the soil to the bedrock layer with high-resolution from 2017 to 2020 in a headwater catchment of the Qinghai–Tibetan Plateau. The results show that hillslope runoff generation exhibited similar trends over the years while exhibiting distinct patterns across seasons. Spatially, slope aspects significantly affect the runoff amount and ratio. The south-facing slope is dominated by overland flow (OF, 84.2–97.0%), while the north-facing slope is dominated by SSF (88.9–97.3%). The runoff depth of the north-facing slope is 11.0 times that of the south-facing slope. The SSF in the deep CZ accounts for 20.8–37.8% of the total runoff along the north-facing slope. Temporally, runoff generation exhibits distinct patterns across seasons. OF exhibits two different patterns, while SSF exhibits five across seasons. Our results indicate that runoff generation in different freeze–thaw stages should be studied by the time phase. Therefore, we propose seasonal or freeze–thaw period-based classification criteria and divide OF and SSF into two and three consecutive periods throughout the calendar year. We suggest that these inferences and observations should be considered in the framework of hydrological models in cold regions.

# Hydropedological Responses to Anthropogenic Soil Importation and Wadi Channel Narrowing in Arid Oman

**Said Al-Ismaily*, Ahmed Al-Mayahi, Salwa Al Harthy, Fatima Al Muraza Ba Abood, Sarah Al Hamrashdi, Anvar Kacimov, Hamed Al-Busaidi, Daniel Blackburn, Rahma Al-Habsi**

**ABSTRACT**

Wadis (ephemeral watercourses) in arid landscapes act as critical ecohydrological corridors linking soil, water, and geomorphic processes. However, these fragile systems are increasingly subjected to anthropogenic alterations that disrupt soil–water interactions and sediment connectivity. This study applies a hydropedological framework to investigate how soil importation and wadi channel narrowing for agricultural expansion affect sediment dynamics and soil chemistry in Wadi Al-Khoud, Oman. Field sampling across three transects (n = 48), combined with laboratory and spatial statistical analyses, revealed significant modification of surface-soil properties and geomorphic stability. Imported "alien" soils, often containing quarry debris and construction waste, altered the native soil composition—elevating $Na^+$, $NO_3^-$, and $K^+$ concentrations by 249%, 33%, and 104%, respectively, relative to control sites. Textural analysis indicated a 4.3-fold increase in fine silt content at impacted locations, while semivariogram modeling demonstrated disturbed spatial continuity of soil texture and chemistry. Between 2010 and 2020, wadi channel narrowing by an estimated 73 m (≈95,800 $m^3$ of imported material) induced a Venturi-type contraction, amplifying flow velocities, sediment scour, and downstream contaminant dispersal. The formation of nabkhas — vegetation-stabilized sand mini-mounds — illustrates altered hydrogeomorphic feedbacks and ecological instability within the terraced floodplain.

These findings underscore the consequences of unregulated land modification in arid environments, where altered soil–water–geomorphology linkages accelerate land degradation and hydrological risk. Integrating hydropedological concepts into land-use planning and policy is essential to safeguard wadis as "natural hydraulic veins" that sustain soil functions, groundwater recharge, and ecosystem resilience in dryland regions.

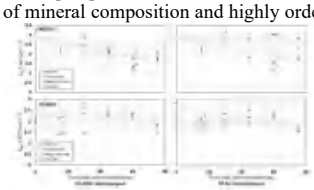
# Biochar-Induced Changes on Soil Nutrient Retention and Saturated Hydraulic Conductivity of Sandy Loam Soil in Lahar-laden Area of Zambales, Philippines

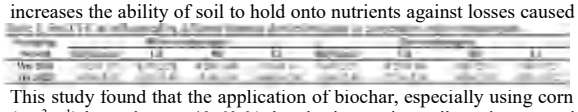
**Jacob B. Labita[1*], Karen S. Bautista, Ph.D.[1], and Angelita C. Marcia[1]**

[1] *Soil and Water Resources Research Division, Bureau of Soils and Water Management, Quezon City, Philippines*



*jacob.labita@bswm.da.gov.ph

## ABSTRACT



Lahar-laden areas in the Philippines are known to have inherent soil constraints, such as high nutrient leaching and low water holding capacity, which could be attributed to sandy loam texture. Negatively-charged biochar soil conditioner is the bio-product of thermal decomposition of renewable feedstock after pyrolysis. Porosity of the material at 50 and 10 µm diameter can affect soil porosity through modifying soil structural properties via surface roughness and contact angle (Rasa et al., 2018). Many local experiments have been conducted on the benefits of biochar in improving soil macronutrients, beneficial microorganisms, and crop yield. However, there are a limited number of studies on its potential to enhance soil nutrient retention capacity as well as other physical properties such as reduction in bulk density, promotion of aggregate stability, and increase in water retention. The aim of the study is to determine the effect of different crop waste biomass-derived biochar combined with organic fertilizer in improving nutrient retention and saturated hydraulic conductivity in sandy loam soil. The on-farm experiments were established in organic-based Sambali Farm, Brgy. Taugtog, Botolan, Zambales (15.304174 N, 120.048256 E) during the wet season of CY2021 and dry season CY2022 from February 2021 to January 2022. The area has an annual precipitation of 2,896 mm with 26 °C average temperature. The Angeles sandy loam soil type (Typic Ustipsamments) is located in a nearly level area of 3% at 18 m elevation with a soil depth of greater than one meter (m). It has high internal drainage with a saturated hydraulic conductivity (Ksat) of 3.11 x 10 -3 cm3/s and has a low ability to hold exchangeable cations with cation exchange capacity (CEC) of 8.68 cmol(+)/kg. The crop used was hot pepper (*Capsicum sp.)* Red Hot F1 variety. The treatments were arranged in split-plot design with application of organic fertilizer as main plots (V1-V2) and biochars at 0.5 t ha-1 (Marcia et al, 2020) as sub-plots (B1-B4) such as rice hull (Rh), coconut husk (Ch), mango trimmings (Mt) and corn cob (Cc). The plot size was 3m x 6m (18 m$^2$) with 0.5 cm plant distance between rows. Scanning electron microscopy (SEM) surface morphology was performed using Hitachi SU8230 FE-SEM with low vacuum of 30 Pa, voltage 15 kV and 8-15 mm working distance from the detector. Soil CEC and Ksat were analyzed using ammonium acetate and constant head method, respectively. The analysis of variance (ANOVA) was calculated using the Statistical Tool for Agricultural Research (STAR) 2.0.1. Tukey's HSD test (at P<5%) was used for pairwise comparison. Data were further analyzed for seasonal variation and trend analysis.

best pore-defined development compared to Rh and Ch. Mt and Ch biochars had larger structure in biochar provides high adsorption capacity attributed from higher crystallinity of mineral composition and highly ordered aromatic structures form (Kloss et al., 2012).

ts obtained lowest *Ksat* (cm$^3$ s$^{-1}$) of 1.21 x 10-3 cm3/s to 1.87 10-3 cm3/s at 60 dat (VxB, *P* value = 0.0389) except for Rh biochar who had the highest *Ksat* (3.01 x 10$^{-3}$ cm$^3$ s$^{-1}$) for WS 2021. Cc biochar alone obtained the lowest *Ksat* (1.21 x 10$^{-3}$ cm$^3$ s$^{-1}$) with 61 % decrease from the initial 3.11 x 10-3 cm3/s. For DS 2022, *Ksat* only decreased only with the application of Ch biochar with Vc of 1.4 x 10-3 cm3/s at 15 data (VxB, *P* value = 0.0005). Decreasing soil Ksat can improve water holding capacity in sandy loam soil during irrigation events (Nawaz et al., 2019), thereby resulting in the increase in soil water retention. The application of biochar resulted in an increase in CEC in all biomass by greater than 43% from WS 2021 to DS 2022 (Table 1). Rh biochar with Vc, Ch biochar with Vc, and Cc biochar alone obtained an increase in CEC by 80-90%. El-Naggar et al. (2018) also confirmed that porous biochar increases the ability of soil to hold onto nutrients against losses caused by leaching.

This study found that the application of biochar, especially using corn cob biomass in sandy loam increased CEC (cmol$^{(+)}$ kg$^{-1}$) by 80-90 % and decreased Ksat (cm$^3$ s$^{-1}$) by as low as 40-60 % thereby improving soil nutrient retention and decreasing the saturated hydraulic conductivity of Angeles sandy loam in two (2) cropping seasons. Induced improvement on soil properties of sandy loam soil were attributed to the porous morphology of corn cob biochar affecting soil porosity through modification of soil structural properties via direct mechanisms for surface roughness and contact These findings are important because it provided evidence on the efficacy of crop wastes derived-biochar in improving the ability of the soil to retain nutrients and residence time of irrigation in sandy loam soils in lahar-laden areas; and consequently, it may reduce the amount of applied fertilizer and mitigate the effects of drought.

**ABSTRACT**

Climate change is severely impacting viticulture in Southern Italy, threatening the economic sustainability of autochthonous varieties like Greco (DOCG) due to increasing drought and thermal stress. Addressing this real-world challenge requires moving beyond empirical observations to a robust hydropedological framework capable of predicting Soil-Plant-Atmosphere (SPA) interactions under future scenarios. This study, part of the GREASE project, presents an interdisciplinary approach applied to a 3-year field experiment (2020-2022) in a Greco vineyard (Avellino, Italy) on a Calcaric Cambisol.

The methodology integrated pedological characterization with the calibration of the agro-hydrological model SWAP. By monitoring soil water content, leaf water potential, and grape quality across different soil (tillage vs. cover crops) and canopy management treatments, the model was validated to simulate the Crop Water Stress Index (CWSI). Crucially, the study identified a specific hydropedological threshold: maintaining a CWSI below 20% at veraison is mandatory to achieve "Ultra Quality Grapes" (UQG) with the optimal sugar/acidity balance. Conversely, stress levels exceeding this threshold led to a significant quality degradation (from Standard to Low Quality), regardless of the soil management adopted, demonstrating that soil management alone is insufficient to mitigate the climate signal. Applying this validated model to future climate scenarios (RCP 4.5 and 8.5), results forecast a progressive rise in water stress (up to +14% by 2100 in RCP 8.5), pushing rainfed vines frequently above the safety quality threshold.

These findings indicate that a transition from rainfed to irrigated viticulture is becoming essential in this pedoclimatic context. The proposed hydropedological modelling approach provides the quantitative basis to redesign irrigation strategies, ensuring the resilience of prestigious wine-growing areas by linking soil hydraulic properties directly to oenological goals.

# Runoff and Sediment Response to Rainfall and Vegetation Cover in the Toutun River Basin（Xinjiang,China）

**Liu Li*, Yajie Wang, Siyao Li, Xiang Li and Xiaoliang Gu**

*Xinjiang Agricultural University (College of Forestry and Landscape Architecture, Urumqi, China)*

*Leona@xjau.edu.cn

**ABSTRACT**

The characteristics of precipitation events, vegetation type, and soil physical properties (including moisture content) are primary factors influencing slope surface runoff generation and soil erosion. Vegetation is a critical factor in mountainous areas due to its role in precipitation redistribution and its profound effects on soil physical properties and moisture content, thereby significantly influencing surface runoff yield and soil erosion.

To elucidate the mechanisms underlying these effects, experimental runoff plots were established in *Picea schrenkiana* var. *Tianschanica* forests at three elevations (1,800 m, 2,200 m, and 2,600 m) in the mid-reach of the Toutun River Basin, Tianshan Mountains (Xinjiang, China). At each elevation, control plots were installed in adjacent grasslands, resulting in a total of 36 plots. A bare ground control was omitted primarily because the natural landscape is predominantly grassland (excluding bare rock), and the grasslands are privately owned by herders, making large-scale destructive experiments unfeasible.

From May to September 2025, long-term monitoring equipment recorded 44 rainfall events and corresponding soil moisture dynamics. Runoff and sediment yield were observed for 16 of these events, leading to the following conclusions: (1) The frequency, amount, and intensity of rainfall events varied with elevation, and the response of soil moisture content at different depths also varied across rainfall event magnitudes; (2) The canopy of *Picea schrenkiana* var. *Tianschanica* significantly altered the amount, intensity, and kinetic energy of throughfall, consequently reducing runoff and sediment yield on forested slopes; (3) Short-duration, high-intensity rainfall events, though infrequent, contributed minimally to soil moisture recharge but had the potential to generate substantial runoff and sediment in a very short period, representing a key concern for geohazard prevention in the region.

In recent years, global climate change has significantly altered the frequency and characteristics of rainfall events in arid mountainous regions. Notably, short-duration, high-intensity events have become more frequent, leading to an increase in associated natural disasters such as flash floods and debris flows triggered by surface runoff and soil erosion. This study investigates the characteristics and patterns of rainfall events and their impacts on runoff and sediment yield under different vegetation covers in the mid-reach of the Toutun River Basin. The findings aim to provide a theoretical basis for research on soil hydrological processes and for the development and parameter calibration of hydrological models in arid mountainous regions.

## ABSTRACT

Groundwater is a vital component of the hydrological cycle, playing a crucial role in meeting the water demands of humans and ecosystems, and an important resource for maintaining economic and social development (Gu et al., 2018; Li et al., 2019). Particularly in arid regions, there are often severe water shortages and uneven seasonal distribution issues(Fang et al., 2021). When surface water and precipitation are insufficient, groundwater serves as a buffer and is especially relied upon in arid areas to meet heightened water demands under climate warming (Condon et al., 2020; Xiao et al., 2018). However, in arid regions, the ecological environment is already fragile, and coupled with the impact of arid climate and human activities, makes groundwater resources susceptible to change, which posing serious challenges to water supply and ecological security (Rohde et a2024). Therefore, understanding the actual situation of groundwater resources and analyzing service value they bring to humans is to provide scientific support for protecting and optimizing ecosystems in arid areas. Although scholars have studied the groundwater ecosystems service value (GESV) in recent years (Cital et al., 2025), these studies mainly focused on economically developed regions and have been limited to construction of indicator systems and temporal evolution of service value. However, they have not further discussion on scale effects, spatial characteristics, and driving factor analysis. This indicates that GESV deserves further research.

Xinjiang Uygur Autonomous Region (Xinjiang) is one of the extremely arid regions in the world and an ecologically fragile area (Li et al., 2021). The region has scarce precipitation, extremely high evaporation, and surface rivers with frequent interruptions and strong seasonality, making it almost impossible to form a stable and reliable surface water source(Li et al., 2022). In this extremely arid environment, people's production and daily life mainly rely on use of groundwater resources, and surface ecology mainly depends on groundwater. Therefore, groundwater occupies an irreplaceable position. According to statistics, the total water resources of Xinjiang in 2020 were about 80.1 billion $m^3$, of which 50.35 billion $m^3$ were groundwater resources. The exploitable groundwater resources reached 25.2 billion $m^3$, accounting for about 50% of the total groundwater resources (Xinjiang Water Resources Bulletin,2020). However, with climate change, rapid population and economic growth, the groundwater level in Xinjiang has significantly decreased in recent years (Guo et al., 2021). This has precipitated a series of ecological and environmental issues, including land subsidence (Fan et al., 2023), water quality deterioration(Yan, 2022), surface vegetation degradation (Chen et al., 2015), shrinking lakes and wetlands (Nie et al., 2023), and land desertification and salinization(Yu et al., 2022). To address this crisis, the government has implemented the most stringent water resource management systems to govern groundwater ecosystems(Jiao et al., 2025; Lin, 2021). Looking ahead, projected future climate change is expected to shift glacial meltwater peaks toward decline while significantly increasing surface runoff uncertainty (Farinotti et al., 2015; Huss and Hock, 2018). Groundwater will remain a critical water resource participating in the hydrological cycle and supporting both natural ecosystems and human communities in Xinjiang (Guo et al., 2021; Xiao et al., 2022). In addition, as a water tower in Central Asia, the dynamic changes of groundwater in the Tianshan Mountains of Xinjiang have an impact on the surrounding areas through hydrological cycles and ecosystem chains (Shang et al., 2016). In this context, researching the groundwater ecosystem service value (GESV) of Xinjiang is of great significance.

This study will take Xinjiang, a typical arid region, as the research area. Based on GIS technology, a monetary quantitative value assessment model will be used to investigate the spatiotemporal distribution and hot and cold spot distribution characteristics of water supply (WS), water purification (WP), carbon absorption (CA), and total groundwater ecosystem service value (GESV) of Xinjiang's groundwater ecosystem at the regional, sub regional (North, South, East Xinjiang), and administrative regional scales from 2005 to 2022. Using a geographic detector model, we focused on studying the natural environment and socio-economic driving factors of GESV, and proposed policy recommendations.

**Conclusions:** As for spatiotemporal characteristics, except for WS, the other WP, CA and GESV presented similar spatial pattern, showing a gradual decrease from northwest to southeast. high value and hotspot areas are primarily concentrated in the western Tianshan Mountains and the southern foothills of the Tianshan Range, specifically in oasis regions such as the Ili Kazakh Autonomous Prefecture, the Bortala Mongol Autonomous Prefecture, and Aksu Prefecture. Low value and coldspot areas are primarily distributed in Eastern Xinjiang, specifically in Turpan and Hami citys. From 2005 to 2022, the GESV in Xinjiang showed a trend of increased first and then decreased, with average GESV of 39.22 thousand yuan/$km^2$. The size of GESV at the subregional scale follows the order of Northern Xinjiang > Southern Xinjiang > Eastern Xinjiang, accounting for 60%, 30%, and 10% of the total GESV in Xinjiang, respectively.

As for driving factors, GESV is influenced by both natural environmental factors and socioeconomic factors. Among them, the interaction between population density, per capita GDP, and other natural environmental factors has the greatest impact on GESV, especially when combined with precipitation, with a q value close to 1. With urbanization and economic development, the impact of human activities on GESV is becoming increasingly evident, leading to the expansion of cold spot areas.

As for policy recommendations, based on characteristics and water usage conditions of different regions in Xinjiang,relevant water resource management measures and policies shall be implemented in a differentiated manner. Strictly control and reduce excessive groundwater extraction in accordance with total volume control targets. To achieve dynamic monitoring of groundwater, in order to forecast, monitor, analyze, and manage the groundwater ecosystem based on the obtained dynamic monitoring data.

**ABSTRACT**

Seasonally snow-covered, seasonally frozen landscapes of north-eastern China are both sentinel regions of climate change and emerging hot-spots of spring drought. Integrating 12 years (2014–2025) of in-situ hydro-meteorological records, multi-source snow data, and soil temperature-moisture observations at the Saihanwula Forest Ecological Station (southern Greater Khingan Mountains, 43°59′–44°27′N, 118°18′–118°55′E, 1300–1400 m a.s.l.), we quantify how snow-cover metrics modulate soil freeze–thaw (FT) dynamics and subsequent spring drought risk.

1. A clear inverted-U response links snow-cover duration (SCD) to the FT period. Medium-snow winters (85–100 mm SWE, 135–150 snow days) prolong FT to 201.0 ± 19.5d, whereas low-snow (<85 mm SWE) and high-snow (>100 mm SWE) winters shorten it to 193.5±7.5d and 193.3±16.2d, respectively. Snow-water equivalent (SWE) is negatively correlated with daily FT rate ($r \approx -0.72$), but the relationship saturates under high-SWE conditions.

2. Process-level diagnostics reveal three distinct regimes:

(i) Low-snow: rapid freezing (1.87±0.68 cm $d^{-1}$) and rapid thawing (2.78±0.98 cm $d^{-1}$) with limited latent-heat buffering;

(ii) High-snow: delayed freeze onset (up to 37d) and earlier thaw completion due to a strong insulation effect at the soil–snow interface;

(iii) Medium-snow: optimal energy balance and hydro-thermal synchrony, maximizing pre-spring soil-water storage ($\theta_v \approx 0.20–0.25$ $m^3m^{-3}$ in 0–40 cm).

3. Coupled snow-frozen-ground degradation amplifies spring-drought propensity. Warmer winters shorten SCD and advance snow-off, truncating the FT window and triggering:

(a) Hydrological-timing mismatch: earlier snowmelt precedes soil thaw, reducing infiltration fraction from 0.62 to 0.38;

(b) Intensified process intensity: higher spring evapotranspiration demand paired with thinner, earlier thawing soil layers increases root-zone water deficit;

(c) Compressed eco-hydrological window: the period with simultaneously unfrozen soils and available snowmelt shrinks significantly.

Consequently, the probability of moderate-to-severe spring drought rose markedly over the study period. These findings demonstrate that non-linear snow-cover feedbacks govern frozen-ground hydrothermal behaviour and spring drought trajectories in cold semi-arid regions. We propose a SWE-based early-warning threshold (20±3 cm) for adaptive water-resource and forest-management strategies under continued warming.

## ABSTRACT

Thermokarst lake development induced by abrupt permafrost thaw disrupts soil carbon and nitrogen cycling, potentially creating a strong positive feedback to climate warming. However, TL impacts on active-layer soil organic carbon (SOC), total nitrogen (TN), and the C:N ratio—particularly across different successional stages—remain inadequately quantified. Furthermore, the unknown roles of local factors and climatic backgrounds severely limit fine-grained predictions of TL-affected carbon and nitrogen responses to future climate change. Here, we investigated eleven TLs on the Tibetan Plateau, including expanding, stable, drying, and drained types characterized by distinct thermokarst microfeatures. We found that, unlike in high-latitude regions, TLs in this warmer, drier alpine setting predominantly caused SOC, TN, and C:N losses, and the most severe declines occurred at the drying and drained stages, suggesting that degenerating TLs are potential hotspots for greenhouse gas emissions. Multi-scale analysis revealed that at the landscape-scale, microfeatures, sand, soil water (SW), pH, and aboveground biomass explained over 50% of the variance in SOC, TN, and C:N at most sites; importantly, the microfeature independently contributed the most, and the effect of local SW shifted from positive at drier sites, likely by mitigating water stress, to negative at wetter sites, likely by exacerbating erosion. Regionally, background factors (climate, grazing, and soil/vegetation properties of controls) explained over twice the variance in carbon and nitrogen metrics compared to within-landscape factors, with the background SW exhibiting the strongest effect. Projections incorporating climate-driven cascading effects through SW and pH showed that while future trajectories varied by TL stage, historical TL-induced C and N losses (relative to controls) were likely irreversible under SSP climate scenarios. Our study provides a mechanistic framework for parameterizing fine-scale thermokarst processes—accounting for microfeatures and key hydro-climatic drivers—currently underrepresented in Earth System Models, thereby constraining a key uncertainty in projecting the permafrost carbon-climate feedback.

**ABSTRACT**

Soil hydrologic processes support ecosystems, regulate the impact of climate change on terrestrial systems and govern feedback mechanisms between water, energy and biogeochemical cycles (e.g., carbon). Soil water-carbon dynamics are two processes that interact to control soil's ecological functions. Although soil water and carbon are tightly coupled in the Earth's Critical Zone (CZ), their coevolution across eco-climatic gradients remains underexplored. The growing availability of harmonized, long-term observations from the National Ecological Observatory Network (NEON) in the United States offers a unique opportunity to examine how hydrologic regimes shape soil carbon storage and turnover, and how carbon dynamics in turn modify soil physical and hydraulic properties. In this study, we leverage NEON soil moisture, temperature, soil organic carbon, and ecosystem flux measurements across contrasting terrestrial ecosystems to investigate the joint dynamics of soil water and carbon across spatiotemporal scales and evaluate how hydroclimatic and site-specific factors (e.g., soil, vegetation, topography) modulate carbon responses to moisture. By framing soil water and carbon as coevolving components of the CZ, this work advances a process-based understanding needed to improve predictions of carbon–water feedbacks under a changing climate and to inform soil and land management strategies aimed at enhancing ecosystem resilience.

## ABSTRACT

Accurate quantification of the water balance is essential for optimizing irrigation and minimizing nutrient loss in paddy fields. However, the effect of cultivation history on the water balance dynamics remains poorly understood. This study examined three paddy fields with different cultivation ages: a very young paddy field (VYPF, 10 years), a young paddy field (YPF, 27 years), and an old paddy field (OPF, > 100 years). In-situ field monitoring (including soil water content (SWC), plant growth indices, and meteorological data) combined with HYDRUS-1D simulations from October 2017 to October 2019 was used to quantify the water balance and identify water-saving potential. The model effectively reproduced observed SWC and water balance components. Compared with YPF and VYPF, OPF exhibited higher SWC at 10 cm and 60–90 cm depths but lower SWC at 20–60 cm. Substantial differences were observed among the three fields in percolation, groundwater capillary rise, and surface runoff, particularly during the rice-growing period. In VYPF, percolation and groundwater capillary rise accounted for 53% and 24% of total water input (rainfall + irrigation), respectively—values that exceeded those of YPF (39% and 18%) and OPF (14% and 9%). Conversely, runoff in OPF (25%) was markedly higher than in YPF (7%) and VYPF (6%). These differences reflect the effects of cultivation history on soil physical and hydraulic properties. Prolonged paddy cultivation increased bulk density in the plow pan and reduced saturated hydraulic conductivity, thereby impeding vertical water flow and enhancing surface water retention. Overall, the results highlight that the assessments of water balance and the design of water-saving irrigation strategies in paddy systems must explicitly account for cultivation duration.

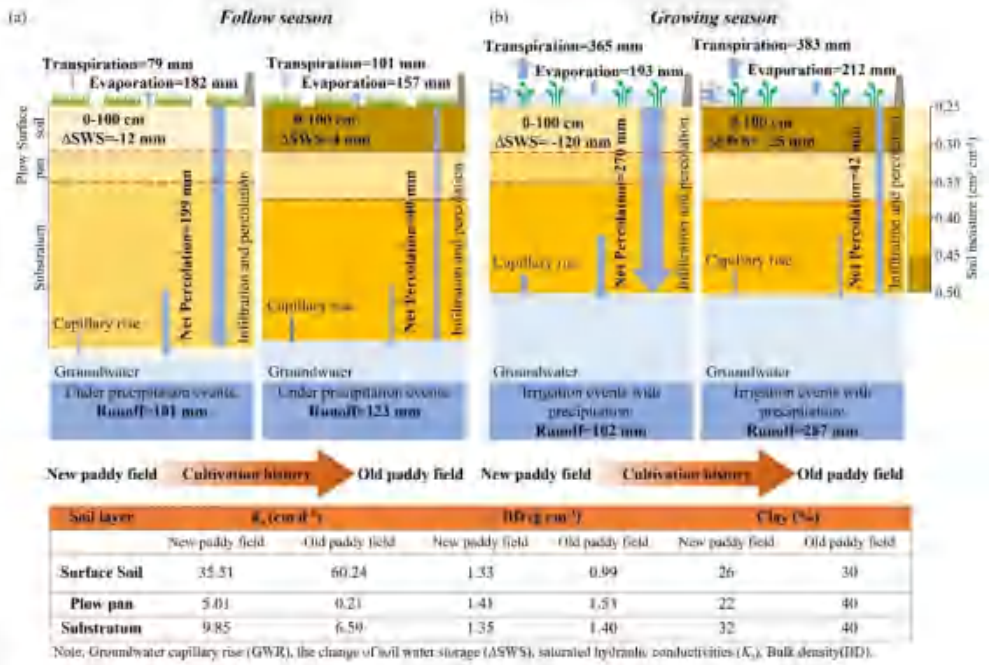

**Figure 1** Conceptual model illustrating changes in water balance components and soil properties with increasing cultivation history. Note: values of water balance components represent averages from 2018 and 2019. Panels (a) and (b) correspond to the fallow and growing seasons, respectively. Yellow rectangles denote soil water content. The change in soil water storage indicates the difference between initial and final water volumes within the soil profile during the respective fallow or growing periods.

* T.Zhao-30@sms.ed.ac.uk

## ABSTRACT

Hydrophobic granular soils, which may develop under natural conditions or through artificial processes, resist or redirect the infiltration of water into the soil matrix. Due to reduced surface wettability, soil water repellency leads to unstable wetting behaviour and the formation of preferential flow paths. While water retention curves (WRC) are important for predicting the hydraulic behaviour and the associated mechanical response, it is difficult to accurately determine them for hydrophobic granular soils. One approach to predict the WRC is therefore to model the particles, pore space, and fluid interaction analytically. Most studies assume smooth spherical particles for the soil particle-water interactions and capillary force calculation. However, the water retention behaviour of hydrophobic granular soils is closely related (via capillary phenomena by Young-Laplace equation) to the symmetry or asymmetry of the pinned water bridges, which is, in turn, governed by the particle surface geometry and orientation. This research therefore aims to develop geometry-aware model framework for determining WRC in hydrophobic granular soils. Different particle shapes (sphere, cube, triangular prism) are investigated to represent realistic soil geometries which alter the morphology of the water bridge. Surface Evolver Software is used to simulate the water bridge morphology for various particle shapes, orientations and sizes. Capillary forces associated with water bridges formed between spherical/cubic glass beads were experimentally measured using a tensiometer (DCAT-25). The force-distance curves and videos of the water bridge's evolution during the measurement process were subsequently obtained. Image analysis was then carried out in Fiji to extract the water-bridge profiles, from which the Laplace pressure was determined. The experimental results show consistency with results previously reported in the literature. The simulation results of the water bridge pressure dynamics show agreement with the corresponding values derived from the experimental data.

**ABSTRACT**

While large-scale vegetation restoration on the Loess Plateau has yielded significant ecological benefits, it has concurrently exacerbated regional water consumption, making the constraints on ecosystem sustainability a critical scientific issue. This study aims to systematically reveal the dynamic coupling mechanisms between vegetation cover (NDVI) and soil moisture (SM) and to construct an NDVI-based ecological threshold system to provide a quantitative basis for optimizing regional vegetation restoration. Based on eco-geographical zoning using a Self-Organizing Feature Map (SOFM) neural network, we analyzed the spatiotemporal evolution and interactions of NDVI and SM by integrating trend analysis, nonlinear Granger causality tests, and the constraint line method. The results indicated that while 96.7% of the region exhibited a significant increasing trend in NDVI, 61.1% showed a decreasing trend in SM, highlighting intensified water resource constraints. Furthermore, a bidirectional nonlinear coupling relationship between NDVI and SM was observed in 97.9% of the area. Notably, this study is the first to reveal a four-stage nonlinear coupling pattern defined by three key ecological thresholds ($\theta_1$,$\theta_2$,$\theta_3$), which sequentially characterize the ecosystem's transition through states of water accumulation, water competition, optimal balance, and ecological overload. The spatial differentiation of the ecological overload threshold ($\theta_3$) quantitatively characterized the constraints on vegetation growth across different zones (e.g., 0.526 in the driest zone R1; 0.669 in the wettest zone R4). An assessment based on this threshold system revealed that 94.9% of the arid zone (R1) is currently in the water competition phase, whereas parts of the high-altitude zones (R5, R6) face high risks of ecological overload. Accordingly, we propose zonal regulation strategies targeting overloaded zones (thinning), balanced zones (enclosure), and potential zones (afforestation), offering refined management bases and methodological guidance for ecological restoration in the Loess Plateau and similar arid to semi-arid regions globally.

**ABSTRACT**

In arid and semi-arid regions, soil moisture is a key factor limiting vegetation growth. Micro-topography significantly influences habitat heterogeneity by regulating water and heat redistribution. However, the mechanisms by which different restored vegetation restoration patterns (tree plantations, shrublands, and grasslands) adapt to this process via differentiated ecohydrological pathways remain unclear. This study conducted community surveys and soil moisture measurements (0-100 cm) on tree plantations, shrublands, and grasslands across different micro-topographies (slope aspect and position) on the Loess Plateau. The Difference Ratio of Soil Moisture (DRSM) and Structural Equation Modeling (SEM) were employed to quantify ecohydrological interactions. Results indicated that: (1) Slope aspect dominated soil moisture distribution ($\beta > 0.85$), forming "water resource patches" on shady slopes and lower slope positions; (2) Grassland diversity was positively driven by soil moisture ($\beta = 1.22$), whereas coverage was insensitive. Shrub canopy expansion showed high dependence on moisture ($\beta = 1.88$) but was subject to direct topographic inhibition. Tree growth exhibited a significant negative correlation with soil moisture ($\beta = -0.38$), with analysis revealing significant moisture depletion in the 60-100 cm soil layer; (3) Overgrowth of woody plants exerted a significant inhibitory effect on understory herbaceous diversity through resource competition ($\beta = -0.50$). This study reveals distinct adaptation mechanisms: grassland direct dependence, shrub trade-off adaptation, and tree competitive consumption. Future ecological restoration practices should shift from single coverage indicators to refined configuration strategies based on "micro-topography–water carrying capacity" to maintain the long-term stability of regional ecosystems.

# Process-Oriented Watershed Delineation in Human-Modified Plain Farmlands: Key Constraints and Recent Advances

**Jiahao Liu[1], EnhengWang[1*]**

[1] *Collage of Forestry, Northeast Forestry University, Harbin, 150040, China*

*E-mail Address of Presenting Author:erxin222@163.com

**ABSTRACT**

Due to gentle topography, ambiguous watershed divides, and intensive human disturbances, traditional terrain-driven watershed delineation methods often fail to capture the actual organization of hydrological processes in plain regions. Farmland-dominated landscapes, representing a transitional system between natural and highly engineered urban environments, have profoundly reshaped runoff generation, connectivity, and flow pathways through irrigation, tillage, and artificial drainage networks. As a result, hydrological responses may initiate locally before being expressed at the catchment outlet, challenging the conventional use of static watershed units.Following the logic of "problems–progress–direction", this study systematically reviews the core challenges and recent advances in watershed delineation for plain farmland regions. We identify three fundamental constraints: (i) limited adaptability of terrain-based algorithms under weak relief and strong human modification, (ii) insufficient quantification of coupled natural–human controls on hydrological connectivity, and (iii) mismatches between data resolution, process scale, and scientific objectives. Correspondingly, we synthesize three major research pathways, including algorithmic innovations, dual natural–human coupling frameworks, and scale-adaptive data strategies.We argue that watershed delineation in human-modified plain farmlands should be reframed as a process-oriented and demand-driven endeavor, shifting from static topographic units toward event-driven, functionally relevant hydrological units that better reflect where and how hydrological and soil-related risks are initiated.

# Redistribution of hydrological and dissolved nutrient by self-organized shrubs: strategies to collect rain and nutrient for surviving in drylands

*gygao@rcees.ac.cn

**ABSTRACT**

Rainfall redistribution by vegetation and associated dissolved nutrient fluxes are critical for water and nutrient cycling in plant-soil system. Shrubs are the dominant vegetation type and show contrasting morphological characteristics in drylands, self-organized being clumped with aggregated canopy or scattered with isolated canopy. However, little is known about the effects of shrub self-organization on rainfall redistribution and dissolved carbon and nitrogen fluxes (DC, DN), which further affects soil moisture recharge and soil nutrient accumulation to resist drought. In this study, we compared water fluxes (including throughfall, stemflow, infiltration, surface runoff, and top-soil moisture) and their DC and DN fluxes between the clumped and scattered shrubs of *Salix psammophila* on the Loess Plateau in China from 2019-2021. The scattered shrubs had a significantly higher throughfall percentage (77.6% vs. 72.5%), but a lower stemflow percentage (5.4% vs. 7.9%) and surface runoff percentage (0.10% vs. 0.37%) compared to clumped shrubs. Moreover, clumped shrubs demonstrated significantly higher DC flux in stemflow, yet lower fluxes in runoff compared to scattered shrubs ($p < 0.05$), while no significant difference of fluxes in throughfall and infiltration was observed. The clumped shrubs had significantly higher plant-derived DC and DN fluxes than those in scattered pattern ($p < 0.05$), whereas there was no significant difference of soil-buffered fluxes between the two patterns. Thus, scattered shrubs collected more net rainfall resulting in higher surface soil moisture, whereas clumped shrubs received greater amount of nutrient inputs leading to increase of soil nutrient content in surface layer. This study reveals the contrasting patterns of self-organized shrubs to harvest rainfall and dissolved nutrient, which provides a new understanding on the survival strategies of xerophytic shrubs from morphological adaptations in drylands.

# Pore Architecture, Water Dynamics, and Climate Sensitivity of Mountain Volcanic Soils: Integrating SEM–DIA and NMR Relaxometry for Hydropedological Assessment

**Alessio Manzo[1], Erika Di Iorio[1*], Paola Bambina[2], Pellegrino Conte[2], Claudio Colombo[1]**

[1] *University of Molise, Department of Agricultural, Environmental and Food Science, Campobasso (CB), Italy*

[2] *University of Palermo, Department of Agricultural, Food and Forestry Sciences, Palermo (PA), Italy*

*erika.diiorio@unimol.it

## ABSTRACT

Mountain soils are inherently fragile systems and exhibit heightened susceptibility to shifts in temperature and precipitation associated with ongoing climate change. Among the factors controlling their hydrological behavior, porosity, permeability, and the physicochemical interactions between soil matrices and water are fundamental, as they regulate water storage, transport, and connectivity. In particular, volcanic Andosols show exceptionally strong relationships with soil water retention due to their abundance of short-range–order minerals (e.g., allophane and imogolite), high specific surface area, and complex microaggregate structures, which collectively confer outstanding water-holding capacity and make these soils critical natural reservoirs in mountain environments.

In this study, twelve volcanic soils, Andosols, from a high-altitude grazing area in the central–southern mountain chain of Italy, were analyzed to investigate how variations in thermo-pluviometric regimes influence the physicochemical processes governing water movement, pore-type distribution, and pore-network architecture. Porosity was quantified using Digital Image Analysis (DIA) applied to thin sections of soil micro-aggregates acquired through scanning electron microscopy (SEM). Two-dimensional reconstructions generated from secondary electron and backscattered electron images enabled detailed estimation of pore-size distributions using ImageJ software. Hydrological connectivity, water-molecule mobility, and the interaction of water with soil surfaces were further assessed through Fast Field Cycling (FFC) Nuclear Magnetic Resonance (NMR) relaxometry, providing complementary insights into pore accessibility and fluid–solid interfacial phenomena.

Image analysis identified pore diameters spanning from 2 to >200 μm and revealed three principal pore-shape classes: rounded, elongated, and intermediate. Preliminary results showed a marked predominance (90–95%) of small elongated pores (2–15 μm), indicative of high microporosity and asymmetrical pore geometry. Larger rounded and intermediate pores were found mainly in the 50–200 μm range. NMR relaxometry independently detected three distinct water-mobility domains that aligned closely with the major porosity classes identified by DIA, corroborating the structural–functional relationships within the pore system.

The combined application of SEM–EDS imagery, DIA, and NMR-based hydrological metrics demonstrates strong potential for high-resolution soil pore characterization and for integrating structural and functional soil information. Crucially, this analytical framework enhances the capacity of current research efforts to anticipate climate-driven impacts on soil processes and water availability, particularly in mountain environments—key regions for freshwater supply—thus contributing to a better understanding of how future climatic shifts may alter hydrological security and soil–water interactions.

# Infiltration-Runoff Processes in Soil-Epikarst Systems on Karst Hillslope in Southwest China

*E-mail: hbchs@isa.ac.cn

## ABSTRACT

Karst landscapes developed on carbonate rocks are characterized by inherent properties such as slow soil formation rates, shallow soil layers, and exceptionally high permeability, which collectively drive rapid hydrological responses. This fast water-rock interaction mechanism enhances regional groundwater recharge potential while simultaneously exacerbating the risks of flooding and drought. However, due to the high spatial heterogeneity and procedural complexity of karst systems, significant gaps remain in understanding the pathways, fluxes, and regulatory mechanisms of hydrological processes.

To address these knowledge gaps, we employed an integrated observational approach using three-dimensional hillslope monitoring plots, combining high-resolution hydro-meteorological measurements with water-isotope tracing methods. This methodology enabled systematic quantification of hydrological processes from soil layers through the epikarst zone.

Our series of studies reveal that due to the high soil permeability in karst slopes, surface runoff generation is limited (runoff coefficient <5%), with hydrological processes being predominantly subsurface-dominated. Rainfall infiltration in the soil is characterized by exceptionally rapid wetting front movement (1373 mm/h), significantly faster than in non-karst regions (17-610 mm/h). While macropore flow serves as the primary preferential flow pathway, the prevalence of soil-rock interface flow represents a distinctive phenomenon in karst systems. Surface runoff is only triggered when rainfall intensity exceeds the soil infiltration capacity and rainfall volume surpasses soil storage capacity; though during extreme rainfall events, infiltration-excess runoff may dominate—constituting a critical component of flood peak formation. Soil thickness is a key structural factor influencing infiltration-runoff processes, regulating infiltration rates, pathways, and response times. As soil thickness increases, the impact of topography on hydrological processes gradually diminishes. Following vegetation restoration, runoff reduction is attributed to enhanced canopy interception and improved root-zone water storage capacity, thereby strengthening soil and water conservation functions. Accordingly, this research advances the theoretical framework of karst hydrology and offers crucial insights for water resource management, disaster risk reduction, and ecological restoration evaluation in karst regions under changing climate conditions. Future work should integrate multi-scale modeling approaches to extend hillslope insights to catchment-scale water security strategies.

## ABSTRACT

Accurate characterization of aquifer hydraulic heterogeneity is essential for understanding water flow, solute transport, and contaminant migration in subsurface systems, yet remains challenging due to limited observation density, tracer detectability, and environmental constraints. Conventional chemical tracers, such as fluorescent dyes and ionic solutes, are often restricted by toxicity concerns, regulatory limits, or insufficient sensitivity, which compromises inversion stability and spatial resolution.

In this study, we present an eco-friendly dual-tracer tomography framework that integrates synthetic DNA fragments and heat to achieve high-resolution characterization of hydraulic conductivity in heterogeneous aquifer media. The approach exploits complementary transport physics: heat provides diffusive, large-scale structural information, while DNA tracers act as advection-dominated, path-stable tracers that preserve sharp travel-time signals. A physics-informed inversion strategy based on travel-time tomography and cross-initialization was developed to fuse both tracer datasets without imposing arbitrary smoothing constraints.

The method was validated in a controlled two-dimensional heterogeneous sandbox aquifer composed of layered sands with strong hydraulic contrasts. Independent thermal, DNA, and dye tracer tomography experiments were conducted, followed by dual-tracer fusion inversions. Model performance was evaluated using twelve independent steady-state pumping tests. Results show that DNA-dominant inversions constrained by thermal priors achieved the highest predictive accuracy ($R^2$ = 0.80, RMSE = 0.95 cm, MAE = 0.67 cm), significantly outperforming single-tracer inversions and dye-based fusion approaches. Thermal-dominant inversions constrained by DNA priors also expanded reliable imaging zones and improved prediction accuracy relative to thermal-only cases.

The proposed framework resolves the trade-off between imaging resolution and environmental sustainability by replacing toxic dyes with biodegradable DNA and residue-free thermal tracers. This strategy enables scalable, high-fidelity subsurface imaging using sparse observation networks, offering a promising tool for soil and groundwater studies in environmentally sensitive settings.

## ABSTRACT

To increase the efficiency of water use in agriculture, wastewater reuse for irrigation is common and becomes increasingly imperative, particularly in semiarid areas. Irrigation often starts with untreated wastewater. Yet, water treatment prior to its use in agriculture is needed to reduce environmental and health risks. However, while replacing untreated wastewater with treated water will reduce the loads of nutrients, carbon and many pollutants that reach irrigated fields, it can increase the fraction of multiresistant bacteria released into the environment and mobilize legacy pollutants accumulated in soils. Therefore, we hypothesized that unforeseen risks arise from the implementation of conventional wastewater treatment in long-established wastewater irrigation systems, due to *i)* the mobilization of pollutants that have been accumulated in soils leading to concentrations, leading to *ii)* an increased selection and spreading of multiresistant bacteria and resistance genes, and *iii)* reduced crop yields and increasing concentrations of pollutants, multiresistant bacteria, and resistance genes in plants as a consequence of concentration effects in the reduced plant biomass. To test these hypotheses, we set up a multi-scale interdisciplinary study at the Mezquital Valley, México. We analyzed the resistant bacteria as well as resistance genes, antibiotics, disinfectants, heavy metals in experimental set-ups considering water quality, dominant soils, and two crops (alfalfa and/or coriander). At the laboratory scale we set-up an incubation experiment, at the greenhouse scale a soil column experiment, and in the field we sampled water, soil and crops irrigated with either treated or untreated wastewater. Additionally, we set up a lysimeter experiment with six 1m deep soil monoliths excavated from long term irrigated fields with untreated wastewater. Since 2019, we have been monitoring the water, nutrient and pollutant balances in response to irrigation water quality change, as well as greenhouse gas emissions and pollutant leachates like nitrates, heavy metals and antibiotics. We will synthesize the main results obtained at each scale and discuss the advantages and limitations of our approach.

# Development of Environmental Benchmark of Cr(VI) in Soils for the Protection of Groundwater Quality

**Qi Zhao[1], Jing Song[1,2*], Tiandong Wang[1], Hui Gao[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

[2] *University of Chinese Academy of Sciences, Nanjing, China*

*E-mail Address of Presenting Author: jingsong@issas.ac.cn

**ABSTRACT**

The heavy metal pollutant Cr (VI) has high toxicity and strong mobility, posing a great threat to groundwater safety. The current relevant soil standards often overlook groundwater safety. It is urgent to establish a Cr(VI) soil environmental References value based on groundwater safety in order to provide support for the supervision of contaminated sites. To establish soil environmental benchmark values for Cr(VI) based on the protection of groundwater and tailored to the specific conditions of China, this study addresses the current practice of directly applying a single foreign-derived parameter (e.g., Kd = 19 L/kg). By tracing the complete contaminant migration pathway—"soil-water partitioning, vadose zone attenuation, and groundwater dilution"—a methodological framework was established. This framework integrates soil adsorption, solute transport in the vadose zone (modeled with HYDRUS-1D), and groundwater dilution processes. Systematic adsorption experiments and soil column leaching tests were performed on 12 typical zonal soils across China to determine Cr(VI) solid-liquid distribution coefficients (Kd) and key vadose zone migration parameters. Corresponding regional hydrogeological data were also compiled through comprehensive research. The results show that Kd values for the twelve soils varied widely from 0.25 to 67.75 L/kg. A significant positive correlation ($r = 0.97$) was found between soil Cr(VI) adsorption capacity and free iron oxide content, with clear regional differences observed. The HYDRUS-1D model effectively simulated Cr(VI) migration through different soil types, achieving high goodness-of-fit ($r^2 > 0.98$). Using the Class III groundwater quality standard limit (0.05 mg/L) from GB/T 14848-2017, soil benchmark values for groundwater protection were derived under different conservatism scenarios. Excluding extreme cases in regions like Yunnan and Hainan—where exceptionally high free iron oxide content and thick vadose zones led to anomalously high benchmark values—the derived values generally fell within a reasonable range of 0.39 to 19.61 mg/kg. These results align well with international Cr(VI) benchmarks for groundwater protection. By comparing, we found that if the adsorption attenuation of the air bag tape is ignored, the baseline value will be underestimated by several orders of magnitude, with the maximum difference factor being 466. This would result in the benchmark value being overly conservative. Quantitatively, this confirms that ignoring vadose zone attenuation could lead to substantial and unnecessary remediation costs. This study proposes a benchmark derivation framework supported by localized parameters and emphasizes the vital role of vadose zone attenuation in pollutant migration for benchmark calculations. The framework provides a more scientifically sound basis for managing soil environmental risks to protect groundwater in China. It also offers a methodological foundation for developing regionally differentiated benchmarks in the future.

# Quantitative Characterization and Prediction Model for the Evolution of Soil Cracks in the Daqing Region

**Xin Zheng**[1*]

[1] *College of Engineering, Heilongjiang Bayi Agricultural University, Daqing, Heilongjiang 163319, China*

*zhxin@ byau.edlu.cn

**ABSTRACT**

This study systematically analyzes the mechanisms by which evaporation rate and the thickness of black soil influence the generation and expansion of soil cracks, with a focus on the physical characteristics of typical soils in the Daqing region. By conducting controlled experiments under varying evaporation rates, soil thicknesses, and initial moisture contents, the study investigates the mass change characteristics during the soil evaporation process. A mathematical model based on mathematical derivation was developed to predict the temporal evolution of soil cracks, enabling a quantitative characterization of the cracking process. The model accurately identifies the critical moments of crack initiation and the key time points when crack expansion stabilizes.

The results indicate that both the evaporation rate and soil thickness significantly affect the crack formation time and expansion rate. A higher evaporation rate accelerates soil moisture loss, leading to earlier crack formation and a marked increase in the rate of expansion. Conversely, a greater soil thickness has a delaying effect on crack initiation and plays an important regulatory role in the crack evolution process and its final morphology. Moreover, a significant interaction exists between the evaporation rate and soil thickness, which jointly determines the timing and development characteristics of soil cracks.

These findings provide scientific support for regional soil moisture management, agricultural irrigation optimization, and drought-related disaster early warning systems. Additionally, the study offers an effective technical pathway and theoretical tools for improving agricultural sustainability and addressing soil structure degradation in the context of climate change.

This translation is aligned with the formal language and style typical of scientific publications, suitable for submission to high-impact journals.

**ABSTRACT**

The Songhua River Basin in Northeast China is a major agricultural region with extensive streamflow records but very limited sediment monitoring, which hinders effective water resource management and soil conservation. This study presents a hybrid modeling approach that integrates the process-based Soil and Water Assessment Tool (SWAT) with a Long Short-Term Memory (LSTM) deep learning network to simulate daily sediment load in data-scarce catchments. The LSTM was trained in one gauged sub-basin to correct biases in the SWAT sediment simulations, and the trained model was transferred to 17 neighboring sub-basins lacking sediment observations. The hybrid SWAT-LSTM model dramatically improved performance at the training site, raising the Kling-Gupta Efficiency (KGE) from 0.20 to 0.79 compared to SWAT alone. When applied to ungauged basins without local sediment data, the framework produced reliable predictions at most sites (12 out of 17 had KGE > 0.4). Model performance was strongly dependent on the accuracy of the underlying streamflow simulation and was non-linearly influenced by catchment area. These findings demonstrate a viable solution for estimating sediment yields in ungauged basins and provide insight into the factors affecting hybrid model transferability in regional sediment load prediction.

## ABSTRACT

In Mollisols, pronounced polarization mechanisms inducing strong relaxation and dispersion lead to systematic distortion of time-domain reflectometry (TDR) waveforms and limit the applicability of conventional TDR analysis methods based on travel-time picking methods and waveform inversion. A physics-guided representation embedding framework with transfer learning was proposed. The framework encodes simulated TDR waveforms using multi-scale response templates to learn low-dimensional embeddings that are robust to characterize and partially decouple electromagnetic responses. Soil water content and bulk density are jointly estimated in the embedding space using support vector regression. Transfer from the simulation parameter domain to the field domain is achieved with only a limited number of measured samples, enabling robust estimation of soil properties in Mollisols from TDR waveforms. The framework was initially trained on about two thousand simulated waveforms and validated through simulation-to-field transfer using 35 measured waveforms. Under the setting, coefficients of determination ($R^2$) for soil water content and bulk density reach 0.91 and 0.70, respectively, with corresponding root mean square errors (RMSE) of 0.01 $m^3$ $m^{-3}$ and 0.07 g $cm^{-3}$. The results demonstrate that the proposed framework provides a robust strategy for retrieving soil physical properties from TDR measurements under limited field calibration.

# Probabilistic and Entropy Models of Soil Properties for Contemporary Processes Assessment

**Irina Mikheeva**

*Institute of Soil Science and Agrochemistry of Siberian Branch of Russian Academy of Sciences,*

*Novosibirsk, Russian Federation*

mikheeva.issa-siberia@mail.ru

**ABSTRACT**

Heterogeneity, variability, and fluctuations in soil properties at all levels of soil organization are major features of soils, as the latter are open dynamic complex systems that evolve over time. This means that the quantitative expression of properties in the soil profile can change gradually, while both the central characteristics and the variability itself change. Our studies have shown that the patterns of variability of even stable soil properties, for example granulometric composition, which are used in models parameters, can change over time. This must be taken into account in mathematical modeling of dynamic soil processes, especially if model calculations are made for large areas and for a long time. Assessment of changes of soil properties at the scale of agricultural fields is important because it allows drawing conclusions about the contemporary processes happening in soils caused by anthropogenic influence and climate changes. We consider them as the contemporary evolution of soil (CES), namely process of changes of soil conditions with time intervals from ten to hundred years. When carrying out spatial soil monitoring, points of approbation in space don't coincide at different time, so it is necessary to use probabilistic models for assessment of states and changes of soils. Therefore we have offered to use probabilistic and information indicators for assessment of condition of soils and their changes. The characteristic of variability of a system property is its probability distribution function within the studied object. Therefore the model of a condition of the soil represents the set of pdf of n soil properties in its k horizons. We have determined the best mathematical functions of pdf of soil properties by applying special statistical procedure to datasets of legacy data. For scalar characterization of the variability of the soil condition the values of the information (statistical) entropy of the soil properties were used. For assessment of changes of soils were used the values of information divergence of soil properties and an increment of their entropy. The entered characteristics allow general scalar estimating extent of influence for the soil forming factors and anthropogenic impacts on probabilistic structure of values of soil properties and its stability. The case studies have been conducted in the big territory at the south of Western Siberia. It has been shown that CES occurs under the anthropogenic influences (long-term plowing, strip agriculture, irrigation) and natural processes caused by climatic trend of warming and by cycles on moistening. It is revealed the changes of probabilistic structure of values of properties of the soil in their horizons. In fact, the received models and estimates are probability and entropy standards of condition of soils which should be used for comparison with the past, current and future native or modelled results in the explored and neighboring territories.

# Advancing Daisy's denitrification function to improve predictions of nitrous oxide emissions from agricultural soils

**Tobias Klöffel*[1], Simon F. Svane[1], Celine R. Grønning[1], Silas N. Ørting[2], Sune Darkner[2] and Lars S. Jensen[1]**

[1] *Department of Plant and Environment, University of Copenhagen, Frederiksberg C, Denmark*

[2] *Department of Computer Science, University of Copenhagen, København Ø, Denmark*

*tk@plen.ku.dk

**ABSTRACT**

Countries are increasingly striving for a Tier 3 approach when reporting greenhouse gas emissions (GHG) caused by their agricultural sector. This approach requires the use of sophisticated models that produce reliable estimates of these emissions. In this context, nitrous oxide ($N_2O$) – a major GHG emitted from agricultural soils – poses a particular challenge as its production in soil is erratic and results from the complex interplay between physical, chemical and biological soil processes.

*Daisy* is a process-based agroecological model, which was developed for simulating water, carbon and, in particular, nitrogen fluxes at the field scale. Yet, *Daisy* still maintains a relatively simple and poorly tested description of denitrification, which is one of the major pathways of $N_2O$ production in temperate agricultural soils. Here, the testing and advancement of *Daisy's* denitrification function is presented, with the aim of improving its ability to predict $N_2O$ emissions.

We capitalized on recently gathered datasets from across Denmark, which cover a range of soil types, crop rotations (including cover crops), and varying supplies of mineral and organic fertilizers. First, crop and soil hydraulic parameters were calibrated against an array of field and laboratory measurements, supported by soil profile descriptions. Subsequently, the fraction of nitrified ammonium emitted as $N_2O$ was estimated from the literature and refined during the calibration process of the denitrification function. Finally, the denitrification function was addressed using iterative cycles of calibration, output analysis and function adjustments. For this purpose, a new *Daisy* tool for numerical parameter optimization was used, allowing for sequential and covariance matrix adaptation evolution strategy (CMA-ES) optimization.

*Daisy's* original denitrification function performed well during intermediate-flux periods, while $N_2O$ emissions were overestimated during low-flux periods when soil mineral nitrogen contents were low. This issue was addressed by exploring the use of nitrate limitation functions of other denitrification models and by taking into account the findings of recent empirical studies. Furthermore, *Daisy* underestimated $N_2O$ emissions after slurry application, probably due to the creation of anaerobic hotspots and the increase in water retention induced by the slurry, which the model cannot account for. In this context, we suggest the possibility of different parameterizations for mineral and organic fertilizers and stress the importance of slurry parameterization. Other aspects discussed in this work are the need to consider the whole nitrogen budget during calibration, and how literature data can help constrain the parameter space during optimization. Lastly, *Daisy's* potential for $N_2O$ emission predictions is highlighted, not the least due to its physically based description of soil water dynamics and root water uptake.

**ABSTRACT**

This study evaluates the impact of agricultural land use choice (e.g. crops versus permanent grassland) on soil hydrological functioning, by analysing pore-size distributions (PSD) and hydraulic properties together with basic soil properties, across lowland soils in England and Wales. Informed by these analyses, hydrological modelling was employed, using two models (HYDRUS-1D and SWAP), to assess the effects of land use (change) on soil water balance fluxes and stores. This study analysed top- and subsoil physical data from UK NATMAP database for sixteen major soil series in England and Wales, varying in texture and drainage conditions, as well as corresponding basic soil properties (e.g. texture, soil organic carbon and pH). The results indicate that land use (change) significantly influences soil structure, PSD and hydraulic characteristics. Largely via increased biological activity and soil organic matter content, grassland promotes the development of increased total pore volume, with the largest increases in the macropore range, and enhances soil hydraulic functioning. Permanent grassland also has increased air capacity, plant-available water capacity, and saturated hydraulic conductivity, compared to cropped soils. Compared to bare arable land (AR) soils, bare permanent grassland (PG) soils generally contain more water due to their greater water retention capacity, but higher evaporation rates associated with these soils leads to reduced deep drainage. Similarly, relative to winter wheat on AR, grass on PG tend to maintain higher soil moisture levels; however, increased water losses via evapotranspiration and canopy interception under grass on PG result in reduced deep drainage.

**ABSTRACT**

A century ago, soil physicists had neither the amount of data nor the scientific computing methods available today. As a result, they had to make (over) simplifying assumptions about many intermediate soil processes that are complex and largely unobservable (e.g., assuming certain pore shapes, equilibrium conditions, or specific forms for soil hydraulic properties). While these simplifications enable tractable formulations, they are shaped by the modeler's view of the system that may bias the true representation of soil processes. At the same time, the increasing availability of high-quality data offers an opportunity to both improve the predictive power of existing models and gain new fundamental soil physics insights. Here, we propose differentiable hybrid modeling (DHM) that combines analytical formulations with flexible, data-driven components to learn uncertain parts directly from data. A key enabler is end-to-end differentiability via automatic differentiation, which allows the entire model, including physical and neural components, to be optimized jointly by minimizing a downstream loss function. We apply this approach to the challenge of partitioning the soil water retention curve (SWRC) into capillary and adsorbed water components. The hybrid model, trained on 483 undisturbed soils from Central Europe, produces smooth and physically consistent SWRC curves and automatically discovers the capillary and adsorptive branches of the curve. Notably, the model reveals a distinctly nonlinear transition between capillary and adsorbed domains, challenging the linear assumptions invoked in previous studies. The methodology introduced here provides a blueprint for learning other soil processes where high-quality datasets are available but mechanistic understanding is incomplete.

*owendroth@uky.edu

**ABSTRACT**

Soils in Western Kentucky that are used for intensive agricultural production are developed on Karst topography. Therefore, they exhibit substantial spatial variability and temporal dynamics of above- and belowground processes that affect crop growth. Managing water and nutrients in these soils and describing crop yield variability through modeling approaches are challenging tasks. The objective of this study is to analyze factors causing spatial crop yield variability and to describe crop yield variability with a deterministic, physically based model and a stochastic approach. In this study, the Root Zone Water Quality Model RZWQM2 which is a deterministic process-based model, and the stochastic state-space approach are used for modeling spatial variability of crop yields. Soil textural data input and parameterization of hydrological model input parameters are studied at different spatial resolutions in the RZWQM2. In the state-space model, relevant site information including remote sensing and topographic state variables is identified for predicting spatial variability of crop yields. The soil type at this 47-ha-field site of this study is a Crider silt loam with an elevation range between 132 and 155 m. Soil textural composition was quantified at a 50-m-grid in five layers from 0 to 100 cm soil depth. Measured soil textural information and the estimation of soil hydraulic properties using the Brooks-Corey equation is compared with the Soil Survey Geographic Database (SSURGO) from the Natural Resources Conservation Service (NRCS) in RZWQM2 simulations. UAV- and Satellite-based remotely sensed information of NDVI and topographic indices based on the Kentucky LiDAR map (Kentucky Government) are used in the state-space model for describing yield variation. Results are shown for a two-year crop rotation.

**ABSTRACT**

Soil organic matter (SOM) turnover plays a major role in the global carbon cycle, while also influencing soil health and fertility.

Accurate modeling of SOM dynamics requires a comprehensive understanding of the complex interplay between biogeochemical and physical processes occurring at small spatial scales.
The availability of carbon (C) and nitrogen (N) resources governs microbial growth, while microbial dynamics, in turn, shape the distribution of C and N within soils. (Dis-)Aggregation processes influence the persistence and degradation of organic carbon, as physical protection of organic matter within soil aggregates promotes carbon storage.

We present a mechanistic, spatially explicit pore-scale model that couples microbial dynamics with evolving soil structure. The model describes microbial growth and necromass formation driven by the enzymatic degradation of particulate organic matter (POM), microbial necromass, and root exudates, explicitly accounting for their C/N ratios, which influence respiration and N cycling [1]. A cellular automaton approach represents soil structure dynamics, including aggregation, occlusion, and the formation of organo-mineral associations that stabilize organic matter [2].

Our simulations based on images of soil aggregates and parameters derived from rhizosphere experiments explore how (i) soil structural heterogeneity and connectivity, (ii) N availability, and (iii) organic matter quality shape microbial activity, soil organic carbon (SOC) stabilization, and C use efficiency.
The simulations reveal and quantify how dynamic pore connectivity controls substrate accessibility and generates transient microscale hot and cold spots of microbial activity. Limited N availability constrains microbial growth, whereas the input of root exudates with favorable C/N ratios promotes biomass formation and increases CUE. The resulting C respiration is consistent with laboratory experiments. Microbial necromass emerges as a long-term SOC pool that becomes physically protected within the evolving soil structure.

By explicitly coupling microbial and structural dynamics, our framework provides valuable insights how pore-scale processes influence soil C and N cycling and long-term soil carbon storage under changing environmental conditions.

*ygzhang@tju.edu.cn

**ABSTRACT**

Accurate, high-resolution soil moisture data are critical for hydrological modeling, climate studies, and ecosystem management. Unfortunately, current existing global products suffer from inconsistencies, coverage gaps, and biases. In this study, we evaluated the surface layers of three widely used soil moisture products, including ERA5-Land, ESA-CCI (v09.1 Combined), and SMAP L4 with resolutions ranging from 0.1° to 0.25°, against in situ measurements from 1,615 stations across five networks, including ISMN, CMA, Cemaden, COSMOS-Europe, and SONTE-China. The in situ dataset, to our knowledge, represents the most extensive global soil moisture compilation to date. It is found that ERA5-Land exhibits high correlation between measured and predicted soil moisture but the data also shows significant bias. SMAP L4 provides the highest accuracy, exhibiting low bias and root mean square error (RMSE), but is limited by its temporal coverage from 2015 to the present. To address these gaps, we developed an adjusted ERA5-Land dataset by fusing ERA5-Land and SMAP L4 using a mean-variance rescaling method optimized for long time-series alignment, which enhanced the spatiotemporal coverage and reduced bias. Validation against in situ measurements demonstrates a reduction in RMSE of 24.6% and an improvement in normalized Nash-Sutcliffe Efficiency (NNSE) of 30.6% compared to the original ERA5-Land products. The adjusted ERA5-Land dataset, which is publicly available, can be used as benchmark for future research and support drought monitoring, weather prediction, and water resource management, contributing to global climate resilience across diverse ecosystems.

**ABSTRACT**

Porous media, such as rocks and soils, are essential for addressing scientific and engineering challenges in hydrology, materials science, and petroleum engineering. Fluid flow in these media originates at the pore scale, where complex geometries dictate macroscopic permeability, a property highly sensitive to factors like porosity, pore-throat sizes, tortuosity, and connectivity. Traditional models, such as the Kozeny-Carman equation, often fail to capture this heterogeneity, leading to inaccurate predictions. Advances in X-ray computed tomography and computational methods, including Lattice Boltzmann simulations and particle packing, enable detailed pore-scale analysis.

The research investigates pore-scale influences on permeability in porous media through computational simulations and imaging data analysis. We explore how material properties affect pore structures and fluid dynamics, advance methodologies for defining representative volumes considering microstructural aspects, and formulate predictive models using data-driven techniques to estimate permeability from fundamental parameters.

The derived model enhances accuracy for diverse heterogeneous systems, bridging simulated ideals with natural geological contexts and surpassing conventional empirical methods.

# Improving Digital Soil Hydraulic Characterization: A Workflow for Enforcing Periodic Boundary Conditions on Tomographic Soil 3D Images

**Marina V. Karsanina[1*], Vladimir A. Shibanov[1], Nikolay M. Evstigneev[2] and Kirill M. Gerke[1]**

*karsanina.mv@mipt.ru

**ABSTRACT**

Predictive modeling of water flow in soils relies on accurate knowledge of the saturated hydraulic conductivity tensor (K). While 3D X-ray microtomography and pore-scale modeling offer a direct way to estimate K from soil structure, a key technical challenge is the creation of a representative digital domain with consistent boundary conditions. Conventional simulations using closed-wall boundaries introduce artificial flow restrictions, contradicting the natural, extensive conditions of a soil sample [1].

This study presents a novel, algorithmic workflow for the generation of seamless periodic boundary conditions for 3D images of complex natural soils. The core innovation is a method that does not alter the original internal structure of the segmented 3D image. Instead, it grows an external layer of porous material whose statistical morphology and transport properties are indistinguishable from the original core. This is achieved by a sophisticated combination of stochastic reconstruction algorithms based on multipoint statistics and correlation functions [2], ensuring the new boundary zone is a faithful continuation of the sample's pore space geometry.

The algorithm specifically tackles challenges inherent to soil porous media, such as complex pore connectivity, presence of isolated voids, and the irregular geometry of solid aggregates. We rigorously tested the effectiveness of the generated PBCs using Stokes flow solver [3], comparing flow fields and resulting K-tensors against simulations with conventional closed boundaries.

The presentation will showcase the algorithm's application on tomographic images of contrasting anisotropic soil samples. The results demonstrate that our method enables physically correct pore-scale modeling with periodic boundaries, effectively representing an infinite medium, as opposed to the unrealistic confined system imposed by closed walls. This computational tool bridges the gap between high-resolution imaging and reliable hydrodynamic characterization, advancing the methodology of digital soil physics and contributing to more robust predictions of soil water dynamics.

**ABSTRACT**

While continuum scale is indispensable due to its low computational cost, the latter benefit is not without its high toll. Major physical properties and processes can be explained only on the pore-scale, as homogenization leads to severe information loss. In their turn, pore-scale models operate using parameters that can be effectively obtained based on molecular scale simulations (e.g., interfacial tension, transport properties of sub-micron pores [1], wetting properties [2]). In this contribution we shall discuss a truly multi-scale paradigm to describe soil processes involving transport properties and soil structure dynamics.

Soil structure defines its hydraulic properties, but, in turn, depends on boundary conditions such as water content. Thus, to correctly represent such properties on all necessary scales and, finally, properly parameterize the continuum scale model, one needs to explore at least the following Russian nesting doll:

1) Molecular scale provides fluid properties, fluid-solid interaction parameters and predict how moisture conditions affect swelling-shrinkage;
2) Microscale operates on classical hydrodynamics and can assess saturated and unsaturated flow properties.
3) Continuum scale is parameterized using properties obtained from microscale simulations or measurements, and heavily relies on representativity concept [3].

The presentation will provide numerous evidences in favor of our approach and showcases of applications on all aforementioned scales. The results suggest that without involving structural soil analysis [4] and modelling on all relevant scales one simply can not upscale to continuum without introducing numerous errors. Moreover, we shall provide a number of open-source solutions to address some of the issues raised in contribution.

**ABSTRACT**

The control of agricultural non-point source pollution is a crucial component of ecological and environmental protection. Inappropriate chemical fertilizer application and land management policies can lead to unabsorbed harmful substances such as nitrates in fertilizers seeping into groundwater through percolation, causing environmental damage. Therefore, it is essential to develop accurate mathematical models to simulate the nitrogen transport mechanisms in the plow layer. Based on a system of nonlinear partial differential equations, the aim of this work was to quantify the diffusion coefficients of black soils through indoor soil column experiments and numerical simulations. The control experiment consisted of three typical soil types in the black soil region, two soil moisture treatments, two fertilization rate treatments, a blank control group, and was conducted with three replications. The results indicate that the vertical migration of nitrate nitrogen primarily occurs in the early stage of percolation, moving deeply into the soil with water flow and posing a high risk of water pollution. In contrast, the vertical migration of ammonium nitrogen mainly takes place in the late stage of percolation, and it is gradually immobilized and consumed by the soil. The nonlinear equation system based on Newton's seepage equation can effectively simulate the nitrogen transport processes in black soil regions. Furthermore, parameter sets tailored to different textured black soils are provided, enabling precise simulation of agricultural nitrogen transport. This study offers an effective method for predicting agricultural non-point source pollution.

# Predicting the Impacts of Metal Nanoparticles on Soil Properties: A Machine-Learning–Based Study of Soil Health Dynamics

**Yaping Lyu[1]*, Peng Zhang[1]**

[1] *Department of Environmental Science and Engineering, University of Science and Technology of China, Anhui, 230026, China*

*E-mail Address of Presenting Author: lyp0213@ustc.edu.cn

**ABSTRACT**

Metal nanoparticles (MNPs) hold considerable promise for precision and sustainable agriculture. However, the interaction mechanisms between different MNPs and soil physicochemical properties, particularly their effects on integrated soil health metrics, remain poorly understood. In this study, we employed four interpretable machine learning algorithms, including XGBoost, Random Forest (RF), Gradient Boosting Decision Trees (GBDT), and Support Vector Machine (SVM), to systematically analyze the interactive influences of seven soil physicochemical properties, three MNP characteristics, and three external environmental factors on seven soil health indicators.

Taking a global perspective, we predicted the effects of MNPs on soil health indicators across 12 USDA soil taxonomy classes (Figure 1). Our results indicate that MNP impacts are highly dependent on soil properties and vary markedly among soil types. For example, Entisols, which exhibit low soil water holding capacity (SWHC) and low soil organic matter (SOM), showed pronounced sensitivity in pH to MNP exposure: the magnitude of pH change ranged from 2.6% to 11.5%, substantially larger than in other soil types (pH change range from −2% to 4%). In contrast, Mollisols and Inceptisols, which are important agricultural soils in regions such as Europe, the United States, Canada, and China, exhibited greater sensitivity of microbial biomass and biodiversity (Shannon index) to prolonged MNP exposure. Over a 365-day exposure period, microbial biomass in Mollisols and Inceptisols declined by 60% to 268%, whereas under short-term exposure (30 days) the decline was only 4% to 20%.

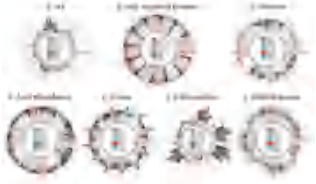

Figure 1. Changes in pH (a), soil microbial biomass (b), Shannon diversity index (c), acid phosphatase (d), urease (e), β-glucosidase (f), and dehydrogenase (g) across different soil types after 30, 180, and 365 days of exposure to metal nanoparticles (MNPs).

We further assessed potential risks of MNPs to soil health at the global scale and identified high-risk regions and soil types (Table 1). For instance, Entisols and Oxisols in tropical and subtropical regions, owing to their low SWHC and SOM, are particularly sensitive to pH alterations, which can substantially affect nutrient availability and ecosystem productivity. Aridisols occurring in arid regions such as the western United States, the Middle East, and Central Asia showed pronounced impacts on microbial diversity and enzyme activities, reflecting the vulnerability of their microbial communities. By contrast, Mollisols and Inceptisols characterized by relatively high SOM and soil clay content (SC) demonstrate greater stability in pH and microbial diversity; nevertheless, long-term MNP exposure may lead to declines in microbial biomass and enzyme activities, with consequent impairments to nutrient cycling and carbon sequestration capacity.

Table 1. Sensitivity analysis of seven soil health indicators to variations in MNP particle size (NPS), concentration (NPC), and exposure duration (ED) under MNP exposure, and the distribution of high-risk countries and soil types. Subscripted letters in parentheses denote regions where sensitivity value distributions differ from the global pattern. [a] NPC sensitivity > 800 mg·kg$^{-1}$ in Russia, Canada, the Indian subcontinent, and Southeast Asian islands; [b] NPS sensitivity = 50–70 nm in North Africa, South Africa, the Arabian Peninsula, and Australia; [c] Under $Fe_3O_4$-NPs, $CeO_2$-NPs, and ZnO-NPs exposure, NPC sensitivity > 600 mg·kg$^{-1}$ in Russia, Canada, Brazil, and South Africa; [d] Under $Fe_3O_4$-NPs and $TiO_2$-NPs exposure, NPS sensitivity > 40 nm in North Africa and South Africa; [e] Under $TiO_2$-NPs and ZnO-NPs exposure, NPC sensitivity > 500 mg·kg$^{-1}$ in Mollisols; [f] NPS sensitivity < 30 nm in Ultisols; [g] NPC sensitivity > 700 mg·kg$^{-1}$ in Entisols; [h] ED sensitivity in Entisols = 120–130 days; [i] NPS sensitivity > 20 nm in Gelisols and Oxisols.

Our observations reveal clear differences between the short-term and long-term effects of MNP exposure. Because the existing literature predominantly focuses on short-term impacts, current assessments may underestimate the true risks MNPs pose to soil health and ecosystem functioning. The findings underscore the necessity of incorporating specific soil physicochemical properties and long-term exposure scenarios in MNP risk assessments. Moreover, this study highlights practical implications for sustainable agriculture and land management. In high-risk areas, mitigation measures such as cover cropping, application of organic amendments, and conservation tillage can be implemented to increase SOM and SWHC and thereby alleviate adverse MNP effects. In fertile agricultural soils, monitoring systems for microbial biomass and enzyme activities should be established to inform adaptive management strategies, for example, crop rotation and reduced reliance on chemical inputs.

By producing global predictions across diverse soil types, this study evaluates potential risks of MNPs to soil health, identifies high-risk regions and countries, and provides data support for targeted follow-up analyses. These results offer a theoretical and data-driven basis for scientifically informed environmental management and sustainable agricultural practices.

**ABSTRACT**

With global warming, arable land in boreal regions is tending to expand into high latitude regions in the northern hemisphere. This entails certain risks; such that inappropriate management could result in previously stable carbon sinks becoming sources. Agroecological models are an important tool for assessing the sustainability of long-term management, yet applications of such models in boreal zones are scarce. We collated eddy-covariance, soil climate and biomass data to evaluate the simulation of GHG emissions from grassland in eastern Finland using the process-based model DNDC. We simulated gross primary production (GPP), net ecosystem exchange (NEE) and ecosystem respiration (Reco) with fair performance. Soil climate, soil temperature and soil moisture at 5 cm were excellent, and soil moisture at 20 cm was good. However, the model overestimated NEE and Reco following crop termination and tillage events. These results indicate that DNDC can satisfactorily simulate GHG fluxes in a boreal grassland setting, but further work is needed, particularly in simulated second biomass cuts, the (>20 cm) soil layers and model response to management transitions between crop types, cultivation, and land use change.

# Process-based modelling of river sediment composition incorporating pedogenetic processes at the catchment scale: the Sendaigawa River basin, Japan

**Atsunobu Kadono[1*], Ryosuke Kamiya[1], and Ifa Kin[1]**

[1] *Tottori University of Environmental Studies (Faculty of Environmental Studies, Tottori, Japan)*

*kadono@kankyo-u.ac.jp

**ABSTRACT**

In recent years, climate change has altered rainfall patterns and intensified precipitation events, leading to situations in which conventional statistical approaches for predicting soil erosion rates and assessing associated hazards are becoming increasingly inadequate. Accurately identifying locations that are prone to sediment-related disasters in advance through the development of more mechanism-based models has therefore become an urgent challenge.

The authors have conducted a series of studies aimed at assessing sediment-related disaster risk at the watershed scale by quantitatively characterizing both the quantity and quality of river sediments (RS) and suspended particulate matter (SPM). Previous studies demonstrated that the elemental composition of RS reflects upstream geology, weathering, and pedogenetic processes, whereas SPM reflects not only these soil-related factors but also contemporaneous meteorological and hydrological conditions, such as changes in river discharge. Furthermore, when RS was fractionated by particle size—gravel (R), coarse sand (CS), fine sand (FS), silt (S), and clay (C)—similarities in elemental composition, particularly in silica content, were detected within specific sub-catchments.

However, an integrated modelling framework that combines soil formation processes, meteorological conditions, and hydrologically driven material transport within the watershed has not yet been established. Therefore, the objective of this study is to develop a climate-driven soil component export model that quantitatively integrates these relationships.

Sampling was conducted at 11 sites within the Sendaigawa River basin, Tottori Prefecture, Japan, consistent with previous studies, on 13 October 2023, 5 August 2024, and 12 November 2024. SPM was collected by filtering 1 L of river water through a 0.45 μm membrane filter. RS samples were fractionated by particle size using sieving and pipette methods into gravel (R), coarse sand (CS), fine sand (FS), silt (S), and clay (C). The elemental composition of all samples was measured using X-ray fluorescence (XRF) spectrometry. In addition, major ion compositions of the filtered river water were determined using high-speed ion chromatography.

The model consists of two main components: a hydrological module that predicts river discharge from precipitation distributions based on simplified hydrological assumptions, and a sediment–water quality module that predicts the export processes of RS and SPM using geological and soil distribution data. The former was validated using observed discharge data provided by the Ministry of Land, Infrastructure, Transport and Tourism of Japan, while the latter was validated using measured elemental and ionic compositions of each fraction obtained in this study. Detailed results of the model validation will be presented and discussed during the presentation.

# Evaluating Conditioned Probabilistic Subsampling for the Validation of 3D Regional Subsurface Models using Legacy Data

**Pablo De Weerdt[1*], Stijn Luca[2], and Ellen Van De Vijver[1]**

[1] *Department of Environment, Ghent University, Ghent, Belgium*

[2] *Department of Data Analysis and Mathematical Modelling, Ghent University, Ghent, Belgium*

*Pablo.DeWeerdt@Ugent.be

**ABSTRACT**

With the increasing availability of soil data in various forms it is more common to develop models using only legacy data. While model development is ideally preceded by sampling design aligned with the desired outcome, pre-existing data can partially fulfil requirements and allow for larger-scale modelling such as regional subsurface characterisation. The resulting models can also serve as tools to identify information gaps and model limitations. Interpreted soil borehole profiles, for example, form the basis of multidimensional subsurface models. The availability of data in a certain study area, however, can still be relatively low given the desired resolution or precision of the model. A deliberate decision on sampling existing datasets in general, and creating subsamples for model calibration and validation in particular, is therefore essential during performance assessment of different models. While cross-validation techniques are commonly applied to maximize data utility, their application in spatial modelling yields overoptimistic performance estimates with high variance, particularly when data are clustered. Probabilistic-based sampling is known to tackle bias, but its effectiveness remains poorly understood for spatially sparse and clustered legacy data.

In this research, the effect of subsampling methods on the validation of spatial interpolation techniques is assessed in a study region with legacy boreholes spanning over a century. Simple random subsampling is compared to conditioned Latin hypercube subsampling of boreholes in terms of true model performance. The conditioning 2D legacy characteristics consisted of age, coordinates and target feature statistics. We evaluated the impact of subsample size and anisotropic autocorrelation structure using the same 2D legacy configuration populated with three different 3D target features: two spatially continuous synthetic distributions and one heterogeneous field-observed peat content distribution. Variance reduction was observed only in the spatially heterogeneous case when the validation subsample size was sufficient (35%) to support conditioning that included the cumulative peat content within a borehole. This demonstrates that conditioned probabilistic subsampling can be more robust than other methods for the validation of models derived from legacy data. Our findings also provide insights into different sources of variance within validation results.

# Generalizability optimization of soil thermal conductivity models: unified estimation of dry- and saturated-soil thermal conductivity

**Xin Zhao, Haigang Li, and Wencan Zhang***

*College of Resources and Environmental Sciences, Inner Mongolia Agricultural University, Hohhot, China*

* wencanzhang@imau.edu.cn

**ABSTRACT**

Soil thermal conductivity (λ, W $m^{-1}$ $K^{-1}$) is a fundamental physical parameter governing coupled water and heat transport in soils, with broad relevance to thermal energy engineering, soil physics and agrometeorology. However, widely used empirical λ prediction models are often limited in their applicability across soil textures, bulk densities and water content ranges. A substantial fraction of the prediction error arises from uncertainties in estimating dry soil thermal conductivity ($\lambda_{dry}$) and saturated soil thermal conductivity ($\lambda_{sat}$). In this study, we optimized the calculation methods of $\lambda_{dry}$ and $\lambda_{sat}$ and incorporated a unified parameterization into five commonly used empirical models to improve their transferability. The validation results based on 213 literature-derived datasets and 175 measured datasets, spanning soil textures from sand to clay, bulk densities of 1.1–1.7 g $cm^{-3}$, and a wide range of total water contents. The improved models consistently enhanced predictive performance. Compared with the original models (RMSE 0.183–0.277; SD 0.458–0.601; $R^2$ 0.893–0.946), the improved models achieved RMSE 0.128–0.166, SD 0.335–0.435, and $R^2$ 0.947–0.959 across all conditions. The contribution of $\lambda_{sat}$ in the two parameters to the accurate prediction of λ is higher than that of $\lambda_{dry}$, and the $R^2$ is ≥ 0.88. Overall, the unified estimation of $\lambda_{dry}$ and $\lambda_{sat}$ reduces the prediction bias without modifying the main structure of the existing models, thereby improving their general applicability across diverse soil scenarios.

* alessandrorosa@utfpr.edu.br

**ABSTRACT**

The historical fragmentation of Brazilian soil data—often confined to non-digital legacy reports or institutional silos—has long hindered large-scale environmental modeling. This study presents the SoilData repository (soildata.mapbiomas.org), a centralized open-science infrastructure designed to safeguard, standardize, and disseminate soil information. Developed and managed as an initiative of the MapBiomas network, SoilData is a member of the National Consortium for Open Science (CoNCienciA). This partnership allows the repository to leverage international standards for data governance, including the attribution of Digital Object Identifiers (DOIs) via DataCite to ensure that datasets are citable and discoverable in global indexes.

The SoilData architecture is built upon a four-stage technical workflow: (1) inventory and acquisition, which combines active rescue of legacy data (digitizing theses, reports, and articles) with voluntary deposits from independent researchers; (2) structuring and standardization, where raw data is transposed into a machine-readable format and subjected to semantic harmonization using standardized vocabularies and unit conversions; (3) quality control, involving automated logical checks for physical consistency (e.g., mass balance of granulometric fractions) and spatial verification to correct georeferencing errors; and (4) publication and safeguard, ensuring long-term preservation and data traceability under a Creative Commons licenses.

The repository currently (Dec. 2025) hosts over 298 datasets, approximately 19,409 points (of which 16,515 are geoReferencesd) and 61,242 samples. When standardized and harmonized, this yields more than 15,000 geoReferencesd points and 45,000 samples of analysis ready soil data (ARD). This ARD dataset provides information on organic carbon content, bulk density, and granulometry up to 100 cm depth. Furthermore, the repository has expanded its scope through specialized thematic groups, such as the Soil Erosion Data Community, to address emerging environmental priorities. By providing a robust, transparent, and citable foundation for pedological research, SoilData serves as a vital tool for democratizing soil information in Brazil and supporting sustainable land management and climate adaptation.

# Estimation of Soil Temperature at Depth Using Time Series of Satellite Imagery

**Seyed Kazem Alavipanah[1*], Fahime Arabi Aliabad[1], Amin Mousavi[1], and Mohammad Zare[2]**

[1] *Department of Remote Sensing and GIS, Faculty of Geography, University of Tehran, Iran*

[2] *Department of Arid Lands Management, Faculty of Natural Resources and Desert Studies, Yazd University, Iran.*

* salavipa@ut.ac.ir

**ABSTRACT**

Soil temperature and its temporal and spatial variations constitute one of the most critical factors influencing not only mass and energy exchange in the soil, but also the magnitude and direction of all physical processes within the soil, either directly or indirectly. Given the practical challenges associated with in-situ measurement of soil temperature at depth, this study utilized land surface temperature (LST) derived from the MODIS sensor, which provides four observations per day. These data were subsequently modeled to generate hourly time series. The percentage of missing data in these images was estimated both temporally and spatially. The application of the HANTS (Harmonic Analysis of Time Series) algorithm for reconstructing MODIS LST time series demonstrated that separate reconstruction of daytime and nighttime images yields higher accuracy compared to combined day-night series. To further improve reconstruction accuracy, the Multivariate Singular Spectrum Analysis (MSSA) algorithm was also employed, and different window lengths were evaluated. Ultimately, a window length of 60 days was selected, achieving the highest accuracy with an RMSE of 1.4 °C. In order to generate hourly-resolution LST time series using only four daily MODIS LST observations per day, six different diurnal temperature cycle (DTC) models were compared. These models incorporated critical parameters such as sunrise and sunset times, day length, and other astronomical variables for each day. Cross-validation results indicated that the DTC models ranked in descending order of accuracy as follows: DTC1 > DTC6 > DTC5 > DTC4 > DTC3 > DTC2. Soil heat flux images derived from MODIS were reconstructed using MSSA and subsequently modeled to hourly resolution. Soil thermal admittance was estimated using the ratio of the amplitude of soil heat flux to surface temperature at different frequencies. Deep learning techniques were then applied to the derived thermal admittance images to obtain soil thermal diffusivity and damping depth images. Analysis of the MODIS-derived damping depth images revealed that damping depth increases with increasing soil depth. Hourly soil temperature at depth was estimated using the sinusoidal analytical solution, based on MODIS-derived surface temperature time series. Validation results showed that the highest accuracy was achieved at 5 cm depth, while the lowest accuracy occurred at 20 cm depth. Except for the 5 cm depth (where the lowest accuracy was observed at 12:30), the lowest accuracy at all other depths was consistently found at 06:30 local time. Monthly average soil temperature variations from the surface to deeper layers were investigated throughout the year. Finally, a novel methodology is proposed for estimating soil temperature at depths of 5, 10, and 20 cm using MODIS imagery. This approach explicitly accounts for day length variation, sunrise and sunset times, thermal damping depth, and phase shift. Identifying and analyzing subsurface thermal behavior is essential for risk management and proper infrastructure planning The subsequent phase of the research is designed to examine underground heat distribution patterns and to identify subsurface heat islands.

**ABSTRACT**

Predicting hydraulic properties is an important task necessary in building multi-scale models for various soil processes. Pore-scale simulations provide a fresh look at this task as they can mitigate numerous experimental problems or apply more realistic boundary conditions [1]. Direct simulations on 3D images of porous media are computationally heavy. With the advent of modern statistical methods in the form of machine learning techniques, one can predict hydraulic properties quite cheaply by leveraging data from direct simulations [2]. There different approaches to the task, for example, it is possible to extract features from the whole soil structure [3]. However, one can apply the technique separately to each pore – this way we can use pore-networks to perform simulations in a more robust way, or to combine multi-scale soil structural features- regular pores and macropores, that are usually addressed separately within modelling domains.

In this contribution, we shall use the latter approach and present results of training a model on different types of pore elements, including macropores. As input dataset, we shall utilize 3D images of soil structures and results of direct flow simulations with Stokes solver [4]. We shall demonstrate how this type of models to build robust solutions on different scales including pore and macropore domains.

**ABSTRACT**

Precise prediction of soil organic carbon (SOC) sequestration remains a challenge due to the complex interplay between microbial metabolism and physical boundary conditions. In this study, we utilize "closed microbial ecosystems" (CES) as a controlled proxy for soil micro-environments to differentiate between transient carbon storage and long-term sequestration. We developed a mechanistic simulation model integrating the Microbial Carbon Pump (MCP) and Partial Oxidation (PO) pathways to quantify the stabilization of carbon across temporal scales.

Our findings indicate that sequestration is driven by the microbial transformation of labile precursors into recalcitrant organic matter [1]. Even in simplified microbial communities, these systems self-organize to persistently cycle carbon, providing a unique lens into the fundamental limits of carbon persistence [2]. Experimental verification using FT-ICR-MS analysis demonstrated that lignin/CRAM-like compounds increased from 34.4% to 61.0% over 38 days, confirming the formation of persistent carbon sinks. Furthermore, our model identifies a "hidden oxygen sink": as microorganisms partially oxidize organic matter to increase its Nominal Oxidation State (NOSC), the resulting compounds become thermodynamically unfavorable for further respiration [3]. By coupling gas pressure dynamics with chemical transformations, this research provides a framework for the precise assessment of carbon sequestration efficiency [4]. These results offer a scalable methodology to improve the accuracy of SOC storage predictions from the micro-aggregate to the global scale.

# A spatially explicit model for watershed nitrogen fate through multi-scale integration of soil biogeochemistry and hydrology

**Liang Hao[1*], and Zhou Feng[1,2]**

[1] *College of Geography and Remote Sensing, Hohai University, Nanjing, China*

[2] *College of Urban and Environmental Sciences, Peking University, Beijing, China*

*E-mail Address of Presenting Author: haoliang@hhu.edu.cn

**ABSTRACT**

Quantifying watershed nitrogen (N) fate is critical for non-point pollution control but remains challenging due to the spatial and temporal decoupling of grid-scale biogeochemistry from watershed-scale hydrology. This limits accurate prediction of N sources, transport pathways, and time lags. To bridge this gap, we developed a novel spatially explicit model (INSIGHT), which tightly couples a high-resolution soil biogeochemical model with a distributed hydrological routing scheme. Through multi-scale data-model fusion, the model was robustly constrained using both in-situ observations across key land uses and watershed outlet monitoring data while explicitly accounting for the spatial heterogeneity of land uses and soil hydraulic properties. INSIGHT demonstrated high performance in a 42 km² agricultural-forested watershed in the lower Yangtze River, simulating streamflow and N export with accuracy (R2, 0.505–0.965, $p < 0.01$). The model accurately captured the spatial heterogeneity of water and nitrogen (N) dynamics across land uses, with strong performance for soil moisture ($R^2$=0.991) and soil N ($R^2$=0.948) in tea plantations, mixed forests, and paddy fields. Model simulations showed that annual N input totaled 660 Mg N $yr^{-1}$, dominated by synthetic fertilizer (51%), organic manure (34%), and atmospheric deposition (15%). N removal occurred mainly through crop harvest (36%), outlet export (12%), ammonia volatilization (14%), and denitrification (11%). Approximately 26.5% of input N was retained in the watershed, primarily as organic N (25.7%), while residual mineral N was low (0.8%) and influenced by precipitation variability. Agricultural soils (30.6% of area) contributed 34.7% of N export due to high fertilization rates. Subsurface flow accounted for 62.4% of N export despite representing only 43.8% of streamflow, highlighting the key role of groundwater biogeochemical retention. Sensitivity analysis showed delayed N export responses (5–30 years) to fertilizer reductions, reflecting significant legacy effects. INSIGHT provides a spatially explicit, process-based framework for high-resolution assessment of watershed N fate, supporting targeted non-point pollution management.

# Fusion simulations based on process-based modeling and AI-technology for groundwater storage and quality in the Mollisol Regions

**Xiaoyu Zhang[1*] and Yong Chen[1]**

[1] *College of Land Science and Technology, State Key Laboratory of Efficient Utilization of Agricultural Water Resources, China Agricultural University, Beijing 100193, China*

*E-mail Address of Presenting Author: zhangxiaoyu518@cau.edu.cn

**ABSTRACT**

Groundwater is crucial for ensuring stable food production and environmental sustainability in the Mollisol region. However, high-intensity agricultural production activities have subjected groundwater resources in Mollisol regions to dual pressures of "water quantity imbalance" and "water quality deterioration". Accurately simulating groundwater storage (GWS) dynamics and predicting associated water quality parameters, such as nitrate ($NO_3^-$) concentrations, are central yet challenging tasks in the Mollisol regions. These challenges arise from the inherent complexity and heterogeneity of subsurface hydrological processes, coupled with often limited observational data. While process-based models such as the Soil and Water Assessment Tool (SWAT) effectively simulate hydrological and nutrient cycles, they frequently exhibit uncertainties in simulating regional GWS dynamics and pollutant transport. This study proposed a fusion simulation framework, integrating the physical mechanisms of the SWAT model with AI-technologies, aiming to sequentially correct systematic errors in simulated GWS and subsequently predict groundwater $NO_3^-$ concentrations in Mollisol regions. The framework implements a two-stage AI-enhanced modeling approach. First, a GWS error correction model was constructed. The GWS error between simulations from SWAT and derived from Gravity Recovery and Climate Experiment (GRACE) data assimilation serves as the learning objective, with multiple variables from the SWAT model used as features. These features were fed into various machine learning (ML) algorithms for training and testing to identify the best error correction model. The results demonstrated that the error correction model improves GWS simulation performance, with the coefficient of determination ($R^2$) increasing by 19.1% to 86.6% over the study period, effectively reducing systematic bias in the process-based model. Subsequently, based on the corrected GWS data, integrated with simulated driving variables from the SWAT model, a groundwater $NO_3^-$ concentration prediction model was constructed, enabling quantitative assessment of groundwater quality at the regional scale. Results indicated that the model possesses strong groundwater $NO_3^-$ concentration prediction potential in Mollisol regions. Feature importance analysis further revealed that nitrogen leaching and fertilizer application rate are the dominant factors controlling $NO_3^-$ concentration. This study demonstrated that integrating based on process-based modeling and AI-technology provides a powerful paradigm for addressing groundwater science challenges in Mollisol regions. The proposed framework not only corrected systematic biases in mechanistic models when simulating GWS but also establishes a data-driven pathway for predicting water quality, thereby providing a References method for addressing groundwater sustainability and pollution risk assessment under changing environments.

# Assessing Future Climate Change Impacts on Soil Erosion, Agricultural Nonpoint Source Pollution, and Crop Growth in the Huai River Basin

**Jiaren Hu[1*] and Yong Chen[1]**

[1] *College of Land Science and Technology, China Agricultural University, Beijing 100193, China*

*E-mail Address of Presenting Author: jiarenhu@cau.edu.cn

**ABSTRACT**

Against the backdrop of global climate change, the Huai River Basin—a vital grain production base and ecological transition zone in China—faces severe challenges to its water and soil resource security and agricultural sustainability. This study employs the distributed hydrological model SWAT (Soil and Water Assessment Tool) to systematically evaluate the impacts of climate change on soil erosion, agricultural nonpoint source pollution, and crop growth in the Huai River Basin under future climate scenarios.

This study first constructed and calibrated the SWAT model tailored for the Huai River Basin, simulating the hydrology and water quality of streamflow, sediment transport, nitrogen and phosphorus migration, and crop growth. Model calibration and validation were performed using the SWAT-CUP (SWAT Calibration and Uncertainty Program) tool. Results indicated that during 2003–2021, calibration for rice, wheat, and maize yields in the study area achieved good performance, with Percent BIAS (PBIAS) values for all six sub-regions falling within ±15% during both the calibration and validation periods. Furthermore, based on streamflow observations from four hydrological stations, the model achieved overall Nash-Sutcliffe Efficiency (NSE)and $R^2$ values exceeding 0.50 during both the calibration period (2009–2013) and validation period (2014–2018), with PBIAS distributed within ±25%, indicating reliable streamflow simulations. Following streamflow calibration, sediment and nitrogen & phosphorus transports parameters were further calibrated using data from two observation sites. Results showed NSE and $R^2$ values exceeding 0.75 at both outlets, with PBIAS maintained within ±25%. This demonstrated the SWAT model's strong applicability and reliability in simulating hydrology, sediment yield, nitrogen & phosphorus transports, and crop yields in the Huai River Basin.

Building upon this fully calibrated SWAT model, this study systematically assessed the impacts of future climate change on hydrology and water quality in the Huai River Basin. Findings indicated that soil erosion within the basin is projected to significantly intensify, with potential increases in erosion intensity. Agricultural nonpoint source pollutants (nitrogen and phosphorus losses) are projected to increase in transport loads via runoff and sediment, posing potential threats to basin water quality. Crops response to future climate change are complex. While some crops may benefit from extended growing seasons, overall production stability is expected to be adversely affected by frequent extreme climate events such as high temperatures and droughts.

**ABSTRACT**

The MapBiomas initiative is a collaborative network that produces annual, spatially explicit environmental information by integrating remote sensing data and cloud-based processing. Initially focused on land use and land cover dynamics, the network has expanded to thematic domains such as fire scars, surface water, and environmental degradation and has been replicated across several countries in the Global South.

Within this ecosystem, MapBiomas Soil is a thematic initiative dedicated to the production of soil information for Brazil. It adopts an iterative development model based on digital soil mapping, in which harmonized field soil observations from the SoilData repository are integrated with environmental covariates to generate annual national collections of soil maps at 30 m resolution. Since its initial release in 2021, successive collections have incorporated new soil data and covariates, progressively expanding the dimensionality of soil information.

Currently, MapBiomas Soil provides annual maps of soil organic carbon (SOC) stocks for the period 1985–2024 (0–30 cm), maps of soil granulometry (sand, silt, and clay) at 10 cm intervals down to 1 m, soil texture maps generated for six depth intervals and three classification levels, and maps of depth to soil stoniness, defined by thresholds of 50% and 90% coarse-fragment volume.

According to Collection 3 (2025), Brazil stores approximately 37.5 Gt of SOC in the topsoil in 2024. More than half of this stock is concentrated in the Amazon, while the highest average SOC densities occur in the Atlantic Forest. SOC stocks are consistently higher in clayey and silty soils and substantially lower in sandy soils, with contrasts approaching a twofold difference in savanna and semi-arid regions. Depth-wise analyses indicate a systematic increase in clay content with depth at national scale, with clayey textures predominating between 60 and 100 cm. Joint analyses of soil texture and four decades of land-use and land-cover change show that land occupation is strongly conditioned by soil physical properties: pasture expansion predominated on medium- and coarse-textured soils, agricultural expansion concentrated on finer-textured soils, and silviculture expanded preferentially where soil physical constraints limit intensive cropping.

Embedded within a broader environmental data ecosystem, these products support pixel-scale, long-term analyses of soil–land-use interactions, allowing soil properties to be examined both as conditioning factors shaping land-use trajectories and as responses to environmental and anthropogenic changes across the Brazilian territory.

**ABSTRACT**

Trace elements (TEs) occur in the environment in small quantities, but can have a disproportionately large effect on humans and ecosystems. Some TEs, including lead and cadmium, are toxic to life and can have deleterious effects on human and ecosystem health, while others including copper and zinc are essential micronutrients for animals and plants. Over the past 50 years, concentrations of essential TEs in staple crops such as wheat have been declining, due in part to selection processes preferring higher yielding varieties, which also take up less nutrients from the soil. This unintended consequence is resulting in food losing its nutritional quality. The mechanisms by which this happens are still under investigation, however the impact of this on human nutrition and health outcomes is well understood. Instances of 'hidden hunger', or TE deficiencies from an energy-dense but nutrient-poor diet, are prevalent in more than one quarter of the world's population. The behaviour and effects of TEs depend largely on their concentration in the environment and their chemical form, or speciation, which is influenced by a range of soil parameters. For example, the presence of TEs including copper, zinc, selenium and iodine in food chains depends heavily on their mechanisms of adsorption, resulting in fractions either more or less bioavailable, in soils. We have developed a mass-balance model that uses easily parametrised input variables to produce accurate estimates of TE accumulation rates in soils. We have validated the model's soil accumulation function using long-term field trial data from New Zealand. However, now we seek to determine whether this model can accurately predict trace element uptake into plants, including food crops. Using data from Rothamsted Research's long-terms field trials, we have parametrized the model with a view to improving its plant uptake prediction capacity. Subsequent improvements to the model have included functions to vary soil adsorption coefficients for TEs over time, and to incorporate yearly-specific weather parameters. This research contributes to improved understanding of plant uptake of TEs, that facilitates improved management of soils leading to better outcomes for human nutrition and soil health.

# The influence of the soil cover on the reliability of soil erosion modelling on the Central Russian Upland

**Andrey Zhidkin[1*], Valentin Golosov[1,2]**

[1] *V.V. Dokuchaev Soil Science Institute, Moscow, Russian Federation*

[2] *Faculty of geography, Lomonosov Moscow State University, Moscow, Russian Federation*

*zhidkin@esoil.ru

**ABSTRACT**

Soil erosion is widely recognized as a major threat to soil cover and food security. The Central Russian Upland (CRU), with area 170,000 km2, is one of the most erosion-hazardous regions in Russia, what is due to the dissected relief, combined with the extensive cultivation of the highly fertile Black soils. In the northern part of CRU, the soil cover is contrasting with a predominance of Phaeozems. In the central and southern parts, the soil cover is relatively uniform with a predominance of Chernozems.

Field studies were conducted in different parts of CRU on 5 arable catchments with areas 0.1-1 km2 and 5 sites with areas 103-855 km2. Soil properties analysis at 1700 survey points were used to calculate the K-factor. Soil erodibility decrease from North to South of CRU by an average of 1.75 times. SD of K-factor in the northern part of CRU is >0.08, while in the central and southern parts is double lower.

In the post-Soviet period, part of the arable land was abandoned, especially in the 1990s and 2000s. This abandonment was driven by soil fertility. First of all, less productive Phaeozems were abandoned. Differences in the area of arable land and the volume of soil losses, calculated using different land use maps, are more than 10-fold in the northwestern districts.

Detailed estimates of soil erosion rates obtained using radiocesium and magnetic tracer methods within arable land in small catchments are in good agreement with model calculations by WATEM/SEDEM for rainfall erosion and Russian regional model of the State Hydrological Institute for snowmelt erosion. Erosion losses measured by soil morphology at a total of 2500 points are in good agreement with those modelled for the agricultural period in the Chernozem zone. However, in the northern part with a predominance of Phaeozems, significant discrepancies are observed between the modeled and measured soil erosion losses, probably due to specific soil-forming processes.

Thus, the quality of soil erosion modeling in the northern and southern parts of the CRU differs largely due to differences in soil cover. The upscaling of soil erosion modeling in the northern part is significantly more complex and requires more detailed input parameters (K-factor and land-use boundaries), compared to the southern part of the CRU. The erosion model's shortcomings include: i) insufficient accuracy in estimating the sediment deposition, both within and outside the arable land; ii) the lack of an ephemeral gully erosion calculation module.

# Spectra-based predictive mapping of soil erosion rates in sloping croplands

**Pu Shi*, Qi Sun, and Lulu Qi**

*College of Earth Sciences, Jilin University, Changchun, China*

*shipu@jlu.edu.cn

**ABSTRACT**

Erosion-induced lateral soil redistribution leads to spatially heterogenous soil composition, which can be captured through the distinctive spectral reflectance of soils under varying levels of erosion influence. This points to the potential of using remotely sensed soil spectra to map soil erosion intensity, as demonstrated by previous studies (Qi et al., 2023; Qi et al., 2024). However, it remains challenging to develop verifiable regression models that are capable of estimating soil erosion rates at high spatial resolution. A key reason for this is the lack of observational datasets for model training. In the presentation, we will report our work on spectra-based soil erosion mapping via remote and proximal sensing of cropland soils in the Phaeozem and Chernozem region of Northeast China. First, a large-scale field survey was conducted to establish a sample set (n=850), 200 of which were measured for $^{137}$Cs inventory for estimating soil erosion rates. Then, laboratory-based soil spectral modelling was adopted as a data augmentation technique to predict erosion rates for the un-measured samples. Based on the large-scale erosion dataset, point-based observations were linked with multitemporal Sentinel-2 bare soil composites to construct a spectra-based remote sensing framework for quantitative soil erosion prediction and mapping. Using the predicted soil erosion map, we will further present the spatially varying relationship between soil erosion and crop productivity, as also confounded by biophysical conditions and the interannual variation in precipitation.

**ABSTRACT**

Soil erosion degrades ecosystem services, decreases agricultural productivity, reduces economic returns, and deteriorates water resources, significantly threatening the World's agricultural soils. Various techniques are available to measure or estimate soil erosion across different scales. Monitoring soil erosion is one of the fundamental approaches required by sustainable land management. However, there is a lack of quantitative measuring techniques that can track changes in soil erosion processes at high spatiotemporal resolution. Land surface deformation has been successfully monitored at different scales with Interferometric synthetic aperture radar (InSAR). As soil erosion is an analogous surface deformation, we aim to develop an InSAR-based method to monitor detachment, translocation and deposition at high spatiotemporal resolution (e.g., mm soil loss, short revisit times) and attribution models are developed for driving factors and for prediction. Three case studies on the use of this new methods in landslide and soil erosion monitoring on the Tibet Plateau, Loess Plateau and Northeast China are presented and discussed.

# Assessments of Gully Erosion Susceptibility in Typical Thick-Layer Mollisol Region of Northeast China

**Fenli Zheng** [1*]

[1] *College of Soil and Water Conservaton Science and Engineering, Northwest A & F University, Yangling 712100, PR China*

* flzh@ms.iswc.ac.cn

**ABSTRACT**

Gully erosion is a predominant form of land degradation in arable lands, leading to soil degradation and threatening ecological security and food production. However, current studies on gully erosion susceptibility (GES) often suffer from variable redundancy and limited model interpretability, which compromise model accuracy and generalizability. To overcome these challenges, this study takes Keshan County, with an area of 3,186.11 km2, located in the typical thick-layer Mollisol region of Northeast China, as a case study. The ten key driving factors affecting gully erosion were selected, and four machine learning models—random forest (RF), logistic regression (LR), support vector machine (SVM), and extreme gradient boosting (XGBoost)—were employed to assess the GES in the study area. Results showed that models based on the ten-factor achieved comparable performance to those using the full-factor across accuracy, $R^2$, area under the curve (AUC), and error indices. Among them, the XGBoost demonstrated the highest predictive accuracy, with the AUC values of 0.904 and 0.881 in training and testing stages, respectively, indicating robust generalization and stability. Notably, the spatial distribution analysis revealed that different models consistently delineate the GES areas. Areas of very low susceptibility constitute the majority of the study area while regions with high susceptibility are mainly concentrated in areas with complex topography. SHapley Additive exPlanations (SHAP) based interpretability analysis further highlights the topographic position index (TPI), annual average temperature (Temp), and digital elevation model (DEM) as the most influential factors, exhibiting pronounced nonlinear impacts on the GES. Overall, the findings offer an effective and interpretable approach for assessing the GES, which can directly support gully erosion prevention and contribute to the long-term protection of Mollisol resources.

# Pasture Restoration Improves Runoff, Soil loss, and Sediment Sorting in a Brazilian Karst Basin

**Henrique M. L. Chaves[1*], Maria Rita S. Fonseca[1], and Isabela Fernanda L. Camargo[2]**

[1] *Watershed Management Lab, Forestry Dept. University of Brasilia, Brasilia-DF, Brazil*

[2]*Forestry Dept. University of Brasilia, Brasilia-DF, Brazil*

*Email: hchaves@unb.br

**ABSTRACT**

Karst landscapes are fragile environments and are difficult to restore once disturbed, causing soil loss and downstream sedimentation. Because of the expansion of the agricultural frontier in the Brazilian savanna during the last 60 years, its karst areas have been subjected to severe degradation, affecting the sustainability of farmers in the region. The research aimed to quantify the erosion rates occurring in degraded pastures in the Brazilian savannah and to evaluate the effectiveness of its restoration, the possible correlation of soil loss with runoff, and whether Gerlach collectors, a simple and unexpensive method to assess soil loss in developing countries, could be used in the erosion assessment in karst areas. In this study, runoff and soil loss in degraded and restored pastures, and in natural savannah were assessed during two years using Gerlach plots at three sites (farms) of the Vermelho river basin, in Brazil. The farms were treated as randomized blocks, and the treatments were degraded pasture, restored pasture, and natural savanna vegetation. After 2 years of pasture restoration, runoff was reduced by 40% and erosion decreased by 50%-80% in the restored pasture treatments, compared to the degraded pasture condition. In most plots, the sediment was enriched with fines, reducing the silting potential of sinkholes and underground rivers in the Vermelho river basin. Furthermore, Gerlach collectors, which are simpler and cheaper than traditional erosion plots, emulated the latter in terms of quantitative soil erosion assessment, facilitating soil loss monitoring in tropical karst areas.

# Influences of slope gradient and length on runoff and soil erosion of arable farmland in Northeast China: A modeling approach with APSIM

**Zhai cheyu[1], Li zizhong[1*]**

[1] *Department of Soil and Water Sciences, China Agricultural University, Beijing, China*

**ABSTRACT**

The black soil region has many ridge cultivation slope farmland, which results in a serious threat of soil water erosion and further corn yield decreasing. Agricultural Production Systems Simulator (APSIM) has been shown to accurately simulate the growth of crop under conservation tillage, whereas few studies have investigated the soil erosion and runoff throughout the complete growth period of crop. In this study, APSIM was calibrated and validated by soil characteristics and corn yield data under rotary tillage (RT), no-tillage without straw mulching (NT), no-tillage with straw mulching (NT-SM) and strip tillage with straw mulching in wide rows (ST-SM) treatments, which were used to investigate the regularity of soil erosion and runoff under slope gradient 3°, 6°, 9°, 12°, 15°, 18°, 21°, 24° as well as length 50 m, 100 m, 250 m, 500 m, 750 m, 1000 m, 1250 m under long-term (1981-2023) meteorological data. The result showed APSIM effectively simulated soil erosion amounts, runoff depth and corn yield with normalized root mean square errors (NRMSE) of 48.30-93.25%, 37.41-77.55% and 5.98%, respectively. The simulated soil erosion amounts significantly increased with slope gradient and length, whereas simulated runoff depth increased with no significant difference. Tillage and climate significantly affected simulated soil erosion amounts (standardized path coefficients 0.56 and 0.63, -0.88 and -0.92) and runoff depth (0.14 and 0.15, 0.50 and 0.56). Conservation tillage (NT-SM and ST-SM) significantly decreased soil erosion amounts and runoff depth compare with rotary tillage, reduction rate progressively increased with slope length and gradient by more than 96% and 25%, respectively. However, reduction rate of simulated soil erosion amounts and runoff depth of NT treatment progressively decreased with slope gradient by 16.62-15.30% and 14.23-12.89%, and significantly lower than NT-SM and ST-SM treatment. Corn yield was decreased under NT and NT-SM treatments by 3.16% and 7.02% compare with RT treatment. The highest corn yield was found at ST-SM treatment 11.40 t ha-1 (2.89%). In conclusion, APSIM was accurately applied to simulate soil erosion and runoff in slope farmland, the effect of decreasing soil erosion and runoff of no-straw-mulching practice was underperforms compared with straw mulching practice in slope farmland. NT-SM treatment was most effective in resisting soil erosion under slopes below 6° and 250 m, ST-SM treatment was more suitable for slopes above 9°and 500 m and increased corn yield.

**ABSTRACT**

Agricultural soils are key carbon reservoirs for achieving carbon neutrality and climate mitigation. Soil organic carbon (SOC) is stabilized within aggregates that limit microbial decomposition and erosion losses. However, soil erosion can disrupt aggregates, enhance SOC mineralization and $CO_2$ emissions, and transport SOC to aquatic systems, reducing carbon stocks in agricultural fields. Although some eroded SOC may be deposited and stored in floodplains or sediments, potentially offsetting emissions, the net effect of soil erosion on carbon neutrality remains uncertain. This study evaluates the impacts of soil erosion on carbon neutrality by jointly considering SOC loss, transport, and redistribution, together with greenhouse gas (GHG) emissions ($CO_2$, $CH_4$, and $N_2O$) from aquatic and depositional environments, changes in fertilizer use, and biomass productivity. Soil erosion effects were examined using four scenarios: (1) SOC transport only; (2) SOC transport with $CH_4$ emissions from wetlands; (3) SOC transport with $CH_4$ and fertilizer-induced $N_2O$ emissions; and (4) SOC transport with $CH_4$, $N_2O$, and biomass changes. Previous studies estimate global SOC loss from soil erosion at approximately 0.9–1.31 Pg C $yr^{-1}$, with further increases projected under climate change scenarios (RCP 2.6 and RCP 8.5). In steep alpine agricultural regions of South Korea, annual SOC losses range from 11.8% to 16.5%, with particulate organic matter being more vulnerable to erosion than mineral-associated organic matter. Erosion-driven SOC redistribution increases $CO_2$ and $CH_4$ emissions in depositional zones and is associated with elevated $N_2O$ emissions from increased fertilizer inputs and reduced biomass productivity, collectively exerting negative impacts on carbon neutrality. Current IPCC greenhouse gas accounting frameworks do not adequately account for erosion-induced SOC loss and redistribution, leading to uncertainties in agricultural carbon budgets and emission assessments. This study demonstrates that reducing soil erosion contributes not only to mitigating sediment and turbidity but also to enhancing carbon neutrality through SOC conservation and reduced GHG emissions. Further research is needed to develop integrated quantitative approaches linking soil erosion, SOC dynamics, and greenhouse gas emissions and to incorporate these processes into future policy and management strategies.

# Impacts of cascading check dams on sediment yield in the middle Yellow River Basin: Insights from 50 years of grid-cell-level simulation

**Guangyao Gao[1*], Yanzhang Huang[1], and Lishan Ran[2]**

[1] *State Key Laboratory of Regional and Urban Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China*

**ABSTRACT**

Check dams, globally built as vital engineering interventions for controlling soil erosion, form complex cascading systems in streams that pose significant challenges for assessing spatiotemporal dynamics of sediment yield (SY) at large basin scale. This study proposed an integrative model framework combining dynamic sediment trapping efficiency of cascading check dams with the Revised Universal Soil Loss Equation (RUSLE), index of connectivity (IC), and sediment delivery ratio (SDR). This model was applied to evaluate grid-cell-based distribution of SY and sediment trapped by check dams during 1970-2019 in the middle Yellow River Basin (with over 47000 check dams). The efficiency coefficient of proposed model increased to 0.71 compared to model ignoring sediment trapping of check dams (0.59). Totally $3.84 \times 10^9$ t of sediment was trapped by check dams over the 50 years, representing 14.41% of actual SY and constituting 41.49% of designed storage capacity. The sediment reduction contribution by check dams ($SRC_{dam}$) decreased from 25.27% in the 1970s to less than 10% in recent years. Notably, the impacts of check dams on SY exhibited considerable spatial heterogeneity, with $SRC_{dam}$ ranged from 73.9% to 0.9% and the proportion of accumulated sediment to storage capacity of check dams ($SAR_{dam}$) varied from 78.1% to 1.1% among sub-basins. The $SRC_{dam}$ increased linearly with check dam density and the share of area they controlled, whereas $SAR_{dam}$ increased with SY from upstream of the check dams as a logarithm function ($P < 0.001$). Further, there was evident trade-off between $SRC_{dam}$ and $SAR_{dam}$ in some sub-basins, indicating that the number of check dams in these basins is insufficient or overmuch. This study provides a practical and data-efficient method for assessing sediment trapping and reduction by cascading check dam systems in large basins, offering valuable insights for optimizing check dam arrangement to enhance their sediment control effectiveness in erosion-prone regions.

**ABSTRACT**

Soil erosion remains one of the most critical global environmental challenges, demanding advanced modelling strategies to characterize its spatial and temporal dynamics. In 2025, the MapBiomas network—an open, collaborative, and multi-institutional initiative—launched a nationwide effort in Brazil to systematically map erosive features, with a specific focus on ephemeral and permanent gullies. This study presents the strategy and implementation of the SoilData Repository erosion community, a centralized infrastructure developed to organize, standardize, and publish erosion records for broad scientific reuse.

To address the persistent issue of data fragmentation, the initiative aggregates erosion records from any year and across the entire Brazilian territory. The database supports flexible data inputs, ranging from single geoReferencesd points indicating gully occurrence to detailed spatial delineations of eroded areas. By harmonizing heterogeneous datasets within a standardized, open-access, and collaborative online platform, the initiative advances open-data practices in soil erosion research.

The resulting database provides the essential ground-truth foundation for integrating field observations with satellite imagery and machine learning techniques to map the spatial extent of erosive features. This workflow enables the upscaling of localized field assessments to national and continental monitoring systems, effectively bridging the gap between site-level observations and large-scale erosion modelling. To ensure traceability, reproducibility, and proper attribution, all datasets published in the SoilData Repository are assigned Digital Object Identifiers (DOIs). This initiative demonstrates a replicable open-science framework and contributes to global efforts toward harmonized and scalable soil erosion monitoring and modelling.

# An Evaluation of the Quantity–Intensity Relationship of Potassium (K) on Some Lowland Rice-Growing Soils

**Sanjib Kar**

*Department of Agricultural Chemistry & Soil Science, Institute of Agricultural Science, University of Calcutta, 35, Ballygunge Circular Road, Kolkata-70019, Kolkata, India*

Email address of presenting authors: sanjib_cu@yahoo.co.in

**ABSTRACT**

The potassium (K) supplying capacities of some lowland rice-growing soils were investigated by employing the quantity-intensity (Q/I) approach. Surface horizons of three soils were characterized by measurement of physico-chemical analysis, quantity-intensity adsorption isotherm for K, and X-ray diffraction of clay fraction. The values of potential buffering capacity (PBCK), labile K (KL), non-specific sites K (KO), specific sites K (KX), equilibrium activity ratio (AReK) and free energy change (−ΔG) were esti-mated from the quantity-intensity curve. The values of PBCK varied from 109.10±10.56 to 117.20±8.36 CmolcKg−1, AReK ranged from 0.0050±0.012 to 0.340±0.004 (molL−1)1/2, and KL differed in the amounts of 0.436±1.47 to 4.793±1.41 CmolcKg−1. The KX values ranged from 0.016±0.98 to 1.044±1.07 CmolcKg−1, −ΔG values differed from −13.30±4.21 to −8.52±3.19 KJmol−1. K present in specific and non-specific sites of clay was changed with clay mineralogy. Higher cation exchange capacity and organic carbon favored the labile K pool. The high AReK ratio indicated higher availability of labile K, and the bulk of that K was preferentially held at the planar surface of the clay crystals. High PBCK values indicated that K availability in these soils was excellent. PBCK was positively correlated with organic carbon (OC) and cation exchange capacity (CEC). The changes of AReK, PBCK, KL, and ΔG were related to the contents of pH, CEC, OC, clay %, and clay mineralogy of the soil. K fertilization is not required in a paddy soil with higher organic carbon and the presence of illite clay minerals.

**Keywords:** Quantity-intensity relationship, labile K, specific K, free energy change, equilibrium activity ratio, and potential buffering capacity of soil.

# Reconciling carbon sequestration value and soil health benefit of organic amendments

**Nanthi S. Bolan**[1]

[1] *UWA School of Agriculture and Environment, The University of Western Australia, Perth, Australia*

*Nanthi.Bolan@uwa.edu.au

**ABSTRACT**

Large volumes of organic amendments including crop residues, compost, manure, biosolids and biochar are increasingly being used as a nutrient and carbon (C) source to improve soil health, and to promote C sequestration (Thangarajan et al., 2013). Organic amendment input to soil is likely to impact C sequestration in soil through (i) increased crop biomass accumulation by enhancing soil physical, chemical and biological properties, and (ii) biochemical stabilisation of organic amendment-derived C in soil (Enebe et al., 2025). However, the enigma of C distribution in organic amendments, which determines whether and how these two processes couple to promote C sequestration in soil remains unknown. Furthermore, one of the problems with the use of organic amendments as a means of terrestrial C sequestration is their relatively fast rate of degradation, leading to the release of greenhouse gases (GHG) including, thereby becoming a source (rather than a sink) for GHG emission. This presentation provides a quantitative analysis of the novel approaches to reconciling soil health benefits with the C sequestration value of organic amendments in farming systems. This presentation will cover the critical analysis of the literature data on the influence of various organic amendments (e.g., compost, manure, biosolid, biochar) application on soil physical, chemical, and biological fertility, and C sequestration, and presents the results of a ***meta-analysis*** of these data from publications. A *treatment effect size estimator* commonly employed in meta-analysis is the magnitude of an experimental treatment mean (i.e., with organic amendment application), relative to the control treatment mean (i.e., without organic amendment application). A typical effect size metric is the response ratio or the relative impact on a measured parameter (e.g., soil bulk density) following organic amendment application compared to that in control treatment. The results from the meta-analysis work have indicated that organic amendment application modulates physical (e.g., moisture retention), chemical (e.g., nutrient accumulation), and biological (e.g., microbial activity) properties of soils while contributing to C sequestration.

**ABSTRACT**

Plant diseases cause 20%-40% of global annual crop losses. Meanwhile, chemical fungicides exacerbate environmental degradation through soil and water contamination, demanding microbial biocontrol. Exogenous microbes from sources like aquatic environments and composts exhibit broader advantages in diversity, functional specificity, environmental adaptability, and large-scale application potential. Insects are another underexplored beneficial microbe reservoirs though their harnessing faces challenges. Conventional single-phase screening methods isolate either volatile or liquid metabolites and fail to capture the multi-dimensional synergies in plant growth environments. We develop a dual-phase screening strategy that integrates volatile organic compounds (VOCs) and liquid-phase secondary metabolites (LMs). Using black soldier fly (BSF) larval frass as a microbial reservoir, we targeted strains with coordinated production of both liquid phase and gas phase anti-pathogen metabolite, optimizing inter-strain interactions to construct an 8-member synthetic community (SynCom). The SynCom inhibited potato black scurf by 70%, significantly higher than individual strains (15%-60%). This advances the application of BSF-derived microbial community in sustainable agriculture, provides ideas for bio-control of plant diseases.

## ABSTRACT

In Vietnam, antimicrobial resistance (AMR) has become an emerging environmental and public health concern due to the widespread use of antibiotics across various sectors, particularly in livestock and aquaculture production systems. Consumption of antibiotics can provide selective pressure, leading to the development of AMR. Antibiotic resistant bacteria (ARB) are often weakly pathogenic commensal bacteria that generally remain asymptomatic in healthy hosts. Antibiotic resistance genes (ARGs) can easily spread AMR among microorganisms via horizontal gene transfer, and when acquired by pathogenic bacteria, they could pose a greater threat to human health. In the soil environment, livestock can excrete ARGs through their manure, and the subsequent use of manure compost can alter the soil's physicochemical properties, thereby affecting the abundance of ARGs. In the aquatic environment, aquaculture waste can introduce ARGs into the water, which may eventually accumulate in sediment. Understanding the distribution of ARGs is crucial for assessing environmental risks and developing effective mitigation strategies. The objective of this study is to clarify current situations of ARGs in compost, soil, and sediments in Vietnam, and to provide a better understanding of how compost application and different aquaculture practices influence the abundance of ARGs in the environment.

Compost, soil, and sediment samples were collected from agricultural farms and shrimp ponds in central (Hue City) and southern Vietnam (Ho Chi Minh City and Tay Ninh Province) in September 2024, and in March and September 2025. In total, 128 soil samples were collected from 17 farms at different depths (up to 100 cm, depending on the site) in fertilized and unfertilized plots, including repeated sampling of the same sites at different times. Twenty-nine compost samples collected were made from cow, chicken, and quail manure, with or without additives (e.g., rice husk, rice straw, biochar, etc.). Seven sediment samples were collected from shrimp ponds (intensive and extensive). Six ARGs (*sul1*, *sul2*, *sul3*, *tetM*, *tetW*, and *ermB*) were selected as target ARGs. Additionally, 16S rRNA gene and the integron integrase gene *intl1* were quantified using qPCR.

Our results indicate that *sul1* and *sul2* were commonly detected in most sampling sites. In both compost and soil, the highest levels of target ARGs were found in Dan Dien commune, Hue City. For compost, ARGs abundance in chicken manure compost was higher than in cow manure compost. For soil, ARGs levels were greater in fertilized soil compared to unfertilized soil. Generally, ARGs abundance decreases with increasing soil depth. For sediment, ARGs levels were higher in intensive shrimp ponds than in extensive shrimp ponds. Our findings highlight the elevated levels of ARGs in chicken and shrimp farming, underscoring the urgent need for reducing the spread of ARGs and ARB.

# $CO_2$ emission from forest soils in Western Japan as affected by water repellency

**Dewpura A.L. Leelamanie[1*] and Morihiro Maeda[2]**

[1] *Department of Soil Science, Faculty of Agriculture, University of Ruhuna, Kamburupitiya, Sri Lanka*

[2] *Graduate School of Environmental and Life Science, Okayama University, Okayama, Japan*

*leelamanie@soil.ruh.ac.lk

**ABSTRACT**

The planetary burden on the Earth's atmosphere due to continued surge in emissions of greenhouse gases (GHGs) has become a serious global threat over the past several decades. Soil, as the largest terrestrial C sink, is susceptible to global warming and the release of GHGs. Soil water repellency is a phenomenon that causes soil to resist spontaneous wetting, influencing potentially all water-involved processes in soils. With increasing water repellency, the thickness of water layers surrounding soil particles becomes significantly thinner, restricting the spatial distribution of water in soil matrix, possibly influencing microbial activities in soil. The objective of this study was to determine the effects of water repellency on $CO_2$ emission from forest soils of Western Japan under different types of vegetation.

Water-repellent soil samples were collected from Japanese cedar (CED) Japanese cypress (CYP), and cedar and cypress mixed (MIX) forests in Tsuyama, Okayama prefecture, Japan. Soils were collected at 0–5 cm (U) and 5–10 cm (L) depths. According to the Köppen-Geiger climate classification, the climate of the area is warm temperate fully humid (Cfa). The litter layer composed of dry leaves, twigs, and the partially decomposed litter mat on the forest floor was carefully removed before collecting soil samples. The contact angle was measured using the sessile drop method. Sub-samples of air-dried soil (10 g) were placed in 100 mL glass vials and sealed immediately using a rubber septum after adding 3 mL of deionized water. The vials were incubated in a chamber at 25°C and the emission of $CO_2$ was measured using gas chromatography. Measurements were taken at 15, 30, 45, 60, 90, and 120 min incubation periods. After 2 h, the vials were opened, covered with polyethylene film (0.02 mm thickness), and kept in the incubator until further measurements. The vials were flushed with atmospheric air, sealed with a rubber septum, and kept incubator for 30 min before taking measurements at 1, 3, and 7 d incubation periods.

The top layers of soils from all three vegetation types showed higher levels of repellency than the lower layers. The emission of $CO_2$ showed two peaks, one at 15 min and the other at 24 h. In CED, CYP and MIX soils, less repellent lower layers showed higher peak emission of $CO_2$. The peak emission of $CO_2$ showed significant ($p < 0.05$) negative linear correlation with water repellency of soil. This effect of water repellency can lead to overall low rates of carbon emission from soils supporting the C sequestration and enhancing the terrestrial C stocks. Understanding the relation of soil water repellency to GHG emissions would provide comprehensive insight of GHG flux from forest soils.

**ABSTRACT**

Organic compost is widely applied to enhance soil quality, yet its effects on greenhouse gas (GHG) emissions remain uncertain. This study examined the impact of various facultative heap composts on the emissions of nitrous oxide ($N_2O$), carbon dioxide ($CO_2$), and methane ($CH_4$). Loamy sand soil (collected from Hue city, Vietnam) was amended at 2% (w/w) with three compost types: immature cow compost (C-1M, 1 month), mature cow compost (C-7M, 7 months), and poultry compost (P-9M, 9 months). All treatments were adjusted to 60% water-holding capacity (WHC) and incubated aerobically at 30°C for 56 days. Gas emissions were measured on days 0, 3, 7, 14, 21, 35, and 56. An application of mature compost (C-7M and P-9M) significantly increased cumulative $N_2O$ emissions from the soil. Poultry compost application led to higher $N_2O$ emissions than cattle compost, likely due to a greater nitrate content and a lower C/N ratio, which promote both nitrification and denitrification. The highest $CO_2$ emission occurred in the C-1M treatment, whereas cumulative $CO_2$ did not differ significantly among C-7M, P-9M, and the control. Notably, more $CH_4$ was emitted under aerobic conditions, and compost addition increased $CH_4$ emissions. These findings emphasize that compost characteristics (e.g., raw material, maturity, mineral N content, C/N ratio) are key determinants of soil GHG emissions. Optimizing these factors should be integrated into compost production and field application guidelines to mitigate GHG emissions.

**ABSTRACT**

Rice residue management is a major agro-waste issue influencing nitrogen (N) fate in paddy systems, yet their combined effects on N uptake dynamics and soil N retention remain insufficiently quantified. To address this, we conducted a mesocosm experiment using soils collected from a farmland comprising six management treatments that crossed two irrigation regimes (water-saving vs. conventional flooding) with three residue options (straw removal, straw return, and weed-mat cover).

A 5 atom% $(^{15}NH_4)_2SO_4$ tracer, consistent with the field fertilizer formulation, was applied during two topdressing fertilizations to evaluate fertilizer-derived N uptake and retention across treatments. Plant sampling was performed 21 days after each $^{15}N$ application to assess $^{15}N$ enrichment and allocation. In addition, soil and pore water samples (if present) were also collected during the second sampling to calculate the $^{15}N$ mass flow among the six treatments.

Preliminary $^{15}N$ tracer results revealed contrasting responses between irrigation regimes. In conventional flooding, the addition of carbon sources such as straw return or weed-mat cover appeared to provide extra carbon sources for anaerobic denitrification, reducing $^{15}N$ uptake efficiency by rice plants. This pattern was consistent across both topdressing applications. In contrast, the water-saving irrigation treatments exhibited lower overall $^{15}N$ recovery compared to flooded conditions, yet the addition of carbon did not induce N limitation. Notably, the straw-return treatment under water-saving irrigation showed the highest $^{15}N$ uptake efficiency among all treatments, which likely due to greater oxygen availability that enhanced straw mineralization and nutrient recycling, thereby alleviating N constraints. Ongoing quantitative PCR and 16S rRNA sequencing analyses will further clarify the development and distribution of denitrifying microbial communities among the different management practices.

**ABSTRACT**

Management of organic wastes derived from agricultural production and food consumption is key to soil health and the development of a regenerative society. In response to the world's growing population, the agricultural sector has met the high demand for more cereals, vegetables, and meat. Organic wastes from these productions often contain high contents of nutrients such as nitrogen and phosphorus, which may be unexpectedly discharged into the environment, deteriorating water quality, or emitting greenhouse gases (GHGs). Moreover, antibiotic resistance genes derived from the livestock industry pose a threat to pandemic risks by contaminating food and water.

We have studied how to wisely use the agro-waste materials mentioned above for soil health conservation: namely, (1) nutrient leaching and GHG emissions from livestock manure compost, (2) biochar application to the soil for mitigation of GHG emissions and for improving water qualities in rural areas, (3) a catch crop-biological soil disinfestation system, (4) use of sediment microbial fuel cells for water quality improvement and less GHG emissions, and (5) dissemination of antibiotic resistance genes in soil.

The presentation will report that (1) similar nitrate leaching occurred both from organic and inorganic N sources after several years, and mature compost can be used for GHG reduction, (2) advanced biochar reduced nitrous oxide emissions from soil, but the biochar's function was declined with aging if the biochar was pyrolyzed at a lower temperature of 500°C rather than 800°C, (3) the catch crop-soil disinfestation system can absorb residual nutrients from the soil after the main crop and reduce nitrous oxide emissions in biological soil disinfestation, (4) application of SMFCs to agricultural drainage sediment and paddy soil was effective in reducing phosphorus release and GHG emissions from the soils, and (5) antibiotic resistance genes were often found in topsoil amended with livestock waste compost. We need to study the efficient use of organic agro-wastes to establish environmentally positive agricultural systems based on soil health in the future.

## ABSTRACT

Reduction of emissions in food waste management, valorization of waste streams, and organic carbon management for sequestration and soil health are becoming increasingly relevant as we approach climatic tipping points. Lactic acid fermentation of food waste has the potential to address and connect these issues, creating improved circularity through application of a simple biotechnology. Lactic acid fermentation can initiate breakdown of a wide range of organic materials through application of a *Lactobacilli* inoculated bran or spray in anaerobic conditions, producing a stable organic soil amendment in a short period of time.

This process, sometimes known as 'Bokashi', is currently used to manage food waste and produce an organic amendment at domestic scales, but further research is needed on carbon storage possibilities and socio-economic constraints to scale up. To date, the greenhouse gas emissions during food waste fermentation or subsequent soil burial have been little studied but are key in assessing the potential environmental impacts and benefits of this method and determining how much carbon could be returned to soil.

Through lab scale incubations using a model food waste comprising of potato and cabbage, we found that emissions were very low. Per kg of feedstock, we measured emissions of 150 – 250mg $CO_2$, and less than 5µg of either $CH_4$ or $N_2O$, after 21 days of closed fermentation. For comparison, literature values for composting of organic municipal waste including food waste show 50 – 60g of $CO_2$, 800 - 900 mg of $CH_4$ and 60 – 70mg of $N_2O$ can be released per kg of input waste on average (Nordahl et al., 2023). Our results therefore indicate a significant possible reduction in emissions and increase in carbon retention.

Results from further fermentations under aerobic disturbance treatments, in which food wastes were fermented in vessels with a large airspace or frequent opening, also indicate that aerobic disturbance influences $N_2O$ emission during fermentation. This has significant implications on ideal fermentation methods at scale.

These initial findings highlight the potential benefits of integrating bokashi-style fermentation into existing food waste management systems, both in minimizing greenhouse gas emissions and in preserving carbon and nitrogen in a form suitable for soil application.

**ABSTRACT**

Heavy metals including Cd and Pb are the main elements of paddy soil contamination. Cd and Pb have impacts on rice crop and people health. The current study assessed the effectiveness of residue-based biochar with high Si content in removing heavy metals (Cd and Pb) from soil-plant systems. A factorial design with four replicates was used to set up the pot experiment. Rice husk and peanut shell residues were pyrolysed to create Si rich biochar and applied at varying rates (0, 2.5, 5.0, 7.5, 10.0 and 15.0 g/kg soil). The contents of soil and plant Cd and Pb were recorded. The results of the investigation demonstrated that the content of Cd in rice soil was higher than the permitted limit. Utilising Si-rich biochar from crop residues could be an efficient way to lower the concentration of heavy metals in rice soil and crop. The most effective adsorption method for removing Cd and Pb from soil was rice husk biochar. The application of these biochars considerably ($p<0.05$) decreased the Cd and Pb in the soil and rice shoots, demonstrating the potential of biochar application in rice soil. While application of 15 g/kg soil of Si rich biochar from rice husk decreased Cd by 21.6% and 31.2% Pb from soil and 31.7% Cd and 35.9% Pb in rice shoots. Therefore, Si rich biochar from rice husk with a high adsorption effectiveness may be a viable substitute source for lowering the buildup of heavy metals and could be the promising and ecological alternatives to synthetic material for heavy metals removal in the soil - plant system.

**ABSTRACT**

Plastic film residue (PFR), arising from the long-term use of agricultural plastic mulching, has emerged as a pervasive non-point source pollutant, severely threatening soil health, crop productivity, and environmental sustainability. Despite growing recognition of this "white pollution," a critical gap remains in the ability to rapidly, accurately, and quantitatively assess its spatial distribution. This technological shortfall leads to inefficient, non-targeted mitigation measures. Addressing this urgent need, this study develops and validates a comprehensive, multi-stage analytical framework based on unmanned aerial vehicle (UAV) imagery for high-resolution PFR detection and quantification. A dedicated UAV-based PFR image dataset was first constructed. Three state-of-the-art semantic segmentation models (DeepLabV3+, SegFormer, and U-Net) were systematically trained and evaluated. Performance was rigorously assessed using key metrics: mean Intersection over Union (mIoU), mean Pixel Accuracy (mPA), mean Precision (mPrecision), and mean Recall (mRecall). Comparative analysis identified the U-Net architecture as the superior model for initial surface PFR detection, achieving a benchmark mIoU of 88.01%. To further enhance segmentation precision, an advanced model was developed by strategically fusing U-Net with EfficientNet. This hybrid approach yielded significant improvements, increasing mIoU by 3.07%, mPA by 2.72%, and mPrecision by 1.04%, thereby establishing a more robust solution for pixel-level mapping of surface-residing PFR. Recognizing that surface detection alone is insufficient for total pollution assessment, the framework innovatively extends to estimate the often-concealed PFR within the plow layer. A sophisticated multi-model fusion strategy was engineered for this purpose, integrating four distinct machine learning algorithms (Multiple Linear Regression, Random Forest, Support Vector Regression and XGBoost). To maximize predictive accuracy and generalizability, a rigorous optimization protocol was implemented, combining random search for hyperparameter tuning with five-fold cross-validation. This design ensures the model's adaptability across diverse regional agricultural settings. The integrated framework presented herein delivers a novel, scientifically grounded, and operationally practical tool. It empowers rapid, large-scale PFR assessment, providing the critical data evidence-based environmental governance, guide targeted remediation actions, and underpin policies for sustainable agricultural management. This work bridges a crucial technological gap, offering a direct pathway from remote sensing data to actionable insights for combating agricultural plastic pollution.

## ABSTRACT

Biochar-based amendments are widely regarded as a promising strategy for improving nutrient availability in degraded soils. However, the extent to which feedstock type, processing conditions, and soil characteristics influence their nutrient-enhancing properties is unclear. This study evaluated the nutrient supply characteristics of biomass amendments produced via torrefaction (220–300 °C) and pyrolysis (450-550 °C), applied to marginal soils of contrasting textures. A factorial laboratory incubation experiment was conducted with four factors at two levels each: soil type (clayey, sandy), feedstock (Loblolly pine, Mesquite), thermal treatment (torrefied, pyrolyzed), and application rate (5%, 20% dry weight), along with two unamended controls for each soil type. Treatments were replicated three times in a completely randomized block design. Nutrient supply rates were monitored in-situ over 16 weeks using Plant Root Simulator (PRS™) probes, with soil burial and retrieval at 2, 4, 8 and 16 weeks. The sandy soil exhibited very low organic carbon (OC, 0.10%), nitrogen (N, 0.01%), and cation exchange capacity (CEC, 5.6 cmol+/kg), while the clayey soil had higher CEC (35.2 cmol+/kg), moderate OC (1.4%), and low N (0.12%). Pyrolyzed biomass had alkaline pH (9.0-10.7), higher fixed carbon (FC, 70–75%) and lower volatile matter (VM, 13–20%) than torrefied forms (pH: 4.3-6.4, FC: 19-26%, VM: 71-80%). Pyrolyzed Mesquite contained greater macronutrient concentration (N: 2%, P: 2.8 g/kg, K: 18 g/kg), up to six to eleven times, higher than Loblolly pine. Torrefied biomass exhibited lower overall nutrient levels, though Mesquite consistently outperformed pine. Following amendment and incubation, soil nitrate declined across treatments, particularly with high-rate torrefied amendments, likely due to sorption and N immobilization. Soil K availability increased with application rate, with pyrolyzed Mesquite being most effective. Soil P response was variable; torrefied Mesquite increased available P in clayey soil at higher application rates, whereas pyrolyzed pine enhanced P availability in sandy soil with increasing rates but reduced it in clay. These results highlight the need to understand nutrient profiles and bioavailability in thermally treated biomass and to tailor amendment strategies to specific soil types.

# Effects of Application of Ferment Solution Produced from Discarded Vegetable Leaves on Soil Microbial Community and Celery Growth

**Zi-Yue Zhang*, Xue-Feng Hu**

*School of Environmental and Chemical Engineering, Shanghai University, Shanghai 200444, P. R. China*

*E-mail Address: zzy256200@shu.edu.cn

**ABSTRACT**

A huge amount of waste vegetable leaves is generated during greenhouse production of vegetables. Discarded leaves of Chinese cabbage were collected and anaerobically fermented to manufacture a ferment solution rich in nutrients, probiotics and enzymes. To study the effects of application of the ferment on soil nutrients and microbial communities, a field experiment on celery cultivation was conducted in suburban Shanghai. It included four treatments: spraying 2% of the ferment solution (FH), spraying 1% of ferment solution (FL), application of chemical fertilizer (CF), and control (CK). The results indicated that the content of available N and P in the soil by the FH treatment was significantly higher than by the other treatments and CK. Moreover, the activities of acid phosphatase, alkaline phosphatase, and urease in the soil by the FH treatment were significantly higher than those by CK ($p< 0.05$), and the activity of dehydrogenase by the FH was significantly higher than by the CF ($p< 0.05$). The FH treatment stimulated the growth of celery plants significantly. The celery yield by the FH treatment was 23% and 43% higher than by the CF and CK ($p< 0.05$); while the incidence of sclerotinia rot in the celery by the FH was 44% and 58% lower than by the CF and CK ($p< 0.05$), respectively. Both the FH and FL treatments improved soil microbial diversity. A total of 158 species of nitrogen-fixing bacteria (NFB) and phosphate-solubilizing bacteria (PSB) belonging to Proteobacteria, Firmicutes, Actinobacteria and Cyanobacteria were detected, and the FH treatment increased the abundance of NFB and PSB of Firmicutes in the soil significantly. The linear regression analysis also demonstrated that the β-diversity of NFB and PSB of Firmicutes was significantly correlated with the AN/TN ratio in the soils ($p< 0.05$). Moreover, there was a significant positive correlation between the β-diversity of PSB of Proteobacteria and celery yield, whereas there was a significant negative correlation between the β-diversity of PSB of Firmicutes and incidence of sclerotinia rot. The spearman correlation analysis also indicated that the abundance of *Brevibacillus composti* and *Priestia flexa* belonging to PSB were significantly positively correlated with AP/TP ratio ($p< 0.05$). Likewise, the abundance of *Bacillus subtilis*, *Paenibacillus castaneae*, *Calothrixsp.PCC7103*, and *Tolypothrix tenuis* belonging to NFB were significantly positively correlated with AN/TN ratio ($p< 0.05$). Furthermore, the abundance of *Bacillus sp. BA3*, *Bacillus sp. ISL-4*, *Peribacillus butanolivorans*, and *Clostridium sp.* belonging to NFB or PSB were significantly positively correlated with the celery yield ($p< 0.05$), and significantly negatively with the incidence of sclerotinia rot ($p< 0.05$). The results fully suggest that spraying 2% of the ferment solution manufactured from discarded leaves improves microbial diversity, increases the abundance of NFB and PSB, and elevates the content of available N and P in the soil significantly, and reduces the incidence of sclerotinia rot in celery plants, thereby increasing the celery yield significantly. The application of the ferment solution produced from discarded vegetable leaves improves soil fertility, reduces incidence of crop disease and pests, increases crop yield, and thus can partially replace chemical fertilizers and pesticides. This method establishes an effective and simple way for recycling agricultural wastes.

# Study on Spatial Distribution Characteristics of Soil Organic Matter in Tea Gardens of Laoshan District, Qingdao Based on GIS and the Impact of Different Altitudes

**Pengfei Sun[1]*, Jiani Ma[1], and Xiangyun Song[1]**

*[1] College of Resources and Environment,*

*Qingdao Agricultural University, Qingdao, PR China*

*1913304498@qq.Com

**ABSTRACT**

The evaluation of soil fertility in tea gardens has received growing attention in recent years. Taking the tea gardens in Laoshan District as the research area, this study collected 412 soil samples to determine the content of soil organic matter. Combined with geostatistical methods, the relationships among spatial distribution characteristics, spatial heterogeneity and altitude were analyzed. The results are as follows:

(1) Analysis of soil nutrients in the tea gardens of Laoshan District showed that the content of soil organic matter in the 0 - 20 cm and 20 - 40 cm soil layers ranged from 6.87 to 29.67 g·kg-1 and from 5.93 to 24.09 g·kg-1, respectively. Based on the mean value, the soil fertility was classified as Grade IV according to the Fertility Evaluation Standard of the Second National Soil Survey of China. The soil fertility in the research area needs to be ameliorated, and the content of soil organic matter is at a medium-low or deficient level. It is recommended to increase the application of organic fertilizers in the tea gardens of Laoshan District.

(2) Results of descriptive statistical analysis and semi-variogram analysis indicated that the coefficient of variation of soil organic matter ranged from 19.92% to 201.16% (with an average of 20.28%), which demonstrated that soil organic matter had moderate variability. The nugget effect of soil organic matter in the 0 - 20 cm soil layer of tea gardens in Laoshan District ranged from 25% to 75%, implying that it was affected by both structural and random factors. The semi-variograms of soil organic matter in the 0 - 20 cm and 20 - 40 cm soil layers were both fitted with exponential models, with the coefficients of determination ($R^2$) being 0.985 and 0.857, respectively, which indicated a good fitting effect.

(3) The results of spatial distribution analysis revealed that the content of soil organic matter in the 0 - 20 cm and 20 - 40 cm soil layers exhibited a distribution pattern of being higher in the eastern and southern parts and relatively lower in the western and northern parts of the study area.

(4) Results of correlation analysis and analysis of variance (ANOVA) showed that the content of soil organic matter in both the 0 - 20 cm and 20 - 40 cm soil layers was significantly positively correlated with altitude, with significant differences observed, which indicated that soil organic matter content was affected by altitude.

In conclusion, based on an extensive dataset, this study comprehensively clarified the spatial variability characteristics of soil organic matter in tea gardens of Laoshan District and its relationship with altitude, which provides a scientific basis for further research on the spatial variability of soil fertility and related studies in this area.

## ABSTRACT

Paddy fields in Kyoto University Farm in Kyoto, Japan were reclaimed in 2016. Horse dung manure has been applied to the fields since the fiscal year 2016, and rice cultivation has started thereafter. From 2017 to the present, we have collected topsoil samples from six of the paddy fields every spring. Five fields have received the application of horse dung manure almost every year, whereas one field did not. By analyzing the soil and manure samples collected from 2017 to 2024, we demonstrate the relationship between the input of the elements by the application of manure and the accumulation of the elements in topsoil. We also show the form of the elements in soil by applying the size fractionation to the soil samples.

Soil samples were collected by dividing the six fields into 90 plots. In each plot, a soil sample consisting of five subsamples was taken from the plow layer. The samples collected from the same field were mixed to prepare composite samples to be analyzed. Air-dried, 2-mm sieved soil samples (bulk samples) were subjected to the 20 µm-mesh nylon mesh sieving to collect sand fraction samples (sand samples). After dry combustion or wet digestion of the bulk and sand samples, the contents of the six elements (C, N, P, K, Ca and Mg) were measured. The contents of the six elements in the manure samples were also measured. Then, the inputs of the elements by manure application were compared with those of the elements in the bulk and sand samples. Besides the total elemental contents, chemical properties of the bulk samples were analyzed by conventional methods.

Among the six elements measured, the inputs of C, N and P by horse dung manure were quantitatively comparable to their reserves in topsoil. Repeated application of the manure increased the total contents of C, N and P in topsoil. As more than 90% of the manure applied were classified as particulate organic matter by the nylon mesh sieving, manure-derived C, N and P accumulated in topsoil existed mainly in the sand fraction, i.e. particulate organic matter fraction. In contrast, the inputs of K, Ca and Mg by the manure were much smaller than their reserves in topsoil. Repeated application of the manure did not increase the total contents of K, Ca and Mg in topsoil. Besides these results, bulk samples having received manure applications showed higher contents of available N, available P and exchangeable cations (K, Ca and Mg) than those without manure application. However, the contents of exchangeable Ca and Mg in topsoil with manure applications decreased gradually from 2017 to 2024, suggesting their leaching from topsoil.

In conclusion, comparing the input of the elements by manure and their total amount in topsoil was useful to predict which elements will accumulate in soil by repeated application of manure. In our case, the application of horse dung manure was effective for increasing C, N and P in the sand fraction of topsoil and maintaining the availability of N and P in topsoil.

# Biotic and Abiotic Catalytic Strategies for Accelerated Humic Substance Formation

**M.M.M.Ahmed, Tsung-Hung Wu, Yu-Min Tzou***

*Department of Soil and Environmental Sciences and Innovation and Development Center of Sustainable Agriculture, National Chung Hsing University, 145 Xingda Rd., Taichung 40227, Taiwan*

*E-mail: abomahmoud1113@gmail.com

**ABSTRACT**

Humic substances (HS) are critical for soil fertility and environmental remediation, yet their natural formation requires decades to centuries. This study examines both abiotic and biocatalytic pathways for accelerated HS synthesis through integrated experimental and computational approaches. We investigated graphitic carbon nitride (g- $C_3N_4$) catalysis in promoting hydroquinone (HQ) oxidative polymerization within $MnO_2$ and $Cr_2O_7^{2-}$ systems. As a Lewis base with substantial surface area, g-$C_3N_4$ enhanced metal oxide-polyphenol interactions through π-π stacking, increasing reaction rates 3-6-fold. Electron transfer facilitated by g-$C_3N_4$ proved crucial for in-situ HQ oxidation, producing HS with improved morphology and larger particle sizes. DFT calculations confirmed that g- $C_3N_4$…HQ…metal oxide complexes exhibit higher binding energies and narrower HOMO-LUMO gaps than binary systems, explaining enhanced kinetics. $^{13}C$ NMR spectra validated predicted HS structures. Building upon these insights, we developed a microbial-mineral catalytic strategy enabling rapid HS formation within 15 days through coupled Saccharomyces cerevisiae fermentation and $MnO_2$ catalysis. Systematic comparison of microbial systems revealed a dual-pathway humification mechanism characterized by UV-Vis, FTIR, XRD, SEM, XPS, $^{13}C$ NMR, and DFT analyses. $MnO_2$ preferentially catalyzed aromatic condensation (30-45% carbon) via surface-mediated radical coupling, while microbial metabolism promoted aliphatic carbon formation (50-60%). The S. cerevisiae-$MnO_2$ system achieved optimal balance (~55% aliphatic, ~35% aromatic), producing hierarchical structures resembling natural humic acids with extended visible-light absorption (≤450 nm), moderate $E_4/E_6$ ratios (3-4), and π-π stacking distances of ~4.0 Å. DFT calculations demonstrated $MnO_2$-facilitated electronic activation with 82% HOMO-LUMO gap reduction and nine-fold binding energy increase (111.13 kcal $mol^{-1}$). This work establishes a mechanistic framework integrating abiotic and biocatalytic approaches for tunable, rapid HS synthesis with environmental applications.

# Global Potential Effects Analysis of Biochar on Crop Yields and Soil Quality

**Zhichao Xu[1*], Run Zhou[2], and Guoren Xu[3]**

[1] *Zhichao Xu (College of Resources and Environment, University of Chinese Academy of Sciences, Beijing, China)*

[2] *Run Zhou (College of Resources and Environment, University of Chinese Academy of Sciences, Beijing, China)*

[3] *Guoren Xu (College of Resources and Environment, University of Chinese Academy of Sciences, Beijing, China)*

*E-mail Address of Presenting Author: xuzhichao@ucas.ac.cn

**ABSTRACT**

Biochar has been widely used for soil improvement, but uncertain results persist due to diverse biochar characteristics, soil properties, and crop responses. Therefore, the effects of biochar on crop yields and soil quality were evaluated using effect sizes from 1011 paired data points from field trials, based on a global meta-analysis method. The results indicated that biochar with a higher total phosphorus concentration (≥1.0%), total carbon concentration (≥70%), specific surface area (≥50 m2 $g^{-1}$), and biochar application rates of 10–30 t $ha^{-1}$ are optimal for improving crop yields. Biochar made from manure (effect size, 42%) exceeded that made from ligneous (22%) or cereal (12%) material. Porous, acidic, or young soil types are optimal for biochar application, while sandy and clay soils are preferred over loam soil. Soils with lower available nitrogen (<80 mg $kg^{-1}$), phosphorus (<10 mg $kg^{-1}$), potassium (<120 mg $kg^{-1}$), pH (<4.5), and cation exchange capacity (<10 cmol $kg^{-1}$) were more effective. The effect of biochar on yield is higher for cash crops (oil plants: 37%, vegetables: 28%) compared to food crops (legumes: 26%, maize: 20%, wheat: 12%), with no significant effect observed on rice. Finally, biochar increases crop yields by improving soil quality through enhanced levels of soil organic carbon, total nitrogen, ammonium-nitrogen, nitrate-nitrogen, and soil pH while reducing soil bulk density. Our research enhances understanding of the relationships between biochar, soil, and crops, aiding researchers, manufacturers, and farmers in making informed decisions regarding biochar selection, planting locations, and crop choices. However, it remains unclear to what extent machine learning can accurately predict crop yield or SOC when biochar is applied to soil. In our study, Random Forest (RF) and Multilayer Perceptron Neural Network (MLP- NN) models were employed to predict crop yield and SOC with 297 paired data from field trials. The results indicated that the RF model (test $R^2$ = 0.83) did not differ significantly from the MLP- NN model (test $R^2$ = 0.84) in predicting crop yield. However, the RF model (test $R^2$ = 0.87) performs significantly better than the MLP- NN model (test $R^2$ = 0.53) in predicting SOC. The most influential features for crop yield were found to be the biochar application rate (15%), initial SOC (13%), biochar pH (10%), and biochar TP (10%). In contrast, the variation of SOC was primarily influenced by latitude (26%), biochar application rate (22%), initial SOC (15%), and biochar pH (13%). Furthermore, both crop yield and SOC variation were influenced by multiple factors, not solely one, and their impacts were not necessarily linear. This study suggests that the optimization of biochar pH and phosphorus content, along with the regulation of its application rate in sandy or clay- rich soils, can simultaneously enhance both crop yield and SOC. In the future, we hope to develop a decision support system with prediction, different scenarios, and consultation capabilities based on geospatial location.

# Revalorization of spent coffee ground as peat alternative for soilless culture

**Rui Yang[1*] and Zhiyong Qi[1]**

[1] *Institute of Urban Agriculture, Chinese Academy of Agricultural Sciences, Chengdu, China*

*E-mail Address of Presenting Author: yangrui01@caas.cn

**ABSTRACT**

Peat is a nonrenewable resource that we are using at alarming rates. Development of peat alternative from organic waste could be a cost- and environment-friendly way of disposal. Biochar, which is usually made from thermochemical conversion of organic waste, may partially replace peat during soilless culture, but the high cost for biochar preparation limits its widespread application. We recently developed a torrefaction process that uses the superheated steam (SHS) as the carrier gas and heat transfer medium. Such technology is a more efficient and economical way to produce biochar. Therefore, this study evaluated the potential of SHS torrefied spent coffee ground (SCG), which is a major biowaste of the coffee industry, as a peat alternative. Results indicate that SHS torrefaction at 300℃ for 30 min could effectively eliminate the phytotoxicity of SCG. When peat is replaced by SHS-torrefied SCG for up to 20% (v/v), lettuce yield was maintained or slightly improved relative to pure peat. The content of Chlorophyll a and b in leaf also increased following the addition of SHS-torrefied SCG. The presence of SHS-torrefied SCG in growing substrate also significantly improved lettuce quality attributes such as the content of soluble sugar, soluble protein, polyphenols, and flavonoids, whereas nitrate content in leaf notably decreased. In conclusion, SHS torrefaction could effectively transform SCG into a peat alternative. The SHS torrefied SCG may replace peat for up to 20% (v/v) in lettuce culture without yield or quality penalty.

# Integrated Assessment of Soil Water-Storing Function across Australia: A Multi-Dimensional Approach to Mapping Soil Security

**Amin Sharififar*, Nicolas Francos, Julio Pachon, Alex McBratney**

[1] *School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW 2015, Australia*

* Amin.Sharififar@sydney.edu.au

**ABSTRACT**

The concept of soil security provides a comprehensive framework for assessing the status and vulnerability of soil functions. This study evaluates the security of the soil water-storing function across Australia by integrating all five dimensions of soil security: capacity, condition, capital, connectivity, and codification. We present a multi-criteria approach that combines biophysical, socio-economic, and regulatory factors to deliver a holistic assessment of soil security. Using the pedogenon concept and the Technique for Order PReferences by Similarity to Ideal Solution (TOPSIS), we ranked soil insecurity across defined soil "districts" treated as management zones.

Indicators of soil water-storing function included raster maps (90 m resolution) of available water capacity (AWC) and soil thermal inertia for the top one metre. Normalised average utility scores of these indicators per genosoils was used to represent soil capacity and phenosoil deviations from genosoils as condition. Soil capital (economic value) was assessed based on a linear regression analysis between water holding capacity and farm price. To capture connectivity, we integrated a map of farmers' awareness of this soil function, derived from interviews and a separate study. Codification was assessed through the presence or absence of federal and state legislation explicitly supporting soil water-storing function protection. All indicators were spatially intersected with soil districts map, then, a decision matrix of scores of each dimension for each district was created to calculate the closeness to ideal scores (using TOPSIS). Finally, each district was ranked based on multi-dimensional vulnerability to water loss. The resulting soil security map identifies zones requiring targeted intervention based on their combined biophysical, socio-economic, and regulatory risks. In addition, the most restricting dimension and degree of restrictiveness was calculated for strategic management and planning. This study demonstrates a practical application of the soil security assessment framework for comprehensive soil protection, enabling identification of where and which dimensions of soil security are most at risk.

## ABSTRACT

The dry-hot valley region of southwestern China is characterized by extremely high temperatures, intense evapotranspiration, and highly fragmented terrain, conditions that lead to severe soil erosion, nutrient deficiency, poor tillage conditions, and generally low soil fertility. These factors substantially constrain the sustainable development of regional agriculture. The rational allocation and regionalized promotion of soil fertility enhancement technologies are therefore essential for achieving efficient agricultural utilization and ecological conservation in dry-hot valleys. However, existing studies have predominantly focused on single crops or small-scale field experiments and lack systematic analyses of technology suitability across multiple farmland types at the regional scale, making it difficult to support precise technology deployment under the complex ecological background of dry-hot valleys. To address this gap, this study takes Yuanmou County in Yunnan Province, China, as the research area. Using multisource spatial data, we identify three typical farmland types in the region: sloping farmland, flat farmland, and newly reclaimed farmland. Based on the ecological characteristics of dry-hot valleys and the distinct constraint factors associated with each farmland type, we conduct suitability evaluation and spatial zoning for the existing soil fertility enhancement technologies matched to these farmland types. The evaluation framework is constructed from three dimensions—soil fertility, economic benefits, and key constraint indicators specific to each farmland type—and a combined weighting method is applied to determine the weights of the evaluation indicators, thereby ensuring the scientific quantification of the index system. Through spatialization of indicators and calculation of a comprehensive suitability index, the study aims to generate spatial suitability zoning outcomes for soil fertility enhancement technologies in the dry-hot valley region. Furthermore, multi-scenario simulations are performed to compare different technology-combination scenarios, revealing spatial differences and comprehensive effects, and exploring optimal pathways for regional soil fertility improvement. Overall, this research establishes a differentiated suitability evaluation system tailored to the ecological context of dry-hot valleys, elucidates the spatial distribution patterns and influencing mechanisms of technology suitability among different farmland types, and provides important theoretical support and practical guidance for regional agricultural sustainability and the scientific promotion of soil fertility enhancement technologies.

**ABSTRACT**

Enhancing the fertility of medium and low-yielding land can provide a crucial guarantee for increasing regional grain production. Anhui Province is a major agricultural and grain-producing province. Identifying the natural attributes, types of constraints, affected areas, and spatial distribution of medium and low-yielding land is the prerequisite and foundation for its transformation. This study is based on the findings of the Second National Soil Survey (Soil Gazetteer of Counties in Anhui Province), the National Type Division and Improvement Technology for Medium and Low Yield Fields (NYT310-1996), and the Cultivated Land Quality Grade(GB/T 33469-2016).It analyzes the natural attributes of soils in Anhui Province, constructs an indicator system for identifying constraints in medium and low-yielding land, and uses the overlaid patches of soil maps from the Second National Soil Survey period and cultivated land from the 1980 land use in Anhui as evaluation units. This method identifies different types of constraints in medium and low-yielding land, establishes a distribution map of such farmland in Anhui Province, and clarifies their spatial distribution patterns. Finally, through analysis of soil samples collected in Lingbi County and Fengyang County in 2025, the accuracy of the distribution of medium and low-yielding land was verified. The results indicate that (1) Anhui Province's medium and low-yielding land encompasses 15 soil types, 520 soil species, 4 types of impediments, and 14 impediment factors, with structural impediments covering the largest proportion of the area (29.82%). (2) In terms of spatial distribution, medium and low-yielding land occupies a larger area in the northern and southern regions, with the primary constraints being six factors: leakage, retention, soil erosion, low in soil organic matter, low in available P and K. (3) The province has approximately 4.77 million hectares of medium and low-yielding land, accounting for 61.25% of its total arable land area. (4) In both 1985 and 2017, there was a highly significant negative correlation ($P<0.001$) between the proportion of medium and low-yielding land across counties in Anhui Province and grain yield per unit area. The findings can provide scientific data support for Anhui Province's exploration of transforming medium and low-yielding land and enhancing agricultural productivity.

**Keywords:** medium and low-yielding land; physical soil property; evaluation method; soil constraint factor; Anhui Province

This paper defines medium and low-yielding land as cultivated land where one or more types of soil impediments-including structural type, chemical type, fertility type, soil horizon type, and environmental type - result in low natural soil fertility levels, relatively low and unstable yields.

# An interactive land suitability tool for Queensland, Australia

**Ben Harms[1*], Evan Thomas[1], James Dearlove[1], Stephen Leo[1], Paul Clarke[1], Michelle Hinckfuss[2], Lew Markey[3]**

[1] *Department of the Environment, Tourism, Science and Innovation, Brisbane, Australia*

**ABSTRACT**

An on-line crop suitability tool (CropSuit*) has been developed for Queensland, Australia. The tool automatically draws on available spatial data to produce visual crop suitability outputs. It operates consistently across the state, highlighting areas that are potentially suitable for specific crops in terms of climate, soil and land attributes.

The tool is the culmination of several attempts to make land suitability information in Queensland more transparent and accessible, involving collaboration between different government departments. It meets a recognised need for increased access to land evaluation information to inform decision making, especially at the pre-feasibility stage where land development, diversification or intensification is being investigated.

The derived spatial attributes are matched against crop growth requirements and assessed as limitations in a traditional FAO style land evaluation framework. The tool operates at various scales – at a regional level, climate factors and slope are the only attributes considered, and the areas are broadly assessed as being suitable or unsuitable. As the user drills down, more soil and land attributes are included. When zooming in to the local level (<1,000 ha), results are displayed in five suitability classes for each of the available crops.

The soil and landscape attributes driving the suitability assessments are drawn from Queensland's Soil and Land Information (SALI) database, other statewide datasets and in some cases from the Soil and Landscape Grid of Australia. The variability of the spatial data is assessed by averaging the attributes for 1600 gridded points within the area selected – displaying the mean, median and standard deviation for attributes where the data is numerical, and a percentage for categorical data.

The reliability of the soil data utilised to produce the outputs depends on the intensity of the underlying soil mapping, which varies significantly across the state. The outputs generated are predictions only – it is recommended that detailed on-ground soil and land investigations be conducted prior to making investments at the property level.

The suitability results are displayed as a mosaic of cells – the size of which depends on the dimensions of the selected area. By clicking on a cell, the attributes for that cell, along with a suitability rating for each limitation are displayed. The user can therefore see immediately why a particular parcel of land may be considered unsuitable for a crop, and which attributes are responsible.

The user has the option of overriding the automatically derived spatial data if more accurate information is available, which the tool then utilises to modify the suitability outputs. The ruleset that determines the suitability results is flexible and can be refined over time, while additional limitations and crops may be incorporated.

## ABSTRACT

Harmonised soil information and land evaluation frameworks are essential for sustainable land management and adequate policy development. Understanding land capability is fundamental for supporting productive agriculture and forestry while minimising the risk of land degradation.

In mainland Portugal, soil mapping has been recently updated and harmonised at 1:100,000 scale using the WRB system. This was achieved by reinterpreting 1:25,000-scale legacy soil maps, in which most soil units were either uncharacterised or incompletely described according to WRB rules, lacking key soil property data. Accordingly, legacy soil data were integrated with land units delineated based on biophysical factors (climate, lithology, and relief). The resulting soil mapping units achieved 76–82% correspondence with legacy profiles under two validation scenarios, confirming the robustness of the proposed methodological framework. The approach enabled the identification of key functional properties and limitations associated with climate and topography, providing a basis for characterising land characteristics and qualities.

The present study contributes to the development of a harmonised land capability map for mainland Portugal under Mediterranean climatic conditions. Major limiting factors include temperature regime, slope angle, rooting depth, fertility, toxicity, soil aeration, water deficit period, erosion risk, carbonate and soluble salt content, terraces, and the proportion of rock outcrops. A hierarchical system was defined to classify each land characteristic or quality into four land capability classes for generic agricultural and forestry purposes, based on minimum class requirements. Subclasses were also identified within each class, according to dominant land limitation(s). Validation through a comparison with the national Land Use/Cover Map confirmed high spatial consistency between predicted capability classes and actual land use.

This integrated framework illustrates how digital soil mapping (DSM) products can underpin evidence-based digital soil assessment (DSA) and guide land-use policy, natural resource management, and spatial planning. The methodology is reproducible, scalable, and adaptable to other Mediterranean or similar environments, thereby bridging the gap between soil mapping and practical applications for stakeholders and policymakers. By providing harmonised and interpretable soil data, this approach supports sustainable land management, optimises productivity, safeguards environmental quality, and contributes to long-term food security.

# Spatial heterogeneity and driving factors of five global arable land datasets in China under a ‘single cropland map’ framework

**Surina[1*], Hasituya[12]**

[1] *College of Resources and Environmental Sciences, Inner Mongolia Agricultural University, Hohhot, 010011, China*

**ABSTRACT**

Accurate and harmonized cropland information is a prerequisite for national land spatial planning, cropland protection red lines, and the construction of a unified ‘single cropland map’ in China. In recent decades, rapid advances in remote sensing have produced numerous global and national land use/land cover (LULC) products, but their heterogeneous classification schemes make it difficult to consistently evaluate cropland accuracy and spatial heterogeneity. In this study, we assessed five mainstream cropland products—CACD, CLCD, GLC_FCS30D, WorldCover V200 and ESRI 10 m—after harmonizing them to the FAO “arable-only” definition and a common 30 m area framework. Spatial heterogeneity among products was evaluated from three perspectives: (1) agreement levels used to map cropland heterogeneity at 30 m; (2) provincial-scale agreement with official cropland statistics; and (3) pixel-level accuracy based on a strict leave-one-out References. We further analyzed agricultural climatic zones, a county-level cropland fragmentation index and multiple environmental factors using an XGBoost–SHAP model to identify the main drivers of minimal agreement. Cropland heterogeneity is generally higher in the west than in the east, and higher in mountainous and plateau regions than on plains; humid subtropical hilly regions, the Tibetan Plateau and arid agro-pastoral ecotones emerge as high-risk areas for constructing a consistent base map. CLCD and CACD show the most reliable area and pixel-level performance, GLC_FCS30D is intermediate, while WorldCover V200 and ESRI 10 m exhibit substantial regional biases. Fragmentation emerges as the dominant driver of high heterogeneity, followed by elevation, temperature and slope. These results provide a single-map–oriented basis for selecting and combining cropland products in different regions to support cropland regulation and food security assessment in China.

# Background concentration and range of potentially toxic elements in Lebanese soils for land suitability assessment

**T. Darwish[1*] and Ch.W. Knapp[2]**

[1] *National Council for Scientific Research (National Center for Remote Sensing, Beirut, Lebanon)*

[2] *University of Strathclyde (Department of Civil and Environmental Engineering, Glasgow, United Kingdom)*

*E-mail tdarwich@cnrs.edu.lb

**ABSTRACT**

Land use planning is a crucial factor of land governance and food security. Land suitability for agricultural production must be linked with soil quality. Soil with potentially toxic elements (PTEs) is one of major concerns because they jeopardize the implementation of SDGs (FAO and UNEP, 2021), contaminate agricultural products and threatens public health (Reis et al., 2025). This work aims at assessing the status of soil pollution in Lebanon as prelude to soil quality predefining the suitability for crop production. This ranges from multifunctional land use in soils with PTEs around the natural background concentration to restricted cropping pattern consisting of technical crops, fruit trees and agroforestry in soils with increasing concentration of PTEs. Based on relatively low soil organic matter content varying between 1% and 3% (Darwish and Fadel, 2017), the suitability for specific type of crops in linked in this study with two factors, PTEs content and soil texture. While the trigger threshold for Cr in clay soil is 100 mg $kg^{-1}$, it decreases to 60 mg $kg^{-1}$ in loamy and silty soil (Carlon, 2007). The results of soil analysis revealed 76.3% and 74.3% of studied soils above the natural background value for Cr and Ni (50 mg $kg^{-1}$ to 40 mg $kg^{-1}$), respectively (Figure 1).

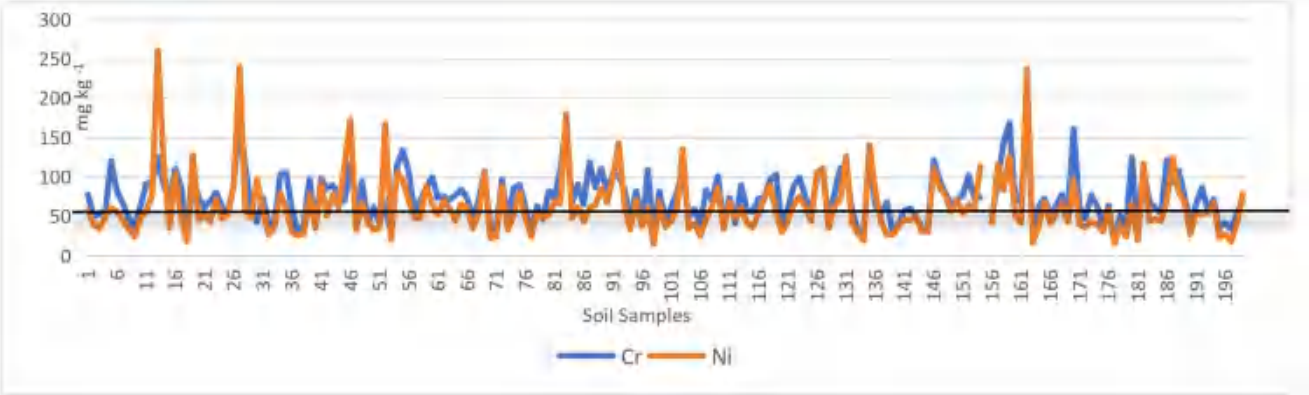

Figure 1. Cr and Ni abundance in selected Lebanese soils (196 soil samples)

The concentration of As and Pb in the root zone showed only 2 soils (1.01%) to exceed the multifunctional land use (20 mg $kg^{-1}$ and 100 mg $kg^{-1}$) for As and Pb, respectively. The content of Cd and Hg was within the permissible level. The geospatial distribution of problematic PTEs will be linked to soil texture and compared in GIS tools with current land occupation to provide recommendations for alternative agricultural and nonagricultural land uses.

# Long-term soil multifunctionality under climate trajectories, land-use transitions, and management practices

**C. Walter[1*], A. Boutier[1], M. Cadel[2], A. Cadero[1], A. Gaillot[3], C. Le Bas[2], B. Lemercier[1], D. Michot[1], D. Montagne[3]**

* christian.walter@institut-agro.fr

**ABSTRACT**

Soils are pivotal to the sustainable provision of a wide range of ecosystem services (SES), including provisioning services (food, water, energy), regulating services (water and air quality, detoxification, etc.) and cultural services. However, the medium- and long-term trajectories of these services under climate change, land-use shifts, and management practices remain poorly documented and therefore still not being fully taken into account in land use planning. The objective of this study was to analyse the joint spatial and temporal changes in a set of ecosystem services provided by soils in two territories that contrast in terms of soil types and socio-economic development. This was realised through the integration of scenario analysis and dynamic modelling.

*Study areas*

The first study area is the 12 km² Kervidy-Naizin watershed (Brittany, France) with a high concentration of livestock, along with major crops of maize, wheat, and both temporary and permanent grasslands. The anticipated evolution of this territory is a transition from intensive agricultural production systems to multifunctional agroecological systems with reduced environmental impacts. The second site is the Saclay Plateau (southwest of Paris), a historically agricultural area of 25 km² under strong urbanization pressure since the 1980s. Land-use categories considered include arable land, grassland, impervious urban areas, and non-impervious urban areas (gardens, parks, simulated as grassland).

*Methods*

The simulations encompassed the period 1991–2050 for Kervidy-Naizin and 1982–2050 for Saclay. Both studies appraised five ES (crop water supply, crop nitrogen supply, carbon sequestration, water quantity regulation, water quality regulation) and biomass production. Climate scenarios (RCP 4.5 and RCP 8.5) and land management scenarios (business-as-usual, European Green Deal, organic farming, energy cropping) were tested in Kervidy-Naizin. Meanwhile, Saclay focused on the combined effects of climate change and land-use transitions.

*Results*

In Kervidy-Naizin, ES provision proved highly sensitive to climate, management, and soil properties (e.g., soil depth). Some services responded synergistically, while others showed trade-offs, highlighting the importance of considering bundles of ES and their interactions.

In Saclay, climate and land-use changes often acted synergistically to reduce SES provision. However, non-impervious urban spaces played a buffering role, mitigating service losses. Responses varied across soil types and services, emphasizing spatial heterogeneity.

*Conclusions*

Collectively, these case studies demonstrate the interactions between climate trajectories, land-use dynamics, and management practices to shape soil-based ecosystem services. They highlight the need to consider multiple services simultaneously, account for synergies and trade-offs, and integrate soil diversity into long-term strategies for sustainable land management and territorial planning.

# Relationships among cultivated land quality, crop yield and economic benefit based on a long-term field experiment with different fertilization and mulching treatments

**Jiubo Pei*, Siyin Wang, Mengmeng Wang, Yao Zhang, Shuangyi Li, Jingkuan Wang**

*Shenyang Agricultural University (College of Land and Environment, Shenyang, China)*

*E-mail Address of Presenting Author:peijiubo@syau.edu.cn

**ABSTRACT**

Clarifying the definite relationship among soil quality, crop yields and economic benefits is of great significance for the rational management of soil quality. A 34-year long-term mulching and fertilization positioning experiment station of Shenyang Agricultural University was used due to the advantages of long-term positioning experiments over 30 years, such as the stable differences in soil quality between different treatments, the controllable and accurate acquisition of evaluation indicators, and the full-process management and economic benefit accounting., 14 treatments including mulching (F) and non-mulching (WF) with single nitrogen application (N2, N4), single organic fertilizer application (M2, M4), combined organic and inorganic fertilizer application (M1N1, M2N2), and no fertilization control (CK) were selected. According to the current national standard of China, "Soil Quality Classification", soil indicators were tested and soil quality was evaluated for different treatments by calculating the comprehensive index of soil quality (*IFI*). The economic benefit was accounted by the input-output data from farmland management, and the relationship between soil quality, crop yield and economic benefit were examined. The results showed, (1) The application of organic fertilizer can stabilize soil pH and increase soil nutrient content, thereby improving soil quality. The treatment with the highest soil quality was WF-M4 treatment, which was 6.78% higher than WF-CK. Single nitrogen application can reduce soil pH and soil nutrient content, leading to a decline in soil quality. The treatment with the lowest soil quality was WF-N4, which was 5.22% lower than WF-CK. (2) Fertilization can effectively increase yield. Under non-mulching conditions, the WF-M4 treatment had the highest yield, which was 161.51% higher than WF-CK. Under mulching conditions, the treatment with the highest yield was F-M2N2, which was 92.55% higher than F-CK. (3) Under single nitrogen application, *IFI* was negatively correlated with yield. The application of organic fertilizer made *IFI* positively correlated with yield. Under single nitrogen application, when the soil quality grade decreased by one level, the yield of non-mulching treatment could increase by 1.84 t $hm^{-2}$, and the yield of mulching treatment could increase by 2.32 t $hm^{-2}$. Under the addition of organic fertilizer, when the soil quality grade increased by one level, the yield of non-mulching treatment could increase by 3.62 t $hm^{-2}$, and the yield of mulching treatment could increase by 3.75 t $hm^{-2}$. (4) Under single nitrogen application, *IFI* was negatively correlated with economic benefit. The application of organic fertilizer led to an optimal combination relationship between *IFI* and economic benefit. Under mulching conditions, the combined application of organic and inorganic fertilizers led to a double-win situation for soil quality and economic benefit. Under single nitrogen application, when *IFI* decreased by 0.01, economic benefit could increase by CNY 1758 to 2717 $hm^{-2}$. Under the addition of organic fertilizer, when *IFI* reached 0.7947 under non-mulching conditions, the economic benefit was the largest, at CNY 13282 $hm^{-2}$. Under mulching conditions, when *IFI* reached 0.7427, the economic benefit was the largest, at CNY 10280 $hm^{-2}$. When *IFI* reached 0.7926, the economic benefit was the largest, at CNY 2678 $hm^{-2}$. (5) The WF-M4 treatment achieved the highest soil quality and the highest yield. The WF-M1N1treatment had the highest economic benefit. That is, under the condition of no mulching, the application of organic fertilizer can enhance soil quality, crop yield and economic benefit simultaneously. In the mulching treatments, to maintain or improve soil quality, the treatment of F-M1N1 or F-M2N2 is required, which can achieve a triple-win situation in terms of soil quality, crop yield and economic benefit.

# Interpretable machine learning models analyze the mechanism of nutrient evolution in red soils of Jiangxi under the dual drivers of climate and social economy

**Chao Xiao**[1*]

*Key Laboratory of Agricultural Resources and Ecology in Poyang Lake Watershed of Ministry of Agri-culture and Rural Affairs in China, College of Land Resource and Environment, Jiangxi Agricultural University, Nanchang, China*

*chaoxiaojxau@163.com

**ABSTRACT**

Understanding the spatial variability and driving mechanisms of soil nutrients is critical for sustainable agricultural management in the red soil region of Southern China. However, decoupling the complex interactions between natural environmental factors and intensifying socioeconomic activities remains a challenge. This study focuses on Ji'an City, a typical red soil area, to predict the spatial distribution of six key soil properties—pH, base saturation (BS), soil organic carbon (SOC), total nitrogen (TN), total phosphorus (TP), and total potassium (TK)—and to unravel their driving forces. We developed an interpretable machine learning framework by integrating multi-source data (climate, topography, vegetation, and socioeconomic indicators) with the SHapley Additive exPlanations (SHAP) approach. The results demonstrated that the optimized machine learning models achieved robust predictive performance, with coefficients of determination ($R^2$) ranging from 0.62 to 0.85 for the validation datasets. The SHAP analysis revealed that the spatial evolution of soil nutrients is governed by a dual-drive mechanism involving both climate change and socioeconomic development. Specifically, SOC were primarily controlled by climatic factors such as mean annual temperature, exhibiting strong zonal characteristics. In contrast, TP, TK, and pH were more sensitive to socioeconomic drivers, such as fertilizer application rates, reflecting the dominant footprint of anthropogenic management. Furthermore, the study identified significant non-linear threshold effects; for instance, SOC levels decreased sharply when temperature exceeded 2°C. These findings overcome the "black box" limitation of traditional modeling and provide a mechanistic basis for site-specific soil management. The study suggests that policy interventions for soil acidification and nutrient balancing in Ji'an City must account for the spatial heterogeneity driven by these coupled climate-socioeconomic forces.

# Soil–Geochemical Controls of NDVI Seasonality in Steppe ecosystems of the Turano–Uyuk Intramontane Depression (Tuva, South Siberia)

**ABSTRACT**

In steppe landscapes under a sharply continental climate, the annual course of the phytoproductive process is governed by soil water regime and nutrients availability / However the contribution of soil–geochemical conditions to intra-seasonal phytomass dynamics remains poorly quantified. This study aims at identifying relationships between moisture regime types, soil properties and the annual course of green phytomass in landscape units of the Turano–Uyuk intramontane depression (Tuva, South Siberia). We tested the hypotheses that (1) the temporal pattern the annual NDVI fluctuations reflects the type of moisture regime and nutrient availability, and (2) combined NDVI and soil–geochemical characteristics can be used to infer the structure of radial and lateral fluxes of water and dissolved substances.

For May–September 1990–2024, NDVI time series were derived from Landsat imagery and smoothed using locally weighted regression (LOWESS) with day of year as the temporal coordinate. We tested whether NDVI fluctuations were related to temperature and precipitation variability measured at nearby meteorological stations. Hydrothermal anomalies were extracted using STL decomposition. In Google Earth Engine, VCI, NDVI derivatives and the Greenest Day of the Year were additionally calculated. In 2024–2025, 31 field sites representing major landscape types were surveyed: landscape descriptions, measurements of green phytomass and litter, and soil sampling from humus horizons were carried out. Soils were classified according to the Russian Soil Classification (2004), and standard physical and chemical analyses were performed.

Five groups of landscape units differing in the combination of water regime and soil–geochemical properties were identified ranging from eluvial xerophytic steppes on cryoarid soils to superaquatic halophytic communities on dark and gleyic solonchaks. Xerophytic and mesoxerophytic steppes exhibit a bimodal annual NDVI pattern (with early July and mid-August peaks) with an intermediate decline and maximum interannual variability in late July; they also show an early-summer delay or short-term decrease in green phytomass, coinciding with low snow water storage and rapid desiccation of light loamy cryoarid soils. Hydromorphic floodplain units and groundwater discharge zones are characterized by later, typically single summer NDVI peaks and reduced interannual variability. In halomorphic superaquatic units with sulfate–magnesium–sodium and chloride–carbonate–sodium salinity and high contents of nitrate nitrogen, available potassium, gypsum and sulfates, NDVI displays the most prolonged summer increase and minimal response to interannual hydrothermal fluctuations.

The results support the hypothesis that the annual NDVI curve is a useful diagnostic indicator of water regime type and nutrient availability in steppe landscape units. The interpretation of the identified sequence as reflecting gradients of radial and lateral water and solute fluxes is consistent with NDVI and soil–geochemical patterns, but remains a working hypothesis that requires direct measurements of water and salt fluxes.

This study was supported by the Russian Science Foundation (RSF), Project No. 24-17-00045.

**ABSTRACT**

Soil multifunctionality reflects the capacity of the soil to provide multiple ecosystem functions and services (Garland et al., 2021). It isjointly determined by biotic and abiotic factors(Y. Shi et al., 2025).The MUSE method-originally a French acronym for Method for the Evaluation of Soil Multifunctionality-is a Digital Soil Mapping (DSM) approach that evaluates-scoresfour soil ecological functions: carbon storage, biodiversity storage, infiltration capacity, and agronomic potential(Branchu et al., 2021). These functions are assessed individually and in combination through a scoring system that enables the spatialization of results and the evaluation of soil multifunctionality.The scoring system allowsalsoguidanceof soil management practices by promotinginformed decision-making aimed at preserving soil functions.

The EU-funded Horizon Europe SPADES(Spatial Planning and Design with Soil)project aims to integrate soil health into spatial planning and design. By promoting soil literacy and gatheringadaptable tools, methods and instrumentsamong thecountries involved inthe project, SPADESis putting soil health at the heart of planning for the benefit of current and future generations.Grenoble-Alpes Metropolis(GAM)isone of 17 SPADES research pilots that form the core of cocreation to learn, develop and test transferableresults-recommendationsregarding soilhealth integration in spatial planning and design.(For further information, see the SPADES project website: Home | SPADES).

Grenoble-Alpes Metropolisisinsoutheastern France, nestled in a valley surrounded by the Alps.Its territory includes a unique combination of dense urban centers, agricultural lowlands, forested hills, and mountainous natural parks, which creates a mosaic of landscapes with distinct soil characteristics and functions. GAM is experiencing urban sprawl, habitat fragmentation, and soil degradation due to construction, infrastructure development, and intensive land use. Soil sealing and compaction are common in peri-urban and commercial areas, while agricultural soils face risks of erosion and conversion. These trends threaten the ecological, agricultural, and climate-regulating functions of soils(For further information, see the SPADES project website: Home | SPADES).Moreover, while the region is environmentally ambitious, integrating soil data and soil health into spatial planning frameworks remains a complex task. Local planning documentsoften lack detailed or accessible soil information, limiting the capacity of planners to make informed, soil-sensitive decisions.

Within the framework ofSPADES project, this study aims to testthe MUSE method at the Grenoble-Alpes Metropolispilot site toassess soil multifunctionality and support soil-informed land-use planning.The outcomesof the study willeventually(ii) helpintegrating soil intelligence into decision-making processes, the approach seeks to guide soil management practices that preserve soil functions, improve soil quality, and promote sustainable land use. As a SPADES pilot territory, Grenoble-Alpes Metropolisintends to operationalize this soil-smart approach in local planning instruments, particularly through the revision of key planning documents, ensuring that soil functions, and sustainability criteria are explicitly considered. (ii) Supportthe development of an improved access to soil data for planners, positioning Grenoble-Alpes Metropolisas a model for soil-conscious territorial planning.

# Assessing the Physico-Chemical Properties and Fertility Status of Selected South African Wetland Soils Using XRF, SEM, and Soil Fertility Index

**Kutu FR[1*], and Aboginije SG[2]**

[1] *School of Agricultural Sciences, Faculty of Agriculture and Natural Sciences, University of Mpumalanga, Mbombela, 1200, South Africa*

[2] *Food Security and Safety Focus Area, Faculty of Natural and Agricultural Science, North-West University, Private Box X2046, Mmabatho 2735, South Africa*

*E-mail Address: Funso.Kutu@ump.ac.za

**ABSTRACT**

Soil fertility status and the inherent quality indices provide fundamental information on the appropriate management strategy required to support crop growth, increase agricultural productivity, and guarantee food security. This study evaluated the physico-chemical features of four selected wetlands in the North West Province of South Africa. Thirteen geo-Referencesd soil profiles were dug in the study areas, and described according to the FAO guidelines for profile description, followed by soil sample collection for various determinations. The soil fertility status was subsequently assessed using X-ray fluorescence (XRF), scanning electron microscopy (SEM), and soil fertility index (SFI). The highest sand, silt, and clay contents were recorded in Pilanesberg Kgama, Mahikeng, and Klerksdorp, respectively. The bulk density of the surface and subsurface soil horizons across all profiles ranged from 1.16 to 1.30 g/cm$^3$ and was statistically comparable. The moisture content ranged from 3.96 to 25.87% (mean=12.75%; CV=54.59%). The mean infiltration rate ranged from 7.58 to 11.83 mm/hr (mean= 9.37 mm/hr; CV=21.1 mm/hr). Soil porosity ranged between 51.19 and 64.00% (mean=56.88%; CV=6.21%) while the silt/clay ratio ranged from 0.34 to 1.09 (mean=0.62; CV=61.96%). Analysis of variance results revealed a significant ($p \leq 0.05$) variation in the silt/clay ratio among the different profiles. Soil pH ($H_2O$ and KCl) across the different horizons ranged from 6.56 to 10.28, indicating slightly acidic to very strongly alkaline. Soil organic matter levels ranged from 0.29 to 7.73% across different soil depths, with decreasing concentrations at lower soil depths. A slightly elevated total N content was observed in the surface horizons with higher available P levels in the surface horizons (range: 0.09 to 55 mg/kg) than the subsurface horizons (range: 0.04 to 49.50 mg/kg) in the respective profiles, mostly at Mahikeng and Potchefstroom. The concentration of extractable micronutrients in all examined profiles was in the order of Mn> Fe>Mo>Cu>Ni>Zn>Cr. The correlation analysis of soil chemical properties revealed that organic matter has a highly significant correlation with total N, a moderately significant correlation with K and Ca, but a negative correlation with Mg, while it showed a highly significant correlation with the C: N ratio. The XRF results revealed the preponderance of P, K, Ca, Mg, S, Cl, and Mn, with fewer Na in key profiles across the different sites, while the SEM images showed that soil samples were mostly characterised by fragments and agglomeration of compacted soil layers, indicating leaching losses within the different horizons of these wetlands. The soils' physical and chemical properties revealed significant potential for wetland soils to support sustainable agricultural production with best management practices.

## ABSTRACT

Climate change is reshaping Nordic climate, altering both temperature and precipitation patterns. Winters are no longer able to maintain stable snow cover, which leads to dry springs, while summers bring heavier rainfall and extended heatwaves. These shifts are disrupting the delicate soil-water balance, putting crop production in Finland under increasing pressure. Different soil types respond very differently to these changes: clay soils are prone to surface flooding, while sandy soils struggle to retain water and rely on groundwater that is often too deep for plants to access. This research is part of the Water and Food Futures project, under Strategic Research Council's Water for Welfare, Security and Peace program. Our goal is to provide robust evidence to support agricultural policy promoting adaptation to climate change by linking climate scenarios, soil- and water dynamics, crops production, and economics through an integrated modelling approach[1].

The bioeconomic framework brings together four interlinked elements: long-term climate projections, crop productivity simulations, soil hydraulic modelling, and economic analysis of water competition. Climate and $CO_2$ levels feed into AquaCrop[2], which has been carefully calibrated for Finnish conditions to capture crop growth and soil moisture dynamics down to 12 soil layers. A novel approach includes new crops and intercropping systems, enabling assessment of productivity, water-use efficiency, and resilience. Model outputs are tested against in-situ soil sensor measurements to ensure grounding in real-world conditions. The novel economic component examines how water allocation options affect both agriculture and biodiversity protection in inland and coastal waters[3].

We aim to identify key temperature and precipitation thresholds affecting crop yields, soil moisture and irrigation demand. This will help to identify cost-efficient adaptive strategies for rainwater harvesting, smart irrigation systems and crop diversification. By accounting for shadow water costs, we will make transparent the trade-offs between farming needs and protecting biodiversity. These findings will feed into practical decision-support tools and shape the next stages of the project, including field trials, adaptive management and policy development.

# Will supplemental fertigation benefit potato productions with a changing climate in Atlantic Canda?

**Sheng Li[1*], Yulia Kupriyanovich[1], Claudia Goyer[1], Dahu Chen[1], Sheldon Han[1], Yefang Jiang[2]**

[1] *Fredericton Research and Development Center, Agriculture and Agri-Food Canada, Fredericton, Canada*

[2] *Charlottetown Research and Development Center, Agriculture and Agri-Food Canada, Charlottetown, Canada*

*E-mail sheng.li@agr.gc.ca

**ABSTRACT**

Potato is the most important cash crop in Atlantic Canada (AC). Potato is very sensitive to water supply but seasonal precipitation in AC usually meets the need for potato growth so that commercial potato cropping is mostly rain-fed in this region. However, with climate change, extreme climate events, including extended period of drought, occurred more frequently in recent years. Introducing irrigation to supplement rainfall can be a viable solution to combat drought. On the other hand, on commercial potato fields in AC, fertilizer is normally applied only once at planting thus significant nutrient loss to the environment through leaching and greenhouse gas (GHG) emissions are observed . Supplemental irrigation provides an opportunity to add fertilizer with the irrigation water (i.e., fertigation) and the application rate can be adjusted according to plant growth. Fertigation can not only increase the efficiency of N fertilizer but also reduce N loss. To test these hypothesized effects of supplemental fertigation, a field study was carried out at McCain Food Farm of the Future in Florenceville, New Brunswick. Three fields were used. Potato was cropped in a three year rotation in these fields and each year, only one field was cropped with potato. Experiments were conducted on the potato field only with three treatments: 1) full fertigation (FF), for which fertigation was applied for the entire growing season. 2) critical period fertigation (CPF), for which fertigation was only applied during the vegetative growth and tuber bulking stages; and 3) no irrigation (NI), as the control. For FF and CPF, N fertilizer rate at banding was approximately 70% of the normal rate and the N added with irrigation water was lower than 30%, resulting in an overall lower N fertilization rate. Water was applied only when soil moisture was below 70% of available water capacity. Irrigation was successful in maintaining desirable soil moisture content. NI had higher emergence rate, longer flowering period, greener leaves at earlier stages, probably due to the higher N fertilization rate at the beginning. The treatments did not show effects on stem counts, plant height and leaf stomatal conductance. The two fertigation treatments showed significantly higher total tuber yield than the control and a similar trend was observed for marketable yield , albeit the difference was not statistically significant. The two fertigation treatments also reduced the occurrence of diseases such as potato early dying and black dot, however, CPF appeared to lead to a higher risk of hollow heart. These results suggested that supplemental fertigation is beneficial in increasing potato crop productivity in AC. Field experiment is ongoing to test the treatment effects on N leaching and GHG emissions.

# Effects of testing non-AI autonomous precision deficit irrigation scheduling onto potato and raspberry crops in Poland.

**R. Wawer*, A. Lopatka, J. Kozyra, M. Matyka**

[1] *Institute of Soil Science and Plant Cultivation - Stat Research Institute, Pulawy, Poland*

*huwer@iung.pulawy.pl

**ABSTRACT**

The direct measurement of soil moisture in root zone provides an unambiguous assessment of current soil moisture and the water deficit (7, 15, 22, 25).). It allows for maintaining moisture strictly within the optimal range for a specific crop species and variety (7).

In modern irrigation support systems, sensors are permanently installed in the root system, measurements are taken hourly, and values are accessed via smartphones, which immediately calculate the optimal dose (7, 8).

It must be noted that tools providing only soil moisture percentage are practically useless unless the soil type is known, as each soil type has a different water holding capacity characteristic (11). For instance, 12% moisture might signify optimal saturation for light loamy sand, but the same value would indicate permanent wilting for clay soil (11).

Case Study: The ENORASIS Decision Support System

Precision irrigation utilizing Agriculture 4.0 technologies is exemplified by the ENORASIS system. Developed between 2012 and 2014 by a team of scientists (including IUNG-PIB) and European IT companies, ENORASIS is an innovative decision support system for agricultural irrigation (12). The project was funded by the European Commission under the 7th Framework Programme (Eco-innovation) (12).

The ICT system (22) determines irrigation needs based on mathematical models using current meteorological conditions, satellite imagery, short-term weather forecasts, and, critically, direct soil moisture measurements taken under the crop (13). Information regarding the required timing and water dose is transmitted to the farmer via SMS (cellular network), the ENORASIS website, and a mobile application (13).

The system was tested at five pilot sites: Poland (2), Serbia, Turkey, and Cyprus (15). These sites were equipped with the wireless sensor network, an automatic meteorological station, and specialized numerical weather forecast services (15). System control was managed via a web browser application and an Android mobile app (16).

Pilot results demonstrated significant effectiveness:

• In Grabów in 2014, ENORASIS-guided irrigation led to a yield increase of 61% for corn and 67% for potatoes compared to non-irrigated plots (16). This was achieved with low operational costs and significant water savings, reaching 42% (16).

• On a raspberry plantation located on shallow sandy soils, direct measurement resulted in a 10-fold reduction in water consumption (18) with no negative impact on yield (18). The owner reported slightly better qualitative parameters for the fruit and healthier plants (18).

# Climate-change-induced Increase in Rain Erosivity in Germany

**Karl Auerswald[1*], Franziska K. Fischer[2], and Tanja Winterrath[3]**

[1] *Technical University of Munich, School of Life Sciences, Freising, Germany*

[2] *Norwegian Institute of Bioeconomy Research, Norway*

[3] *German Weather Service, Offenbach, Germany*

*auerswald@tum.de

**ABSTRACT**

Rising air temperatures are shifting precipitation regimes by reducing snowfall in favor of rainfall, increasing atmospheric moisture capacity, and promoting a transition from advective to more convective rainfall. These changes should also modify rain erosivity.

Analyses of rain-gauge measurements and high-resolution radar rainfall data indicate that rain erosivity has doubled between the 1960s and 2025 in Germany. The trend has intensified markedly since the early 1990s, closely tracking the acceleration of global temperature rise. Notably, this substantial increase in erosivity has occurred without corresponding changes in monthly precipitation totals, raising questions about the suitability of the commonly used Modified Fournier Index as a proxy for estimating rain erosivity from climate projections.

The intra-annual distribution of erosivity has also shifted, with disproportionately strong increases during the cold season. As a result, the susceptibility of crops to erosion has changed. In particular, crops providing limited winter ground cover, such as winter wheat, now face substantially higher erosion susceptibility. Considering both the rise in rain erosivity and the heightened susceptibility to erosion, soil erosion in winter wheat has increased approximately fourfold over the past few decades due to climate change.

# Mapping Gully Erosion Across the European Union

**Pasquale Borrelli[1*], Panos Panagos[2], Christine Alewell[3]**

[1] *Department of Science, Roma Tre University, Rome, Italy*

[2] *European Commission, Joint Research Centre (JRC), Ispra, Italy*

[3] *Environmental Geosciences, University of Basel, Basel, Switzerland*

*pasquale.borrelli@uniroma3.it

**ABSTRACT**

Gully erosion represents one of the most severe forms of land degradation in Europe, yet its large-scale distribution and drivers remain poorly documented. The 2022 LUCAS survey provides the most comprehensive EU-wide assessment to date, combining in situ and on-screen observations across 399,591 locations to map visible gully erosion features. The resulting GE-LUCAS v1.1 (Borrelli et al., 2025a) inventory identifies 3,116 sites (~0.8% of surveyed points) affected by gully erosion, with a pronounced concentration in Mediterranean regions such as Spain and Italy . Land-cover analysis shows that olive orchards alone account for ~25% of all mapped gully observations, highlighting their disproportionate exposure to severe soil degradation.

Insights from recent assessments of Mediterranean olive systems reinforce this pattern (Borrelli et al., 2025b). Intensive ground-cover removal, cultivation on increasingly steep terrain, and climate-driven droughts and high-intensity rainfall have created conditions where soil loss in olive groves routinely exceeds 29–47 t $ha^{-1}$ $yr^{-1}$, and can surpass 455 t $ha^{-1}$ $yr^{-1}$ in gully-affected areas. Spatial analyses from Andalusia further estimate 300,000–350,000 gullies in olive landscapes, far exceeding earlier approximations. These findings show that gully erosion in olives is not an isolated phenomenon but part of broader, interconnected degradation pathways involving water and wind erosion, tillage, nutrient depletion, and declining soil organic carbon.

The GE-LUCAS v1.1 dataset thus provides critical evidence that Mediterranean olive systems are emerging as early warning indicators of accelerating land degradation in Europe. Together, these results underscore the urgent need for targeted, soil-conserving management and policy interventions capable of building resilience in erosion-prone agroecosystems.

# Can soil magnetism affect the soil response to the magnetized water?

**Rama T. Rashad[1] and Alshymaa M. Guda[2*]**

[1] *Soils, Water and Environment Research Institute (SWERI) - Agricultural Research Center (ARC), Giza (Egypt)*

[2] *Earth's Geomagnetism Lab, National Research Institute of Astronomy and Geophysics (NRIAG), Helwan (Egypt)*

*shimaaguda@yahoo.com, alshymaa@nriag.sci.eg

## ABSTRACT

Climate change induced soil and water salinization, necessitating sustainable remedies. Magnetized water (MW) technology enhances irrigation efficiency and alleviates salinity effects on soil productivity. However, several soil variables may constrain the efficacy of MW technology for irrigation. The impact of the soil magnetism (SM) on soil response to MW remains insufficiently investigated, highlighting a knowledge gap. Here we present a mineralogical, magnetic, and chemical characterization for 5 distinct Egyptian saline and non-saline soils; clayey, calcareous, and sandy soils. Furthermore, we selected 3 samples for an experimental study to evaluate their response to MW considering changes in their physico-chemical characteristics. The assessed magnetic properties: mass specific susceptibility ($\chi_{lf}$), frequency-dependent susceptibility ($\chi_{fd}$%), normal remanent magnetization (NRM), and S-ratio showed a great reliance on the mineralogical and chemical composition. The soils rich in Al, Fe, Mn, and Ti showed the highest $\chi_{lf}$ and NRM values in the range 27.6 - 8.86×$10^{-7}$$m^3$/kg and 6.83-18.6×$10^{-7}$A/$m^2$.kg for $\chi_{lf}$ and NRM; respectively) while minimum values are in soils rich in Si and Ca that were 0.37×$10^{-7}$$m^3$/kg and 0.97×$10^{-7}$A/$m^2$.kg for $\chi_{lf}$ and NRM; respectively. Calcareous and saline soils underwent MW treatment where their response was assessed via the change in physico-chemical characters; hydraulic conductivity (HC), aggregate-size distribution, pH, electric conductivity (EC), zeta potential (ζ), $CaCO_3$ (%), OM (%), soluble anions and cations, and magnetic properties. The aggregate-size distribution showed an increase in fine fraction (<90μm) in the calcareous sample while an increase in the coarse fraction (1-2 mm) by 38.2 and 35.7% took place in saline samples. Hence, MW increased the HC in saline soils by 31.4% (loamy sand) and 77.1% (sandy loam) rather than calcareous soil where HC is reduced by 25.1% compared to the non-magnetized water (NMW). Both MW and NMW significantly decreased the EC where soluble cations and anions ($Na^+$, $K^+$, $Cl^-$, and $Ca^{+2}$) were mostly washed. However, the decrease by MW is less than NMW by 12% and 26.8% in the calcareous soil and loamy sand soil; respectively and more than NMW by 31.12% in the sandy loam sample. The MW has slightly decreased the $\chi_{lf}$ and NRM for all samples with no significant changes in S-ratios, while the $\chi_{fd}$% significantly dropped by 47.36% and 88.76% in the saline samples, indicating a great reduction in the super-paramagnetic (SP) particles content. Overall, MW affects the soil chemically, physically, electrically, and magnetically. The interactive effect of MW and SM, depending on the aforementioned factors, may decide its efficiency for MW technology application in the agricultural field. However, the overall effect of the MW on soil cannot be predicted, and each soil type may be a special case of complex interactive factors differing with soil conditions and irrigation water source.

# Theory and Demonstration of Smart Water and Soil Management Technologies for Black Soil Cropland

**Huanjun Liu**[1*]

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun 130012, China*

*liuhuanjun@iga.ac.cn

**ABSTRACT**

Extreme climate change has heightened the uncertainty of hydrological processes in the Black Soil Region, northeast China, leading to concurrent risks of drought and waterlogging alongside runoff-induced erosion, which threatens soil conservation and crop production. Drawing upon the differentiated soil, climate, and agricultural production factors in Northeast China, this study establishes a smart water and soil management strategy for Black Soil cropland to adapt to climate change. By utilizing an integrated space-air-ground monitoring system to assess soil physicochemical properties and the type and severity of degradation, we constructed a precision water control system that integrates surface and subsurface measures—specifically contour tillage, cultivable ridges, subsurface drainage, and vertical shafts. The system is coupled with soil optimization techniques, such as variable fertilization to achieve comprehensive regulation of water and soil resources. Furthermore, supported by an intelligent management platform and mobile APP, the system enables the intelligent configuration of the full operational workflow, encompassing "monitoring, diagnosis, decision-making, and execution." The implementation of this integrated system facilitates precise water regulation and soil optimization management, significantly enhancing the capacity for soil erosion control and water use efficiency under extreme climate conditions, thereby providing tailored solutions for the sustainable utilization of soil resources.

[5] *Gan Shaoan (School of Land Engineering, Chang'an University, Xi'an)*

*E-mail: hanshuanglei@chd.edu.cn

**ABSTRACT**

As one of the most serious soil erosion regions in the world, the Loess Plateau has received extensive international attention for the effectiveness of soil and water conservation stages and the ecological adaptability of vegetation configuration patterns. In recent years, large-scale afforestation has significantly improved the vegetation cover of the Loess Plateau, and the erosion condition has been mitigated at a stage, and the ecosystem function has been initially restored. However, the early vegetation restoration process exists species configuration homogenization, spatial layout homogenization and other problems, despite the increase in vegetation cover, but the stability of the vegetation structure is insufficient, transpiration caused by the increase in the soil moisture deficit is also increasingly apparent, part of the regional vegetation restoration has exceeded the ecological carrying threshold, a serious constraint on the long-term stability of soil and water conservation benefits. In response to the lack of vegetation sustainability exposed by the current ecological restoration mode of "promoting the whole region", we propose an adaptive zoning management strategy based on topography, rainfall pattern and climatic gradient, delineate differentiated vegetation restoration zones, and construct near-natural vegetation restoration standards in different habitats, in order to optimize the vegetation restoration layout and optimize the water and soil conservation management strategy for the Soil and Water Conservation Program on the Loess Plateau under the background of climate change. This provides theoretical support and practical paths for the optimization of vegetation restoration layout and the sustainable and stable performance of soil and water conservation benefits in the context of climate change on the Loess Plateau.

# From Free-Draining to Flood-Forming: How Compaction and Slaking Generate Runoff in Sandy Soils Under Extreme Rainfall

**Paul Henry Lunt[1*], Rupert Goddard[1], Richard Smith[2] and Will Blake[1]**

[1] *Faculty of Science and Engineering, School of Geography, Earth and Environmental Sciences, University of Plymouth, Plymouth PL4 8AA, UK*

[2] *Environment Agency, Manley House, Kestrel Way, Exeter, Devon, EX2 7LQ, UK*

*paul.lunt@plymouth.ac.uk

**ABSTRACT**

Climate change is increasing the frequency and intensity of extreme rainfall in the UK, with annual totals rising by around 30% in Southwest England over the last century and storm intensities exceeding 30 mm $hr^{-1}$. Light sandy soils, such as the Bromsgrove series over Triassic sandstone, are naturally free draining and typically saturate at only 40–50%. As a result, the UK Centre for Ecology and Hydrology Flood Estimation Handbook classifies them as low risk for overland flow. However, recent flood events linked to cultivated sandy soils have revealed a growing vulnerability, with sediment-laden runoff damaging homes, infrastructure, and drainage systems.

Intensive land management can transform these normally permeable soils into runoff-prone surfaces. Compaction from machinery or livestock reduces infiltration capacity, while extreme rainfall can trigger slaking, where rapid aggregate breakdown forms a thin sand–silt seal that further restricts infiltration. Together, these processes create conditions in which even free-draining sandy soils generate overland flow.

To investigate these mechanisms, field trials (July–October 2025) compared infiltration and sediment runoff under soil water-deficit conditions. Replicated plots of cultivated bare soil, newly established grassland, and maize (growth stage 5-6) were subjected to simulated rainfall at 74 mm $hr^{-1}$, representing a projected late-21st-century 1-in-150-year event for Southwest England under Hadley Centre RCP 8.5 scenarios. Surface runoff ranged from 36% in compacted maize plots to zero in newly established grassland. Bulk density in wheelings reached 1.55–1.90 g $cm^{-3}$, compared with 1.22–1.30 g $cm^{-3}$ in untrafficked soils. Soil organic matter was low (3.5–4.0%), typical of long-term cultivated mineral soils. Exposed post-harvest soil produced peak sediment concentrations >20,000 mg $L^{-1}$, while grassland produced none and trafficked maize plots yielded 2,000–8,000 mg $L^{-1}$.

Laboratory rainfall simulations supported these findings: aggregate stability was initially 60–80% after 40 minutes at 74 mm $hr^{-1}$ but fell below 10% on second exposure, demonstrating that aggregate breakdown is cumulative. Repeated rainfall progressively weakens aggregate structure, increasing susceptibility to sealing and runoff.

Overall, the results show that sandy soils long regarded as free draining can become flood-forming systems when affected by compaction and surface slaking. In contrast, grassland cover and good soil condition maintained infiltration even under extreme rainfall, highlighting the importance of soil management in mitigating climate-driven runoff risks.

## ABSTRACT

Soil erosion, exacerbated by climate change, threatens agricultural productivity and carbon sequestration in the Yangtze River Basin (China), highlighting the need for effective conservation strategies. However, the combined impact of climate change and land use change on soil erosion remains poorly understood, and the effectiveness of agricultural conservation measures at the basin scale is largely unknown. Here, we develop a cross-scale framework that integrates process-based modelling (using the PESERA model), meta-analysis, and machine learning to project future trajectories (2020-2060) of soil erosion, aboveground biomass (AGB), soil organic carbon (SOC), and crop yields under multiple climate and land-use scenarios, and to quantify the implementation effects of agricultural conservation practices across the Yangtze River Basin. Our results show that soil erosion rates showed an increasing trend under all four SSP scenarios, but with varying magnitudes of increase. Specifically, the increases in soil erosion were particularly pronounced under SSP2-4.5 and SSP5-8.5 scenarios, reaching 54.0% and 50.4% above the 2020 baseline level by 2060, respectively. In contrast, the increases were relatively moderate under the sustainable development pathway SSP1-2.6 and the regional rivalry pathway SSP3-7.0 scenarios, at 8.8% and 10.3%, respectively. AGB increased significantly under the SSP1-2.6, SSP2-4.5, and SSP3-7.0 scenarios (with increases ranging between 19.5% and 20.7%), but showed a smaller increase (11.1%) under the SSP5-8.5 scenario. The trend in SOC was closely related to emission levels: it increased (by approximately 7.6%) under low-emission scenarios (SSP1-2.6 and SSP2-4.5), but decreased (by 4.0% and 6.9%, respectively) under high-emission scenarios (SSP3-7.0 and SSP5-8.5). Crop calorie output increased slightly (by 3.8%) under SSP2-4.5, remained essentially stable (a slight decrease of 0.1%) under SSP1-2.6, but decreased by 12.4% and 38.5% under SSP5-8.5 and SSP3-7.0, respectively. An optimized combination of soil and water conservation measures (SWCM) can substantially reduce mean soil erosion on croplands by 75.3%, while increasing SOC by 20.7% and crop yield by 15.4%, relative to a no-conservation scenario (SSP5-8.5). Bridging field evidence with basin-scale projections, our integrated analysis demonstrates the value of targeted SWCM implementation in enhancing soil conservation, carbon sequestration, and food security, providing timely insights for climate-resilient land management in the Yangtze River Basin and beyond.

**ABSTRACT**

Soil erosion by water is depending on the classical factors like soil erodibility, rainfall erosivity landuse and landcover pattern as well as agricultural management practices and topographic characteristics. Having the respective combination and intensities of these factors specific soil erosion processes may develop. Thus, different soil erosion processes can be simulated if the relevant input data are available. However, the role of other influencing factors such as frost process dynamics, the influence of soil fauna, subsoil features, or the role of Paleo-landscape features is often neglected in soil erosion assessments. Particularly, the Paleo-landscape features may play a more significant role than expected, at least in specific environments characterized by different climatic conditions in the past. Our study investigates two different case studies in semi-arid areas of Southern Africa and in a cold Northern-hemisphere climate. In our study we particularly focus on gully erosion. We show that paleo-processes and related landscape characteristics still influence present day dynamics. We show for the two study cases why and where in the present-day landscape soil erosion processes may occur. The results reveal that the prediction of soil erosion susceptibilities increases significantly if Paleo-landscape features are taken into account.

## ABSTRACT

Soil and water are fundamental resources for human and other living organisms, and their degradation can entail irreparable consequences. It also plays a key role in food security, the national economy, and sustainable agriculture. Therefore, efficient and effective protection of soil and water, in light of population growth and unsustainable exploitation of natural resources, is of particular importance. The presence of waste arising from various activities has created short- and long-term adverse environmental impacts. Today, environmental protection and waste recycling are among the most critical issues in human societies. Given the finite nature of resources, researchers are seeking ways to optimize the use of unusable waste. Among various additives and modifiers, biochar can play a significant role in waste management. In this regard, this research was planned to manage rice waste and convert it into morphogenetic porous biochar for use at a 5% weight to control and reduce surface runoff and its components. For this purpose, rain simulation experiments on loess soil were conducted on the scale of small experimental plots with dimensions of 0.5×0.5 m with a slope of about 15% under rainfall with an intensity of about 70 mm $h^{-1}$ lasting for 30 min with three repetitions in the Rain and Erosion Simulation Laboratory of Tarbiat Modares University, Iran. The results of the study showed that the treatment combined with porous rice straw biochar significantly ($p<0.001$) increased the time to runoff, runoff volume, and runoff coefficient by 87.65%, 70.72%, and 70.33%, respectively, compared with the control treatment. According to the results, morphogenetic porous biochar can be used as an effective and sustainable solution for managing erosion-sensitive soils and for improving conservation agriculture, soil and water conservation, and waste management. The outcomes of this study provide a solid scientific basis for developing actionable guidelines to safeguard soil and water resources and improve the performance of agricultural products.

# Slope Aspect Affects Soil Quality and Its Response to Soil Erosion on Temperate Gentle Sloping Farmlands

**Ziyi Gu[1, 2], Yang Yang[1, 2*], Tingting Peng[1, 2], Hui Zhang[1, 2], Xin Wei[1], Yingna Liu[1]**

**ABSTRACT**

Slope aspect is a significant terrain attribute influencing soil physical and chemical processes. Yet its impact on soil quality and erosion has rarely been studied on gently sloping farmlands. The objective was to evaluate the effects of slope aspect on soil quality and its response to soil erosion in the black soil region of northeast China, a temperate environment featuring gently sloping farmlands. Over a nearly north-south symmetric sloping farmland spanning ~ 3500 m, fifteen soil physical and chemical properties were investigated at every 40 m, and an integrated soil quality index (SQI) was calculated combining principal component analysis and scoring functions. The mean annual erosion rate (ER) was estimated using the cesium-137 tracing technique. Compared to the south-facing slope, the north-facing slope possessed significantly lower pH and higher saturated hydraulic conductivity, sand content, and almost all the essential nutrient contents, therefore overall better soil quality ($p < 0.05$). No statistical difference was spotted in ER between the two slopes ($p > 0.05$); however, erosion was found to deteriorate soil quality via distinct pathways. On the north facing slope, erosion affected SQI predominantly through its negative impact on soil organic carbon content and wet-aggregate stability, and conservation tillage practices were suggested. However, on the south-facing slope, the detrimental influence was primarily driven through the depletion of soil nutrient contents, particularly available phosphorus and total nitrogen, and contour tillage and hedgerows were strongly recommended. These findings hold important practical implications for agricultural management in temperate environments.

# Biochar application ameliorates soil and water loss on the soil-mantled karst slopes: mechanisms and benefits

**Longshan Zhao[1,2*], Ruyi Zi[1], Xiaoai Yin[1], Chunhua Fan[1], Ying Hu[1], Nana Zhou[1] and Zhen Han[1]**

*[1] College of Forestry, Guizhou University, Guiyang 550025, China*

*E-mail: longshanzh@163.com

**ABSTRACT**

Karst regions face severe challenges associated with soil erosion and land degradation. Their unique geological structure, characterized by shallow soil layers covering highly permeable bedrock, leads to significant surface soil loss and substantial "hidden" subsurface soil and water leakage through fissures and conduits. This phenomenon not only accelerates rocky desertification but also causes severe nutrient depletion and poses considerable agricultural and ecological risks. Biochar, a porous carbonaceous material with high adsorption capacity and chemical stability, has emerged as a promising soil amendment. However, its synergistic mechanisms in controlling the dual-surface and subsurface soil and water loss processes on karst slopes remained inadequately understood. This study employed an integrated approach combining field in-situ monitoring, controlled micro-plot experiments, and laboratory analyses. On soil-mantled karst slopes, experimental plots were established with different biochar application rates (e.g., 0 wt%, 1.36 wt%, and 2.72 wt%). We comprehensively monitored surface and subsurface runoff volumes, soil loss quantities, and changes in nutrient concentrations (e.g., nitrogen, phosphorus). Concurrently, we analyzed responses in soil physical structure (e.g., aggregate stability, porosity, water infiltration and retention characteristics), chemical properties (e.g., organic matter, pH, nutrient forms), and microbial community structure (via high-throughput sequencing). The findings reveal that biochar significantly regulates hydrological processes by improving soil physical structure. It enhances soil aggregate stability and pore connectivity, thereby delaying rapid water infiltration, reducing the risk of strong subsurface preferential flow, and increasing soil volumetric water content by 15-25%, which markedly improves soil drought resistance. Consequently, biochar effectively reduces total surface runoff (by 25-35%) and soil loss (by over 35%), while simultaneously decreasing subsurface runoff (by 10-20%) and its associated sediment transport. Regarding nutrient retention, biochar directly immobilizes nutrients like nitrogen and phosphorus in the soil via its adsorption capacity, leading to a reduction in nitrate-nitrogen and soluble phosphorus losses via surface and subsurface pathways by 20-30% and 15-25%, respectively, thereby significantly mitigating non-point source pollution risks. Furthermore, biochar indirectly enhances soil fertility by modulating the soil bacterial community; it notably enriches beneficial phyla such as Actinobacteria and Proteobacteria, which promotes the decomposition and sequestration of soil organic matter and drives carbon and nitrogen cycling, ultimately improving fundamental soil fertility. In conclusion, biochar plays multiple roles in soil and water conservation and fertility enhancement in karst regions. Its mechanism of action constitutes a multi-pathway synergistic process, initiating from the improvement of soil physical structure, extending to the regulation of hydrological processes, and culminating in the optimization of nutrient cycling and the enhancement of microbial ecosystem functions. This research provides a solid theoretical foundation and an effective technical pathway for ecological restoration and sustainable agricultural development in these vulnerable areas.

# A systematic identification of multi-scale relationship between sediment load and environmental factors in the Ten Tributaries region of the Yellow River Basin

**Jian Luo*, Xuan Zhang, and Ruihong Yu**

*School of Ecology and Environment, Inner Mongolia University, Hohhot, China*

*jian.luo@imu.edu.cn

**ABSTRACT**

The sediment load is an important indicator that reflects soil erosion in a watershed. The temporal variation of sediment load usually has scale dependence and is influenced by different environmental factors. However, due to the potential overlap of various factors at different scales, the complex multi-scale relationship between sediment load and its potential influencing factors remains unclear. The aim of this study was to analyze the multiscale correlations among runoff, precipitation, evaporation, and NDVI on monthly sediment load in the Ten Tributaries region of the Yellow River Basin from 2007-2021. The results showed that the sediment load, runoff, and precipitation showed strong variability, while evaporation and NDVI showed moderate variability in three watersheds (Maobula, Hantaichuan and Xiliugou) of the Ten Tributaries region. The original time series of the sediment load, runoff, precipitation, evaporation and NDVI were all decomposed into six intrinsic mode functions (IMFs) and a residue based on multivariate empirical mode decomposition (MEMD). The cumulative variance contribution rates of IMF1, IMF2, and IMF3 of variables all exceeded 90% within the three watersheds. The TDIC shows the associations between sediment load and the controlling factors changed significantly with the scale, which have multi-scale dynamic properties. Runoff was the key factor affecting sediment load in Maobula and Xiliugou watershed. In Hantaichuan watershed, runoff dominated sediment load dynamics from IMF1 to IMF5, whereas PET governed the sediment transport process at IMF6. Three machine learning models, multilayer perceptron (MLP), convolutional neural networks (CNN) and particle swarm optimization-support vector regression (PSO-SVR) were applied to forecast sediment load in different basins. Integrating MEMD with ML significantly enhanced sediment load prediction accuracy.

# SOIL MANAGEMENT AND CONSERVATION FOR AGRICULTURAL SUSTAINABILITY IN MALI VILLAGES

## ABSTRACT

The agroecosystems of Mali (West Africa) are experiencing degradation of Plinthic soils driven by surface crusting, low permeability (2.5–12.7 mm $h^{-1}$), low soil organic matter (7.8–22.8 g $kg^{-1}$), and consequent severe sheet erosion. Beyond inadequate management and limited use of Soil and Water Conservation Practices (SWCP), decision-relevant information for sustainable soil conservation and food security remains scarce. This study evaluated the potential to implement SWCP through a Technical Demonstration Unit (TDU) aimed at mitigating soil degradation and sustaining agricultural productivity in the villages of Siani and Bandiagara II. Within the TDU, three SWCP were established on the level contour: narrow-based terraces (NBT), stone cordons (SCN), and vegetation cordons of *Pennisetum purpureum* (VCN). These practices were tested with the following intercrops for corn (*Zea mays*) and cotton (*Gossypium hirsutum*): *Brachiaria ruziziensis* (IZB, IGB), *Vigna unguiculata* (IZV, IGV), *Arachis hypogaea* (IZA, IGA), corn + *Stizolobium aterrimum* (IZS), cotton + *Stylosanthes guyanensis* (IGS), and controls without SWCP (ZWC, GWC). In 2024, IGS was replaced by cotton + *Crotalaria ochroleuca* (IGC). In 2022, IZS produced 13.50 t $ha^{-1}$ of green biomass and the highest corn grain yield (4.40 t $ha^{-1}$). For cotton, green biomass reached 4.50 t $ha^{-1}$, with the highest lint + seed yield of 1.27 t $ha^{-1}$ under level planting. In 2023, for corn, the SCN with IZS produced the highest green biomass (19.92 t $ha^{-1}$) and grain yield (4.24 t $ha^{-1}$). For cotton, SCN with IGA produced the highest green biomass (13.25 t $ha^{-1}$) and lint + seed yield (2.50 t $ha^{-1}$). In 2024, NBT with IZV achieved the highest corn green biomass (29.83 t $ha^{-1}$) and grain yield (6.83 t $ha^{-1}$). For cotton, the highest lint + seed yield was 2.43 t $ha^{-1}$, while the highest green biomass (7.24 t $ha^{-1}$) occurred under VCN with IGA. Overall, adoption of SWCP increased biomass inputs and maintained soil cover, resulting in higher corn and cotton yields that consistently exceeded national averages in Mali.

**ABSTRACT**

Slope length is a critical topographic factor influencing sheet erosion, yet conventional whole-slope averaging fails to reveal dynamic variations of erosion rate across continuous slope length. This study, conducted indoor rainfall simulations with 5 rainfall intensities (0.800, 1.040, 1.700, 2.475, and 2.835 mm $min^{-1}$), 5 slope gradients (0.1763, 0.2679, 0.3640, 0.4663, and 0.5774), and 5 slope lengths (0.4, 0.8, 1.2, 1.6, and 2.0 m), defined slope position runoff rate ($R_i$) and slope position erosion rate ($D_i$) as continuous spatial functions of slope length via calculus, and systematically analyzed their variation characteristics and driving mechanism. Results indicated that $R_i$ increased and then decreased along slopes in most cases, with the turning point moving from approximately 0.8 m down to 1.0 m under increasing rainfall intensity. $D_i$ with slope length showed a decrease-increase trend under steep slopes with high rainfall intensity and an increase-decrease trend under gentle slopes with low rainfall intensity, with turning points migrating downslope as rainfall intensity and slope gradient increased, as well as being susceptible to net deposition at slope bases under certain circumstances. Regression equations suggested that the effect of rainfall intensity on $R_i$ and $D_i$ diminished with slope length, while the effect of slope gradient strengthened on lower slope segments. For entire slopes, rainfall intensity played the greatest role in erosion (Pearson's r = 0.71, total effect = 0.71), followed by $R_i$ (0.68, 0.19) and sediment concentration (0.59, 0.45). Spatially resolved structural equation modeling (SEM) revealed progressive control shifts along the slope, confirming three-phase erosion dynamics: upslope rainfall-driven erosion (direct path coefficient = 0.86), mid-slope runoff-mediated transport (0.75), and downslope sediment-regulated deposition (0.65), reflecting a hydrodynamic transition from raindrop detachment to flow-driven transport and sediment deposition. This study reveals slope erosion-deposition dynamics and provides a theoretical basis for the parameterization of slope length in process-based erosion models.

**ABSTRACT**

Setting tolerable soil loss (TSL) targets is necessary for sustainable land use and land management practices. In this study, we developed a new approach to monitor sustainable land management using widely available remotely sensed data, such as fractional vegetation cover (FVC) data derived from satellite data (MODIS, Landsat and Sentinel) (Yang et al. 2022). The method is based on the concept of maintaining sufficient vegetation cover to meet the TSL goals which vary spatially and temporally, not being static as in most reported studies to date. We determined monthly TSL thresholds based on long-term natural erosion rates, soil and landscape capabilities, and land uses at a given location. Where vegetation cover is more than that required to meet the TSL goal at a given location and time, the site is deemed to be managed sustainably (Gray et al. 2023). Monthly FVC and rainfall erosivity time series over the period from 2001 to 2025 have been used to estimate hillslope erosion rates and compared with the TSL targets across New South Wales (NSW), Australia. These monthly indices are then combined to form yearly sustainable land management indices (SLMI) over the 26-year period (2001-2025). We applied this new method across NSW and assessed the SLMI against soil and landscape capability classes and their spatial and temporal variation across local land service regions. High-resolution satellite data and field measurements have been used to validate the estimated FVC and erosion rates at selected field sites. Findings from this study can be used to identify the locations and periods of time with hillslope erosion exceeding a desirable TSL threshold level and indicate where management actions might be required to improve the soil condition over areas of concern. This new method is also globally portable as the required input datasets are widely available.

**ABSTRACT**

Rainfall erosivity is one of the most dynamic factors in the soil erosion process. The increase in soil erosion caused by high rainfall erosivity, and the subsequent loss of soil nutrients, can lead to reduced food production and ecosystem services. This research predicts rainfall pattern changes, rainfall erosivity and erosion risk across New South Wales (NSW) using the NSW and Australian Regional Climate Modelling (NARCliM) projections. We predict the rainfall erosivity across NSW under current and future climate changes under low to high emission scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0) from the baseline (1990–2009) to the future (2025–2100) periods. We utilized the Revised Universal Soil Loss Equation (RUSLE) to estimate monthly time-series soil erosion risk. The results indicate that the annual average rainfall erosivity is approximately 12% lower under the low emission (SSP1-2.6) scenario and 6% lower under the high emission (SSP3-7.0) scenario across NSW compared to results from observations. This might be due to the projected temperature rise, and consequently the increases in vegetation cover. Despite the underestimates, the absolute bias (0.25) from the NARCliM2.0 projection is far less compared to the previous versions (0.46 for NARCliM1.0 and 0.42 for NARCliM1.5). This improvement is consistent across all seasons, indicating the refinements in the new version (2.0) and its enhanced capacity to predict soil erosion with higher accuracy. Such improvements are crucial for reliable climate modelling and can significantly impact regional decision-making in climate adaptation strategies. With the ongoing development of NARCliM2.0, we expect enhancements particularly at higher temporal resolutions (hourly or sub-hourly) to enable better capture of extreme rainfall events.

# Slope Gradient Modulates Pathways of Soil Erosion-Induced Corn Yield Losses in Northeast China's Black Soil Region

**Yuwen Jin[1], Shengchang Huai[1], and Changai Lu[1*]**

*[1] Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing 100081, China*

jinyuwen19961211@163.com

**ABSTRACT**

The Northeast Black Soil Region is a vital grain production base in China, contributing >40% of the national corn output. However, soil erosion on sloping farmlands drives progressive thinning of the mollisol layer and fertility decline, threatening both national food security and sustainable black soil utilization. Through a two-year field experiment on two representative slopes (3° vs. 5°) in this region, we investigated spatial patterns of soil erosion and corn yield, and elucidated mechanisms linking erosion to yield losses. Key results indicate: (1) Net erosion rates reached 4,482.90 and 3,864.50 t $km^{-2}$ $yr^{-1}$ for 5° and 3° slopes, respectively, classifying both as moderate erosion (significantly exceeding the tolerable loss limit of 200 t $km^{-2}$ $yr^{-1}$). The 5° slope exhibited a 16.00% higher erosion rate than the 3° slope ($p < 0.05$). (2) Soil erosion/deposition rates strongly correlated with corn yield ($R = -0.72$, $p < 0.001$), with each 1 t $ha^{-1}$ $yr^{-1}$ increase in erosion reducing yield by 0.04 t $ha^{-1}$. (3) Mollisol thickness negatively correlated with erosion rate ($p < 0.05$) but positively correlated with yield ($p < 0.05$), confirming erosion indirectly reduces yield by thinning the mollisol layer. (4) On the steeper 5° slope, higher erosion directly reduced yield while also exerting indirect effects via mollisol loss; in contrast, on the gentler 3° slope, yield enhancement was achievable by increasing soil organic matter (SOM) and reducing soil erodibility (K-factor). Summary, Erosion control measures (e.g., mulching) should be prioritized on steep slopes (≥5°) to maintain mollisol thickness, while gentle slopes (≤3°) benefit more from organic amendments that boost SOM and reduce erodibility, thereby securing corn productivity.

# Effects of the size of biodegradable superabsorbent polymers on interrill erosion

**T. Tatsuno[1*], R. Nakamura[2], J. Kashiwagi[1] and S. Hamamoto[1]**

[1] *Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan*

[2] *School of Agriculture, Hokkaido University, Sapporo, Japan*

*t.tatsuno@agr.hokudai.ac.jp

**ABSTRACT**

Superabsorbent polymers (SAPs) have been applied in agricultural fields to improve productivity. SAPs can also influence soil erodibility through various mechanisms, such as suppression of rainfall-induced surface runoff due to water absorption, swelling–shrinkage–induced disruption of soil structure, and reformation of soil aggregates through incorporation of soil particles into the gel matrix. However, quantitative data applicable to erosion prediction models such as USLE and WEPP remain limited. Furthermore, conventional SAPs may potentially act as new sources of microplastic pollution. The biodegradable SAPs has recently been used. In actual farmland, granular biodegradable SAPs are spread by machine, so it is necessary to evaluate the effect of changes in size due to decomposition on erosion. In this study, laboratory experiments were conducted to examine the effects of biodegradable SAPs and their sizes on interrill erosion caused by raindrop impact under rainfall conditions.

The soil of light clay was collected from the upland field in Hokkaido University, Japan. A commercially available biodegradable SAPs (EFP, EF Polymer Co., Ltd.) were separated into two size fractions: 1-5 mm and 0.053–0.5 mm. Each SAP was mixed into the soil at mass ratios of approximately 0.002% and 0.02%, respectively. 0.02% is an excessive concentration that is 10 times higher than that applied to farmland. Together with the untreated control, five soil treatments were prepared. The prepared soils were packed into erosion test boxes. One day before the experiment, the soil was moistened to a volumetric water content of approximately 36% to enhance its susceptibility to erosion. The soil boxes were placed on an inclined platform, and simulated rainfall was applied at intensities of 20–40 mm $h^{-1}$ for predetermined durations. Runoff samples were collected at 5-minute intervals to measure the amount of runoff water and eroded sediment. After rainfall, soil samples were collected from soil box to measure soil physical properties.

In this study, there was no clear difference in the start of runoff from soil regardless of treatments. This was supported with the lack of significant differences in the saturated hydraulic conductivity of the soil under each treatment. Furthermore, there was no significant difference in interrill erodibility factor calculated form runoff water and eroded sediments. The interrill erodibility factor is related to the stability of soil aggregates, and there was also no difference in the mean weight diameter of soil aggregates for each treatment. In this study, it was considered that the difference of SAP size and the excessive application may not have a significant effect on soil interrill erodibility. Future studies should examine the potential aggregate stabilization caused by long-term decomposition of biodegradable materials and its impact on erosion.

## ABSTRACT

Soil erodibility serves as a crucial indicator for assessing soil sensitivity to erosion and is a vital parameter in soil erosion prediction models. The mixed transformation of *Robinia pseudoacacia L.* forests leads to variations in the root morphology of understory vegetation, which subsequently affects soil erodibility. This study focused on five typical mixed forests: *Robinia pseudoacacia L.* with *Prunus sibirica L.*, *Prunus davidiana Franch.*, *Hippophae rhamnoides L.*, *Amorpha fruticosa L.*, and *Pinus tabuliformis Carrière.* The study analyzed how soil erodibility changed after mixing the *Robinia pseudoacacia L.* forests, as well as the response mechanisms to root morphology and aggregate stability. Simultaneously, the study has explored an estimation method for soil erodibility in woodland, utilizing parameters of aggregate particle size distribution. The results showed that mixed planting of *Robinia pseudoacacia L.* with *Prunus sibirica L.*, *Prunus davidiana Franch.*, and *Pinus tabuliformis Carrière* reduced soil erodibility by 1.33%, 3.72%, and 3.79%, respectively. In contrast, mixed planting with *Hippophae rhamnoides L.* and *Amorpha fruticosa L.* increased soil erodibility by 6.09% and 3.63%. The soil erodibility of ephemeral gullies increased by an average of 7.18% (5.43%-8.37%) compared to slopes. Changes in root traits and aggregate stability resulting from the mixed planting of *Robinia pseudoacacia L.* accounted for 93.5% of the soil erodibility. Aggregate stability was the primary factor influencing soil erodibility, with a standardized path coefficient of -0.865 ($p$<0.001). Roots primarily reduced soil erodibility indirectly by enhancing aggregate stability, with a standardized path coefficient of 0.553 ($p$<0.01) for the effect of roots on aggregate stability. In the TORRI and EPIC models, estimating soil erodibility based on soil aggregates was feasible on the Loess Plateau ($R^2$=0.26, $p$<0.05; $R^2$=0.52, $p$<0.001), aligning with the hypothesis of this study. The research findings clarify suitable tree species for mixed afforestation and provide scientific References for optimizing planted forest transformation.

# Early detection of runoff erosion as gully prevention strategy in sandy tropical soils, Kananga, Democratic Republic of Congo (DRC)

**Arabela Vega-Aguilar[1*], Carles Raïmat-Quintana[2], and Pilar Andrés-Pastor[3]**

[1] *PhD Candidate (Terrestrial Ecology, Universitat Autònoma de Barcelona, Spain)*

[2] *Senior Scientist-CEO (Engineering, Kuroba Quatre SL, Lleida, Spain)*

[3]*Senior Scientist (Ecology and Soil biodiversity, CREAF, Barcelona, Spain)*

*arabela.vega@gmail.com

**ABSTRACT**

Early detection and reduction of runoff erosion aim to prevent gully erosion in sandy soils in Africa. Gully erosion is considered a menace in African cities because of its recurrent spatial distribution on densely populated areas, were young and vulnerable population converge, exacerbated by social, health and political factors. This phenomenon has been documented only for the past decade. Fanjana *et al* (2025) report 18 African countries where gully erosion has been studied. The Democratic Republic of Congo (DRC), the Central African Republic (CAR) and the Republic of Congo are some of the most affected. Gully erosion has also been documented in Brazil, the city of Buritucupu being the most affected (Ferreira and Ferreira, 2021), with similar origin, size and affectation as in Africa. Mawe *et al.* (2025) identified 2922 urban gullies across 26 cities in the DRC using satellite imagery. However, no field data or site testing was conducted in either case. In Kananga DRC, we have documented gully erosion through satellite imagery and demonstrated exponential growth since 2010, UAV-lidar, photogrammetry and cloud point techniques have been used to map urban growth, vegetation cover and soil management practices in between seasons.

Spectral firms are proposed to recognize the ground features of runoff erosion associated with gully erosion development, and the specific conservation agricultural practices as a NBS prevention strategy. We propose UAV-lidar as the ideal mapping and monitoring tool for the spectral firm assessment, since it can provide a rapid, consistent, repeatable, non-destructive, and objective sampling method to assess potential erodibility due to plant-soil properties based on land-crop reflectance.

Preliminary findings point to linear infrastructure, uncontrolled urban growth and unfit agricultural practices as the main causes of soil erosion in Kananga. Thus, drainage masterplans, urban planning, landscape management and conservative soil use are some of the erosion strategies that could serve for hazard reduction.

This communication is about assessing soil degradation and stability risks and evaluating the effectiveness of NBS to reduce soil erodibility through the combination conservation agriculture, and engineering risk management in urban and peri-urban environments, also aiming to prevent runoff erosion to avert gully development in climate change challenged areas.

**ABSTRACT**

Soil erosion contributes to declining soil health in agricultural land. Tillage erosion has been recognized as a major form of soil erosion, and its contribution often exceeds that of water and wind erosion in cultivated fields. However, tillage erosion has mostly been studied at the field scale, and little effort has been made to map it at regional or global scales. The major challenges for such large-scale mapping include: (1) existing tillage erosion models are all field-scale models and are not suitable for regional or global applications; (2) a lack of erosivity data for diverse cropping systems; and (3) insufficient field-scale topographic data.

To address these challenges, we developed a simplified modeling framework, the Tillage Erosion Risk Indicator (TillERI), for estimating tillage erosion, and demonstrated its application for mapping tillage erosion risk in Canada. The TillERI model operates at the spatial level of Soil Landscape of Canada (SLC) polygons, the mapping units of the national soil database. Tillage erosion was calculated as the product of tillage erosivity and landscape erodibility. Tillage erosivity was determined for major cropping systems (defined by crop type and tillage type) based on their typical tillage sequences. Cropping data were extracted from the Census of Agriculture (a national agricultural survey conducted every five years). Tillage erodibility was calculated using topographic data (slope length and gradient) generated for major landforms in the national soil database. The resulting tillage erosion rates were aggregated at the SLC polygon, provincial, and national levels.

Our results showed that the risk of tillage erosion on Canadian cropland has steadily declined since the 1980s, largely due to the adoption of conservation tillage, particularly no-till systems. The shift from annual crops to perennial crops also contributed to this declining trend. Among the provinces, tillage erosion risk was highest in the prairie provinces, where landscapes are dominated by hummocky and undulating landforms. However, areas with unsustainable levels of tillage erosion were present in every province. The TillERI results can help decision-makers better identify hotspots of tillage erosion and design policies to mitigate its impacts. The methodology can be adapted and applied to other countries or at the global scale.

*E-mail Address of Presenting Author: jyjiao@ms.iswc.ac.cn

**ABSTRACT**

To clarify the long-term development characteristics of gullies and explore the significant influencing factors of gully erosion for providing a theoretical References for soil and water conservation on the Qinghai-Xizang Plateau under the background of climate change, this study extracted the morphological parameters and development rates of stable gullies, developing gullies, and newly formed gullies on the alluvial-proluvial fans at the southeastern foothill of the western Nyainqêntanglha Mountains, based on high-resolution remote sensing images of 1970 and 2025. Spearman correlation analysis was employed to identify the significant influencing factors of the development rates of developing gullies and the morphological characteristics of newly formed gullies. In 2025, the average lengths of stable, developing, and newly formed gullies were 265.42 m, 401.61 m, and 123.12 m, respectively; and the average areas were 12 350.93 $m^2$, 7 517.52 $m^2$, and 1 055.36 $m^2$, respectively. The average linear development rate of developing gullies was 2.35 m/a, and the average areal development rate was 21.24 $m^2$/a. The linear development rate was significantly positively correlated with catchment area and near-surface air temperature ($p<0.05$). The areal development rate was significantly or highly significantly positively correlated with catchment area, elevation, and near-surface air temperature ($p<0.01$). The length of newly formed gullies was significantly positively correlated with catchment area and near-surface air temperature ($p<0.01$), and significantly negatively correlated with the maximum freezing depth of seasonal frozen ground ($p<0.05$). The area of newly formed gullies was highly significantly positively correlated with catchment area, annual precipitation, and rainy season precipitation ($p<0.01$), but highly significantly negatively correlated with the maximum freezing depth of seasonal frozen ground ($p<0.01$). Gully development is primarily influenced by catchment area and elevation, while gully formation is jointly influenced by catchment area, annual and rainy season precipitation, annual average temperature, and freezing depth of frozen ground. Therefore, under the background of climate change and human activities, gullies on the Qinghai-Xizang Plateau have significant development potential, and need pay more attention to its control for protection the more precious soil resources.

# Comparative Erodibility of UK Soils Under Different Climate Change Scenarios

**Johnson Oluwaseun Odukoya[1], Kathryn E. Bartlett[2], and Robert Simmons[1]**

[1] *Faculty of Engineering and Applied Sciences, Cranfield University, Cranfield, Bedfordshire, United Kingdom*

[2] *Crop Nutrients, Anglo American Plc, Woodsmith Mine, Sneaton, Whitby, North Yorkshire, United Kingdom*

*johnson.odukoya@cranfield.ac.uk

**ABSTRACT**

Climate change is increasing the frequency and magnitude of extreme rainfall events significantly increasing the kinetic energy (KE) available to breakdown and reorganize aggregates at the immediate soil surface. This has implications for soil erosion, runoff generation and flood risk. The inherent erodibility of UK soils to extreme rainfall events is currently unknown. This study quantifies the comparative erodibility of twelve UK soils subjected to an 80 mm/hr rainfall event of 5, 8, and 14 minute duration, corresponding to return periods of 5, 10, and 30 yrs, respectively. Soil textural classes investigated included sandy clay loam, sandy loam, silty clay loam, clay and clay loam agricultural soils. Air-dried sieved (<2.0 mm) soils were uniformly packed into 100 mm internal diameter and 50 mm deep PVC microcosms and subjected to the respective rainfall events. Splash detached material was collected in a 300 mm diameter concentric ring collector and post-rainfall unsaturated hydraulic conductivity ($K_{un}$) measurements made using a Minidisk infiltrometer to assess soil erosion and runoff risk, respectively.

As expected, across all soil types, the quantity of splash detached material increased with increasing storm return period indicating increased soil erosion risk. Similarly, across all soil types, increasing storm duration significantly decreased $K_{un}$ implying an increased risk of runoff generation. For the extreme 30 yr return period storm event, counter intuitively the clay soils from Westbury, Wiltshire were significantly more erodible than the sandy loam soils from Northumberland both associated with similar crop rotations. The least erodible soil was a silty clay loam from Salisbury, Wiltshire. No statistically significant correlations were observed between the mass splash detached material or $K_{un}$ and a comprehensive range of physico-chemical soil parameters investigated or soil mineralogy. These results demonstrate the highly variable response of UK soils to extreme rainfall events and highlight the need for continuing research.

# Evaluation of Silt Socks and Wollastonite-Enhanced Socks in Sediment and Phosphorous Management

**O. Udume[1], V. Tran[1], T. Li[1*], M. Thimmanagari[2], E. Chiang[1]**

[1]*College of Engineering, University of Guelph, Guelph, Canada*

[2] *Ontario Ministry of Agriculture, Food and Agribusiness, Canada*

tianying@uoguelph.ca

**ABSTRACT**

Soil erosion is a threat to global agricultural systems, affecting top-soil integrity, crop productivity, and water quality (Liu *et al*., 2020). Agricultural runoff is a source of phosphorus pollution, driving eutrophication, algal blooms, and poor water quality (Andrade *et al.,* 2020). A current strategy for erosion management is silt socks (SS) — tubular mesh fabrics packed with dried miscanthus. The addition of wollastonite has shown promise in removing phosphorus from wastewater and agricultural runoff (Huang *et al*., 2019). The study evaluates the sediment removal efficiency of silt socks (SS) and wollastonite-enhanced socks (WS) and investigates the relationship between wollastonite particle size (Ps) and phosphorus removal efficiency. Four treatments were evaluated: soil only (control), SS, WS (1.19< Ps <2), and WS (0.50<Ps <0.71). Large bins filled with sandy loam soil were placed on a 15° slope, and a 1-hour simulated rainfall (78 mm/hour) was applied. Runoff samples were collected to measure runoff volume, dissolved phosphorus concentration, pH, electrical conductivity (EC), and sediment. Results showed that WS socks significantly improved erosion control and phosphorus retention. WS (0.50< Ps <0.7) reduced soil erosion by 94.39%± 0.02% compared to the control. Phosphorus concentration in runoff decreased by 46.47% with WS socks of a smaller particle size range compared to SS alone. This demonstrated the effectiveness of WS socks in reducing sediment and phosphorus leaching from agricultural runoff. As a part of future work, the effect of the packing density on the removal efficiency of runoff, sediment, and phosphorus is being studied. Through varying the miscanthus weight and the sock diameter, different packing densities (0.1, 0.15, 0.17, 0.2g/cm³) can be achieved.

# Synergistic Effect of Coal Fly Ash and Polyacrylamide on Enhancing Sandy Soil's Resistance to Wind and Water Erosion

**Kai Yang[1*] and Yitong Wang[2]**

[1] *Beijing Normal University (College of Water Sciences, Beijing, China)*

[2] *Yangzhou University (College of Hydraulic Science and Engineering, Yangzhou, China)*

*E-mail Address of Presenting Author: yangk@bnu.edu.cn

**ABSTRACT**

Sandy soils in arid and semi-arid regions are highly vulnerable to both wind and water erosion, leading to severe land degradation and nutrient loss. This study investigated the synergistic effect of coal fly ash (FA) and anionic polyacrylamide (PAM) as amendments for enhancing the resistance of sandy soil to these dual erosion threats. Through a combination of field experiments in the sandified land in the Inner Mongolian Reach of the Yellow River and laboratory rainfall simulations, locally sourced high-calcium FA and PAM granules were thoroughly mixed with sandy soil to form a consolidated soil layer (CSL) at 0–0.3 m depth in the field and a 0.2 m amended layer under indoor conditions. The results showed that the CSL significantly reduced the wind erosion rate (WER) by up to 69% during the dry seasonal period (autumn to spring) compared to untreated control, with the 10% FA + 0.05%–0.1% PAM treatments exhibiting the most durable resistance. This improvement is attributed to the filling effect of fine FA particles and the adhesive action of PAM, which together improve soil aggregation and surface crust formation. Establishing *Achnatherum splendens* on the CSL further provided long-term stabilization, reducing the WER by 82%–92% compared to the bare CSL after 8 months, demonstrating the efficacy of a combined biochemical approach to sand fixation. Under simulated rainfall conditions (1.5 mm/min, 40 min, 10° slope), the co-application of 10%–15% FA and 0.01%–0.02% PAM altered the hydrological processes within the amended soil layer. With increasing application rates of FA and PAM, the runoff intensity increased, the time to runoff initiation shortened, and the average infiltration rate decreased. Moreover, a higher FA application rate of 15% combined with PAM resulted in a prominent increase in the cumulative sediment yield. Whereas, the 10% FA + 0.01%–0.02% PAM treatments maintained the cumulative sediment yield at a level statistically indistinguishable from untreated control. Post-rainfall analysis revealed that the amendments significantly increased water retention within the soil profile. This is due to FA increasing capillary porosity and PAM forming viscous solutions that hinder water seepage, thereby enhancing moisture availability for plants. Beyond erosion control, the FA-PAM system enhanced the soil's capacity to retain nitrogen (N). The concentrations of $NO_3^-$-N and $NH_4^+$-N retained in the soil profile after rainfall increased markedly with higher amendment rates, demonstrating a significant improvement in nutrient holding capacity. The combined use of FA and PAM created a synergistic effect that effectively stabilized the sandy soil against both wind and water erosion. This amendment can not only mitigate soil loss but also improve soil moisture conservation and nutrient retention, offering a comprehensive and sustainable solution for combating desertification and promoting ecological restoration in vulnerable sandy landscapes.

# Tillage erosion - the blind spot in soil conservation

**Peter Fiener[1*], Lena Katharina Öttl[1], and Florian Wilken[1]**

[1] *Water and Soil Resource Research, Institute of Geography, University of Augsburg, Germany*

*peter.fiener@geo.uni-augsburg.de

**ABSTRACT**

Tillage erosion has a frequently underestimated impact on soil systems. It plays a key role in soil degradation, especially in regions dominated by large agricultural fields situated on rolling hills with short slope lengths, as typically found in former ground moraine regions in the northern US and Canada, as well as in the northern parts of Europe (e.g., northern Germany, Denmark, Poland).

It is often assumed that non-inversion tillage, as used in soil conservation systems, is associated with reduced levels of tillage erosion compared to conventional inversion tillage. Based on this assumption, non-inversion (mulch) tillage would be a method to simultaneously combat all types of erosion (water, wind, and tillage).

In this presentation, we summarise data from our own experiments, along with an evaluation of other studies that challenge this assumption. We conducted a set of paired-plot tillage erosion experiments on different slopes in Northeastern Germany, comparing a mouldboard plough with a non-inversion chisel plough while keeping tillage parameters (tillage speed and depth) constant. The study's findings demonstrate that non-inversion tillage results in a significantly higher degree of downslope soil translocation compared to inversion tillage. The soil translocation distance was found to be 1.3–2.1 times larger in cases involving non-inversion tillage. Similar results are somewhat obscured in other studies, as smaller tillage depths are often assumed when calculating erosion rates from soil translocation in the case of non-inversion tillage. However, especially in highly mechanised large-scale farming, tillage depths of non-inversion tillage often reach those of inversion tillage, while tillage speed in the case of non-inversion tends to be faster and hence even accelerates tillage erosion.

Consequently, the effectiveness of non-inversion tillage as a measure to reduce total soil erosion remains unclear., especially in regions dominated by tillage erosion. In general, tillage erosion needs to be more consistently considered in soil conservation planning.

*pasquale.borrelli@unibas.ch

**ABSTRACT**

Soil erosion remains one of the most serious environmental problems faced globally, with direct consequences for agricultural output, food security, and the health of land ecosystems. This presentation reviews current scientific understanding of the geographic distribution of erosion and the main forces that shape it at pan-EU and Global scale, with particular attention to the combined effects of water and wind erosion, tillage, gully formation, and biomass removal. By using advanced spatial modeling methods together with large international datasets, the analysis pinpoints major areas of concern and clarifies the human and climatic pressures that intensify land degradation.

A key section of the talk reports the key finding of the Global Soil Erosion Mapping Initiative, an international collaboration that now includes 300 researchers. The initiative seeks to create high resolution, standardized, and regularly updated global maps that document visible erosion features and related degradation processes. A defining feature of this effort is its structured visual interpretation of very high resolution satellite and aerial images, which allows experts to detect and categorize erosion indicators such as gullies, sediment deposition zones, and badland landscapes. This image guided approach strengthens both the accuracy and the contextual relevance of erosion assessments, especially in complex environments or regions with limited data.

The presentation ends by considering how these findings can inform efforts to build soil resilience. This includes targeted conservation practices, sustainable land management strategies, and policy measures grounded in scientific evidence that aim to protect soil as a limited and nonrenewable resource.

**ABSTRACT**

Water erosion poses an obvious threat to cultivated land quality and grain security in black soil regions of the whole world. Straw mulch serves as an effective water erosion control measure for soil improvement as well as soil and water conservation. However, the intra-annual dynamics of soil properties and their drivers for soil aggregate stability and erosion resistance under straw mulch remain unclear. The objectives of this study were to reveal the variations and driving mechanisms in key soil properties, aggregate stability and erosion resistance by a field situ monitoring method with three straw mulch amounts (CK, no straw mulch; $MR_{50}$, 4.5 t $hm^{-2}$ straw mulch; and $MR_{100}$, 9.0 t $hm^{-2}$ straw mulch). The results demonstrated that straw mulch application in longitudinal furrows significantly enhanced soil physical properties, as evidenced by marked increases in soil moisture content (SMC), and macroaggregate (> 0.25 mm) content ($R_{0.25}$) ($P < 0.05$). Compared to the CK, the soil organic matter (SOM) content increased by 3.80 g $kg^{-1}$ and 3.85 g $kg^{-1}$ under the $MR_{50}$ and $MR_{100}$ treatments, respectively. Concurrently, soil erodibility decreased substantially, with reduction factors of 2.5 and 4.5 relative to CK under $MR_{50}$ and $MR_{100}$. Furthermore, straw mulch promoted acidification in the acidic soil, leading to a decrease in pH from 5.97 to 5.81 under the $MR_{100}$ treatment. Structural equation modeling (SEM) revealed that soil erosion resistance was driven directly by SOM, SMC, and clay content, as well as indirectly by clay content through its effects on SOM and SMC. In conclusion, straw mulch in longitudinal furrows should be promoted due to its high efficiency in improving soil properties. These findings offer insights to enhance soil erosion control and optimize straw utilization.

## ABSTRACT

Soil erosion is one of the most serious causes of land degradation in West Africa, where large areas of cultivated land are losing productivity. Despite this, the dissemination of soil conservation practices has been slow, mainly because there are no locally adapted criteria or standards for soil conservation planning. Establishing such standards is essential for assessing soil erosion risks and guiding farmers toward appropriate management strategies from a long-term perspective. This study aimed to quantify how cumulative soil erosion, crop type, and fertilizer application affect crop yields on major soil types in the Sudan Savanna, and to develop the first soil conservation criteria in Africa that enable farmers to select suitable conservation practices according to their biophysical and socio-economic conditions.

Field experiments were conducted over three years (2022–2024) at the Saria Station of INERA in Burkina Faso, on three representative soils of the Sudan Savanna: Ferric Lixisols (LX-fr), Petric Plinthosols (PT-pt), and Pisoplinthic Petric Plinthosols (PT-pt.px), which differ in the effective soil depth for crop cultivation (LX-fr > PT-pt > PT-pt.px). To simulate cumulative soil erosion, five levels of topsoil removal were artificially applied (0, 2.5, 5.0, 10, and 15 cm). Two crops (sorghum and cowpea) were grown under fertilized and unfertilized conditions, with five replications per treatment.

The three-year average yields of sorghum in the unfertilized 0-cm removal plots were 219, 97.2, and 68.8 kg ha$^{-1}$ on LX-fr, PT-fr, and PT-pt.px, respectively, while those of cowpea were 271, 208, and 186 kg ha$^{-1}$. Yield reduction with increasing erosion depth was more pronounced in PT-pt.px, which had the shallowest effective soil depth, than in LX-fr. Sorghum was less sensitive to soil loss than cowpea on LX-fr, while fertilizer application had a stronger positive effect on PT-pt.px, where the baseline yield was lowest. Assuming an annual soil erosion rate of 2 mm yr$^{-1}$ without conservation (Zougmoré, 2003), two scenarios were modeled: (i) adoption of at least one soil conservation measure reducing erosion by 40%, and (ii) adoption of multiple measures reducing erosion by 70%. The simulation indicated that maintaining at least 80% of the current yield after 25 years would require different strategies depending soil type and crop: for sorghum on LX-fr, no action may be needed; for sorghum on PT-pt.px, fertilization or multiple conservation measures are required; for cowpea on LX-fr, either fertilization or one conservation measure is necessary; and for cowpea on PT-pt.px, multiple conservation measures or fertilization are essential.

In conclusion, we quantified yield decline rates of sorghum and cowpea under progressive soil erosion across three contrasting soil types and developed soil conservation criteria that predict long-term yield sustainability based on soil type, fertilization, and conservation effort. This represents the first attempt to establish soil conservation standards for sub-Saharan Africa, providing a framework for farmers to select feasible conservation strategies according to their field conditions and management capacity.

## ABSTRACT

Soil erosion poses a severe challenge to ecological sustainability. However, existing studies predominantly focus on total erosion estimation and conventional spatiotemporal variations, leaving a gap in understanding the spatial patterns, heterogeneity, and spatial transmission effects of driving factors at a macro scale. To address this, this study introduces the concept of "spatial marginal effects." Based on multi-source data from 2000 to 2020 across six cities, including Fuxin, and integrating Remote Sensing (RS) and Geographic Information Systems (GIS), an in-depth analysis of soil erosion was conducted. During the study period, the soil erosion modulus in the Northeast Cinnamon Soil Region exhibited phasic changes. The intensity of erosion exacerbated after 2010, peaking in 2013 at 435.67 $t \cdot hm^{-2} \cdot a^{-1}$. Time-series analysis identified 2009 and 2014 as critical turning points, reflecting significant fluctuations in erosion intensity. Notably, in 2014, the erosion status in Tongliao, Chaoyang, and their surrounding areas showed significant improvement. Between 2000 and 2020, the dominant land use types in the region were cultivated land and grassland. The total area of land use change was 12,519.34 $km^2$, accounting for 6.61% of the total study area. The changes primarily involved cultivated land and grassland. From 2000 to 2010, cultivated land area decreased slightly while grassland area increased. However, after 2010, this trend reversed: cultivated land area rebounded significantly to levels exceeding those of 2000, while grassland area declined sharply. Concurrently, areas of forest land, water bodies, and unused land decreased, whereas urban construction land increased. Both total soil erosion and its primary driving factors (rainfall erosivity, slope length and steepness, soil erodibility, and vegetation management) exhibited significant positive spatial correlations and spatial agglomeration. The Spatial Durbin Panel Data Model (SDPDM) quantified the "spatial marginal effects" of these driving factors, confirming that their influence transcends regional boundaries to produce spatial lag and spillover effects. This demonstrates that the synergistic action of driving factors within a region and in adjacent areas significantly impacts soil erosion.

**ABSTRACT**

Soil security is crucial for humanity's future, and water erosion poses a serious threat to soil security, yet research on erosion processes and mechanisms urgently needs to be strengthened. By analyzing erosion mechanisms and building mathematical models and verifying them with indoor and outdoor test data, studies on the erosion and transport processes have been conducted. The results demonstrated the energy dissipation in the process of storm runoff erosion was related to the water-sediment characteristics, the Froude number (Fr) of the storm runoff flow, the ratio of flow velocity to the initiation module velocity for erosion (V/V*c), and the square difference ratio of flow velocity and sediment friction velocity. The erosion transport equation was presented and verified with a large amount of indoor and outdoor data. Integrated this formula into SWAT resulted in an improved version, SWAT-S, which enhances sediment load calculation performance. SWAT-S was evaluated in the Yanhe River Basin of the Loess Plateau in China using the coefficient of determination ($R^2$), Nash-Sutcliffe efficiency (NSE), percent bias (P-BIAS), and ratio of root mean square error to observed standard deviation (RSR). The results indicate that SWAT-S is more successful than SWAT in simulating monthly sediment load. During calibration, $R^2$, NSE, |P-BIAS|, and RSR improved by 5.08%, 17.65%, 2.92%, and 10.00%, respectively. During validation, these improvements were 1.18%, 10.39%, 45.45%, and 18.75%, respectively. Additionally, SWAT-S overestimated sediment load by 2.66 million tons during the flood season from June to September compared to SWAT, and it better matched observed data. The above results indicate that the given equation could unify rill erosion sediment transport with channel and river sediment transport processes, and compared to famous formulas, it has higher computational accuracy. The SWAT-S improved by the formula could enhance sediment estimation performance, which is beneficial for the widespread application of the model in more global regions.

# Long slope erosion-deposition patterns under different tillage systems driven by multiple erosion forces in the Chinese Mollisol region

**Fenli Zheng** [1*]

[1] *College of Soil and Water Conservaton Science and Engineering, Northwest A & F University, Yangling 712100, PR China*

* flzh@ms.iswc.ac.cn

**ABSTRACT**

The special geographic characteristics coupled with unreasonable tillage activity and coexistent multiple erosive forces (rainfall, snowmelt, and wind) induce severe soil erosion in the Mollisol region of Northeast China. However, the studies on long slope erosion-deposition patterns under different tillage systems driven by multiple erosion forces are rare. Therefore, this study was to identify the effects of flat tillage (non-ridge tillage, FT), longitudinal wide-ridge tillage (LWT), and traditional longitudinal ridge tillage (LRT) practices on the spatial patterns of long slope erosion-deposition and sediment transport along the three natural long slopes with 320 m slope length by using Rare Earth Elements (REE) tracing method during the rainfall, snowmelt and wind erosion periods. Soil erosion rates driven by rainfall, snowmelt and wind were 1678.5–2558.5 t $km^{-2}$ $a^{-1}$ for the FT, 1089.0–1468.9 t $km^{-2}$ $a^{-1}$ for the LWT and 181.9–314.4 t $km^{-2}$ $a^{-1}$ for the LRT, respectively, in which the sediment yield with the FT, LWT and LRF driven by rainfall and snowmelt accounted for 88.0 %-96.4 % of the total sediment yield. During the rainfall erosion period, the erosion regime was dominated on the slopes with these three tillage practices, whereas deposition only occurred at the slope toe. For the FT, 73.6 % of the sediment mass was deposited at the 0–120 m slope length. A total of 50.7 % of the sediment was deposited at the 0–80 m slope length with the furrows of LWT, whereas all the sediment was transported out of the entire slope with the furrows of LRT practice. During the snowmelt erosion period, a spatial pattern with erosion-deposition alternations was observed for the FT and LWT, whereas the erosion regime dominated on the slope with the LRT practice. During the wind erosion period, there were evident periodical changes with strong-weak alternations for all three tillage practices. The findings of this study served as a scientific References for implementing precise soil conservation measures for controlling compound soil erosion in the Chinese Mollisol region.

# Exploration of Multi-Scale Spatiotemporal Differentiation and Influencing Factors in Yuanmou County Based on SBAS-InSAR

**Xuan Yang[1*], Yifan Dong[2]**

[1] *Department of Physical Geography, Institute of International Rivers and Eco-Security, Yunnan University, Kunming, China*

[2] *Institute of International Rivers and Eco-Security, Yunnan University, Kunming, China*

**ABSTRACT**

Based on SBAS-InSAR, this study obtained the deformation rate of Yuanmou County from January 2020 to October 2024. Spatially, the deformation spatial differentiation was classified into three levels: the county scale, regional scale (sedimentary area and bedrock area), and local scale (gully walls, gully beds, and slopes within both the sedimentary and bedrock areas). It was found that in terms of the mean annual deformation, there was no significant difference between gully and non-gully areas. The erosion in the sedimentary area was significantly greater than that in the bedrock area. At the local scale, erosion was highest on gully walls, followed by gully beds, and then slopes; however, the differences among these three units within the sedimentary area were relatively small. Using Random Forest and SHAP for multi-scale feature importance ranking, the results showed similar rankings across multiple scales, indicating the robustness of the findings. The main influencing factors varied across scales: elevation was the most critical factor at the county scale, soil mechanical composition was the dominant factor at the regional scale, and different factors controlled deformation at various local units. To enhance model interpretability, SHAP trend analysis was employed, which captured the non-linear relationships between key features and deformation, revealing the complexity of environmental factors' influence on deformation. Notably, the importance of NDVI exceeded that of rainfall rate at multiple scales. Temporally, the analysis revealed an increasing trend in both erosion amount and deformation magnitude in Yuanmou County. Based on the Random Forest importance ranking, NDVI showed a decreasing trend interannually, while the importance of elevation increased. The interannual changes in deformation may be related to the decrease in NDVI. Seasonally, the importance of NDVI increased during the dry season, while that of elevation rose during the rainy season, demonstrating that deformation is associated with seasonal soil moisture regulation.

# Effects of Different Land Use Types on Soil Multifunctionality and Their Driving Mechanisms in Karst Fragile Ecosystems

**Zhen Han[1,2], Nana Zhou[1], Jie He[1], Yuanze Xu[1], Yaying Feng[1], Longshan Zhao[1,3*]**

*[1]College of Forestry, Guizhou University, Guiyang 550025, China*

*[3]Key Laboratory of Karst Georesources and Environment of Ministry of Education, Guizhou*

*E-mail Address of Presenting Author:zhan@gzu.edu.cn

**ABSTRACT**

Elucidating the effects of different land use types on soil physicochemical properties and microbial community characteristics in karst regions, and further revealing how these factors regulate soil multifunctionality, is of great significance for ecological management in rocky desertification areas. However, the underlying mechanisms remain unclear. This study was conducted in a typical rocky desertification area in southwest China, where five land use types—cropland, grassland, shrubland, plantation forest, and secondary forest—were selected. Soil samples were collected at different depths (0–10 cm, 10–20 cm, and 20–30 cm) to systematically evaluate five key aspects of soil multifunctionality: nutrient supply, microbial growth efficiency, soil organic matter (SOM) decomposition, nutrient cycling, and plant–microbial symbiosis. The results showed that microbial growth efficiency, SOM decomposition capacity, and overall soil multifunctionality in cropland and grassland were significantly lower than those in forested lands. The surface soil of shrubland exhibited the highest soil multifunctionality, with significant variations observed across soil depths for all functions. In addition, cropland and grassland had higher bacterial α-diversity, and their bacterial and fungal community structures significantly differed from those of forested lands. Shrubland showed higher bacterial community stability and network complexity, while plantation forest displayed the highest network complexity. Driver analysis indicated that soil microbial network characteristics significantly influenced soil multifunctionality, but soil physicochemical properties had a higher independent explanatory power. Structural equation modeling further confirmed that soil organic carbon (SOC) is a key variable linking different land use types and soil depths to enhanced soil multifunctionality. These findings highlight the positive role of shrubland restoration and establishment in improving soil multifunctionality in rocky desertification areas, which can enhance the precision and effectiveness of ecological restoration and promote the transition of regional ecosystems from "degradation repair" to "functional enhancement."

*E-mail: hongguangliu0791@hotmail.com

**ABSTRACT**

Vegetation damage from REE mining, compounded by intense rainfall, triggers the runoff-driven spread of contaminants and resulting ecosystem degradation. These disturbances may extend to arbuscular mycorrhizal fungi (AMF), a key plant symbiosis that influences soil structure and water infiltration; however, the extent and mechanisms of such impacts remain insufficiently understood. This study aimed to investigate the responses of AMF communities to heap leaching (HL), in-situ leaching (IL), and ecological restoration (ER), and their role in regulating runoff under simulated rainfall. Our results showed that HL and IL caused pronounced soil desertification and acidification, respectively. HL markedly reduced AMF abundance and diversity, whereas ER partially restored these attributes but did not reach levels at the Ore site (OR). Clay content, nutrient levels, and precipitation emerged as the primary drivers of AMF community variation across REEs mining areas. Inoculation with indigenous AMF enhanced ryegrass growth and hyphal abundance and effectively reduced runoff generation under simulated rainfall. Collectively, the evidence demonstrates that REEs mining activities disrupt AMF communities primarily through soil desertification and acidification, and although ER improves AMF attributes, full recovery remains limited. Indigenous AMF play a significant role in regulating runoff production, underscoring the importance of conserving and re-establishing AMF communities to support ecological restoration in REEs mining landscapes.

# Measuring tillage and water erosion under different tillage systems in a commercial potato farm in Atlantic Canada

**Fangzhou Zheng[1*], Sheng Li[1], Yulia Kupriyanovich[1]**

[1] *Fredericton Research and Development Center, Agriculture and Agri-Food Canada, Fredericton, Canada*

*E-mail fangzhouzheng@gmail.com

**ABSTRACT**

In Atlantic Canada (AC), tillage intensity in commercial potato farms is the highest among all crops. Tillage disturbs soil, leading to both water and tillage erosion, resulting in declining soil health. In a commercial potato farm field in New Brunswick, Canada, experiments were conducted to quantify tillage and water erosion under conventional and conservation tillage. Tillage erosion was assessed with tillage translocation experiments using point tracers buried at two depths to track soil movements by tillage operations. Water erosion was assessed by measuring soil surface residue coverage and surface roughness using drone images and by rainfall simulation experiments. For primary tillage, moldboard plough (MP) moved tracers at both depths much further than chisel plough (CP). For planting, tillage translocation was at similar level to that for CP. For planting plus harvesting of potato, tillage translocation exceeded the level for MP in the primary tillage. MP resulted in significantly less Surface Coverage Raito than CP, although the values were very low for both tillage treatments. Random Roughness Index was significantly lower for CP, only 63% of that for MP. The Chain Roughness Index (CRI) was significantly lower for along than across tillage direction. CRI for CP was significantly lower, about 82% and 62% of those for MP in the across and along direction, respectively. In the rainfall simulation experiments, CP significantly increased the time to runoff initiation and infiltration by 2.7 and 2.1 times, respectively. CP also significantly reduced runoff discharge, sediment yield and Flow Weighted Mean Sediment Concentration by 53-98%, 82-99% and 35-61%, respectively. Overall, conservation tillage was found to have lower risks for both tillage and water erosion in the study field.

**Keywords:** tillage translocation, rainfall simulation, conservation tillage

# Soil Erosion in the European Union: A major threat for EU agriculture

**Panos Panagos**[1*]

[1] *European Commission, Joint Research Centre (JRC), Ispra, Italy*

*panos.panagos@ec.europa.eu

**ABSTRACT**

Over the past decade, the European Commission's Joint Research Centre (JRC) has refined the Revised Universal Soil Loss Equation (RUSLE) model to assess water-induced soil erosion across Europe for the References period of 2010. This updated framework, termed RUSLE2015, integrates the most recent pan-European datasets for critical input parameters, including rainfall erosivity, soil erodibility, land cover-management, topography, and support practices (Panagos et al., 2015). The model has been applied to quantify water erosion-induced soil loss for the years 2000, 2010, and 2016, with latest assessment extending to 2023. Recent analyses (Panagos et al., 2020) indicate that the mean annual soil loss from water erosion within the European Union (EU) is approximately 2.4 t $ha^{-1}$ $yr^{-1}$, representing a 9% reduction since 2000. A recent estimate for 2023 confirms the trend as soil rosion loss is declining by 4% compared to 2016 (Borrelli and Panagos, 2025) . This decline is primarily attributed to the adoption of improved soil conservation practices in agricultural systems, driven by the Good Agricultural and Environmental Condition (GAEC) standards under the Common Agricultural Policy (CAP).

Previously, a significant research gap existed regarding wind erosion due to the absence of continental-scale assessments. To address this, the JRC evaluated wind erosion susceptibility across Europe using the Revised Wind Erosion Equation (RWEQ) model (Borrelli et al., 2017). Additionally, the JRC has advanced methodologies to quantify soil loss from other non-rainfall-driven processes, including crop harvesting (Panagos et al., 2019), tillage erosion (Borrelli et al., 2023), post-fire erosion (Vieira et al., 2024), and gully erosion (Borrelli et al., 2025). These contributions have enhanced the spatial and process-based understanding of erosion dynamics in Europe, encompassing both water and wind erosion, as well as anthropogenic and landscape-specific mechanisms.

Future projections suggest a 13–22.5% increase in water erosion-induced soil loss across the EU by 2050, primarily driven by anticipated increases in rainfall intensity under climate change scenarios (Panagos et al., 2021). Under Representative Concentration Pathways (RCPs) 2.6, 4.5, and 8.5, rainfall erosivity is projected to rise by 15.7–25.5%, with corresponding proportional increases in erosion rates. To mitigate these risks and inform adaptive management strategies, the EU Soil Observatory has prioritized the development of the EU Soil Erosion Modelling (EUSEM) Platform. This platform integrates advanced geospatial analytics and process-based modeling to provide high-resolution, spatio-temporal soil erosion estimates. Such data are critical for supporting EU policy frameworks, including the Soil Monitoring Law, the CAP, and the Sustainable Development Goals (SDGs), by enabling evidence-based decision-making for soil conservation and land-use planning.

# Drainage network connectivity controls phosphorus transport and export

**Ehsan Zarrinabadi[1*], David A. Lobb[1], Masoud Goharrokhi[1] and Eric Enanga[2]**

[1]Department of Soil Science, University of Manitoba, 13 Freedman Crescent, Winnipeg, Manitoba, R3T2N2, Canada

[2]Department of Physical and Environmental Sciences, University of Toronto, 1265 Military Trail, Toronto, Ontario, M1C1A4, Canada

Ehsan.zarrinabadi@umanitoba.ca

**ABSTRACT**

Phosphorus losses from agricultural landscapes contribute to freshwater eutrophication and have been considered a key water quality concern in the Red River Valley of southern Manitoba, Canada., which is characterized by clay-rich Chernozemic and Vertisolic soils. Crop production mainly relies on surface drainage (i.e., man-made shallow, in-field drains) and tile drainage to remove excess water and lower the water table. A dense network of in-field surface drains, often on the order of 20-25 km per land section (~ 259ha), connects fields to ditches and streams, increasing hydrologic connectivity and the potential for phosphorus transport during erosive runoff events. Tile drainage is increasingly being adopted to manage excess water on poorly drained soils in this region, which can further increase dissolved phosphorus export under certain soil and management conditions. This study assessed the integrated effects of drainage systems (i.e., surface and tile drainage) on phosphorus transport within the soil profile and overland flow over a four-year period (2022, 2023, 2024, and 2025) in the typical landscapes of the Red River Valley in southern Manitoba. Soil and crop samples were collected over tile lines and between tile lines, as well as across surface-drained positions. Soil phosphorus status was characterized using total phosphorus, water-extractable phosphorus, and Modified Kelowna–extractable phosphorus. Runoff and associated sediment and nutrient exports were quantified at edge-of-field monitoring stations using automated samplers triggered during runoff events. A surface water retention structure receiving tile discharge was also monitored to assess tile-drain effluent water quality. Results showed that higher concentrations of TP, WEP, and MKP are found in the surface soil layers, especially in tile-drained plots. Moreover, no significant differences were observed in crop yields (canola, wheat, and soybean) between surface and tile drainage, though tile drainage led to slightly higher variability in yield. Nutrient and sediment export varied substantially across major erosive events, indicating strong event-driven nutrient loss dynamics, particularly under conditions of limited soil surface cover by crops in spring. The findings highlight the need for targeted mitigation strategies that disrupt phosphorus connectivity along the field-ditch drainage continuum (e.g., field-edge vegetated buffer strips, managed harvest of buffer and ditch vegetation to remove accumulated phosphorus in biomass, and in-field water retention structures) to reduce peak flows and trap sediment and particulate phosphorus during high-flow events.

## ABSTRACT

Sustainable land use planning requires spatially explicit evaluation of soil and landscape properties to balance agricultural productivity with environmental stewardship. This study applies a multi -criteria soil and land evaluation framework combined with rule-based land conversion scenarios to identify opportunities for improving ecosystem services while maintaining productive capacity in agricultural landscapes. The aim of the study was to detect how to allocate land uses to increase biodiversity and pollination services, prevent water erosion with minimal reductions in crop yield. We focused on a 5 km × 5 km landscape window in Märkisch-Oderland, Brandenburg, Germany, using GIS layers of topography, soil properties, land use, meteorological data, and multispectral satellite imagery. NDVI-derived soil productivity estimates were used as the primary indicator of arable potential, while InVEST models assessed soil erosion and pollination services.

Marginal arable land was identified using integrated indicators oflow soil productivity, slope-driven erosion risk, and landscape position, representing areas with limited capacity for stable crop yields.

Four scenarios converted these marginal areas into grassland buffers, flower strips, or mixed arrangements to evaluate trade-offs among soil conservation, habitat provision, and arable production. Results indicate that grassland buffers reduce mean soil erosion from 5.93 to 4.61 t ha_¹ yr_¹, while flower strips increase pollinator abundance by 50 % in pollinator-dependent crops. Mixed placements improve habitat richness and provide a balanced enhancement of multiple ecosystem services with minimal loss of productive area. These findings demonstrate how GIS-based soil and land evaluation and spatially targeted land use planning can optimise soil function, ecosystem services, and agricultural productivity simultaneously. The study provides a practical framework for integrating soil and landscape assessment into sustainable land management strategies, offering actionable guidance for policymakers and farmers to support resilient agroecosystems.

## ABSTRACT

The Congo Basin, home to the world's second largest tropical rainforest and river network, plays a crucial role in the global carbon (C) cycle. However, rapid population growth and land-use changes are intensifying geomorphic and biogeochemical disturbances. Consequently, the basin is experiencing accelerated soil redistribution, whose impacts on lateral C transfer along the land–ocean aquatic continuum (LOAC) remain largely unknown. By integrating the most comprehensive observation dataset available with a state-of-the-art land surface model (ORCHIDEE-$C_{lateral}$), this study quantified the magnitude and temporal evolution of lateral C fluxes in the forms of particulate organic carbon (POC), dissolved organic carbon (DOC), and carbon dioxide ($CO_2$) over the past five decades, and assessed the impact of these lateral C transfers on the terrestrial C budget.

The calibrated ORCHIDEE-$C_{lateral}$ model explains 73%, 84%, 78%, and 84% of the spatial variation in observed river water discharge, sediment discharge, POC concentration, and DOC concentration in the Congo River network, respectively. It also captures well the seasonal variations in riverine water discharge, sediment discharges, water surface extent, and riverine $CO_2$ partial pressure. Using the calibrated model, we reconstructed the historical evolution of C fluxes and transformations along the LOAC. Since 1970, lateral C (i.e., POC, DOC, and $CO_2$) input from land to river has increased significantly (Mann–Kendall $P < 0.001$), with POC, DOC, and $CO_2$ rising by 51%, 20%, and 29%, respectively. The increase in POC is primarily driven by land-use change, followed by climate change and rising atmospheric $CO_2$. Of the terrestrial C entering the Congo River network, 61% of DOC and 67% of POC remain within the river–floodplain complex—approximately two and three times the proportion retained in the Amazon and European river networks, respectively. These results suggest that the majority (> 60%) of the laterally transported terrestrial C is stored or transformed inside the Congo Basin rather than being exported to the ocean or released to the atmosphere. With the projected rapid population growth and land-use expansion in the Congo Basin, lateral C fluxes along the LOAC are expected to intensify further, reinforcing the Congo Basin's role as a major inland C buffer that reshapes the regional land–ocean C balance.

# Check dams as a major terrestrial sink for eroded sediment and organic carbon on the Chinese Loess Plateau

**Yi. Zeng**[1*]

**ABSTRACT**

Lateral transfer and deposition of terrestrial organic carbon (OC) represent a critical but poorly constrained component of the global carbon cycle, largely because OC burial in dryland depositional environments remains insufficiently quantified. While substantial progress has been made in understanding OC sequestration in aquatic systems, the fate of eroded OC deposited on land is still unclear. Here, we assess sediment retention and OC burial by check dams on the Chinese Loess Plateau, a region characterized by extreme soil erosion and the highest density of check dams worldwide. Using extensive field surveys combined with remote sensing analyses, we provide a large-scale, observation-based estimate of sediment and OC sequestration by these structures. We show that 50,226 active check dams intercepted 10.2 ± 0.6 Pg of eroded sediment between 1970 and 2020, equivalent to approximately 46% of the sediment load historically delivered by the Yellow River, once the world's largest fluvial sediment source to the ocean. Based on 86 deep sediment cores, we estimate that check dams buried a total of 21.6 ± 9.9 Tg of OC over the past five decades, corresponding to an average burial rate of 468 g C $m^{-2}$ $yr^{-1}$—nearly an order of magnitude higher than that reported for global lakes and reservoirs. Moreover, the OC burial efficiency of check dams (~80%) is substantially higher than that of most other depositional environments, indicating effective long-term stabilization of eroded carbon. Given the widespread use of check dams for erosion control across dryland regions worldwide, our findings identify check dams as a previously underappreciated terrestrial carbon sink that should be explicitly incorporated into regional and global carbon budgets.

**ABSTRACT**

Topography is an important factor affecting soil erosion and is measured as a combination of the slope length and slope steepness (LS-factor) in erosion models, such as Universal Soil Loss Equation (USLE), Revised Universal Soil Loss Equation (RUSLE), and Chinese Soil Loss Equation (CSLE), etc. However, global high-resolution LS-factor datasets have rarely been published. Challenges arise when attempting to extract the LS-factor on a global scale, specifically the limited coverage of the Shuttle Radar Topography Mission (SRTM) beyond 60°N latitude, the presence of mixed noise artifacts within raw elevation data, and the systematic errors introduced by projecting spherical geodetic coordinates onto planar systems during calculation. This study establishes a comprehensive framework to generate a new global 1-arcsecond LS-factor dataset (DS-LS-GS1) by integrating improved data preprocessing with a novel calculation algorithm. First, to enhance data accuracy, we apply an adaptive low-rank group sparse model based on edge preservation (ALGS_EP). This denoising algorithm addresses the mixed noise inherent in SRTM data by leveraging gradient constraints, successfully removing 97.6% of random and stripe noise while preserving essential terrain structure. Second, to construct a seamless global digital elevation model (DEM), we propose a topographic relief fitting mosaic method (TRF-60). This method utilizes heuristic breadth-first elevation fitting order search and adaptive local topographic relief fitting algorithm to eliminate seamlines when mosaicking SRTM with quasi-global DEMs at high latitudes, ensuring consistent topographic continuity. Based on a seamless, denoised global DEM, we developed an improved method to estimate the LS-factor. This method calculates slope gradient and slope length directly from geographic coordinates (longitude and latitude), eliminating the need for projection transformation (termed LS-WPC). Using this method, we produced a global 1-arcsec resolution LS-factor dataset (DS-LS-GS1) and integrated the algorithm into a software tool (LS-Tool). The LS-WPC method recalculates the value of each grid cell size and updates the corresponding slope steepness and slope length computation equations. This method avoids the error caused by projection at the global scale. Validation of the Himmelblau–Orlandini mathematical surface shows that errors are less than 1%. We assess the LS-WPC method on 20 regions encompassing 5 landform types, and $R^2$ of LS-factor are 0.82, 0.82, 0.83, 0.83, and 0.84. Moreover, the computational efficiency can be enhanced by up to 25.52%. DS-LS-GS1 can be used as high-quality input data for global soil erosion assessment.

# A topographic relief fitting mosaic method for eliminating seamlines of the SRTM and additional quasi-global DEM mosaics at 60°N latitude

**Songyuan Li[1], Zhuang Yan[1], and Hongming Zhang[1*]**

[1] *College of Information Engineering, Northwest A&F University, Yangling, China*

*zhm@nwsuaf.edu.cn

**ABSTRACT**

The Shuttle Radar Topography Mission (SRTM) 1 arc-second is a quasi-global digital elevation model (DEM) of excellent quality that has undergone multiple revisions, including addressing data gaps, filling voids, and flattening water, and is always applied to worldwide terrain analysis, such as topographic mapping and disaster management. As SRTM has no data collection at latitudes above 60°N, it is necessary to expand SRTM coverage by introducing additional quasi-global DEMs of those areas. This extended process completes the SRTM and other DEM mosaics at 60°N latitude. Unfortunately, because multi-source DEMs have non-negligible elevational differences, seamlines can be easily observed and existing mosaic methods cannot eliminate seamlines, which may result in unnatural topographic relief. This study proposes a topographic relief fitting mosaic method (TRF-60) that conforms to the natural SRTM terrain. TRF-60 uses a heuristic breadth-first elevation fitting order search from seamlines to determine the mosaic order of grids and then obtains a suitable blending elevation value of each grid in the mosaic output using an adaptive local topographic relief fitting algorithm. By designing heuristic mosaic conditions consistent with local slope changes, it takes further advantage of the continuity within neighborhoods to use a heuristic breadth-first search instead of row-column traversal. Within a heuristic breadth-first search, DEMs are partitioned into six-level regions by constraining the slope and decomposing the mosaic problem into mosaic subproblems in regions with similar topographic features. This study devised an adaptive algorithm to calculate mosaic elevation blending weights on different landforms, while maintaining the local flow directions. In addition, this study smoothed the slope-constrained region edges to avoid new seamlines. Compared with the first and last (FL), weighted average (WA), and feathering-based blending (FBB) methods, TRF-60 not only solves the seamline problem, but also obtains the best representation of elevation, slope, contour, and river networks. In addition, the SRTM and Advanced Land Observing Satellite (ALOS) world 3D-30 m (AW3D30) mosaics (SAMs) exhibited more consistent terrain details and denser contours. The SRTM and Copernicus DEM mosaics (SCDMs) have a higher accuracy and express more natural contours and river networks. Overall, the SCDMs had better data quality. TRF-60 exhibits a smooth transition of elevation values in the multi-source DEM mosaic and provides a quality solution for similar mosaic problems.

# Long-Term Dynamics and Driving Mechanisms of Wind Erosion Across China (2001–2024)

## ABSTRACT

Wind erosion is a major driver of land degradation in arid and semi-arid regions of China, yet large-scale assessments are often limited by simplified representations of vegetation cover. Most existing wind erosion models focus primarily on photosynthetically active vegetation, potentially underestimating surface protection during dormant seasons when non-photosynthetic components, such as standing residues and litter, remain effective.

To address this limitation, this study enhances the Revised Wind Erosion Equation (RWEQ) model by explicitly incorporating both photosynthetic and non-photosynthetic vegetation fractions into a unified vegetation protection framework, derived using a linear spectral unmixing approach. Based on this improved model, national-scale wind erosion dynamics across China from 2001 to 2024 were reconstructed at fine spatial resolution.

The results reveal pronounced spatial heterogeneity and strong seasonal variability in wind erosion intensity. Erosion hotspots are primarily concentrated in arid and semi-arid dryland regions, with the highest erosion rates occurring during periods of limited green vegetation cover. The mean annual wind erosion across China was estimated at 2.16 t $hm^{-2}$, and statistically significant declining trends were detected over 49% of the national land area. Over the past two decades, a general reduction in wind erosion risk is observed across much of China, particularly in regions influenced by ecological restoration and land management programs.

Further analysis indicates that atmospheric conditions, especially wind-related factors, dominate the interannual variability of wind erosion at the national scale. Vegetation recovery plays a critical moderating role by enhancing surface protection and reducing erosion susceptibility, whereas soil moisture exhibits a comparatively weaker influence. By more accurately representing seasonal vegetation structure, this study provides a refined assessment of wind erosion processes and offers useful insights for evaluating ecological restoration outcomes and supporting climate-adaptive land management strategies.

**ABSTRACT**

The soil erodibility factor (K) is the main data required for large-scale soil erosion investigation and mapping using soil erosion models. For soil erosion evaluation at the slope scale, the erodibility factor (K) can be directly quantified through field measurements from a unit runoff-plot. In watershed and regional-scale soil erosion assessments, the soil erodibility factor is commonly estimated and mapped by employing soil property data and soil erodibility models. Currently, there are four models commonly used for calculating regional soil erodibility factor, including the K-factor algorithm proposed by the Universal Soil Loss Equation Handbook (USLE-K), the K-factor algorithm proposed by the Revised Universal Soil Loss Equation Handbook version 2 (RUSLE2-K), the K-factor algorithm proposed by the Erosion Productivity Impact Modeling (EPIC-K), and the K-factor algorithm based on the Deometric Mean Diameter-based model (Dg-K) proposed by Römkens. However, it remains to be studied which algorithm is more suitable to calculate soil erodibility factor (K) in the global scale. While, soil erodibility factor (K) is mostly calculated based on soil physical and chemical property data, which does not involve the content of rock fragments in these algorithms. The influence of rock fragments and their distribution difference on soil erosion requires further study. In this study, USLE-K, RUSLE2-K, EPIC-K and Dg-K algorithms and SoilGrids v2 data released by ISRIC were used to estimate the global soil erodibility factor (K) and generate a K map with 250m resolution, and analyze the spatial pattern, hotspot areas and main controlling factors of the estimation results. The measured data of soil erosion factor (K) were retrieved by literature search, and the data of 106 points, 1868 runoff plots and 12181 plot years were collected. The measured database of K factor value was established. The applicability of the four algorithms mentioned above was then analyzed, and their estimated values were tried to be modified. Then the USLE-K algorithm was taken as an example to calculate the effect of rock fragments in the soil profile and rock fragments on the soil surface. The results showed that (1) The spatial patterns of global K factors estimated by the USLE-K, RUSLE2-K, EPIC-K and Dg-K models are similar, showing that values are higher in the Northern Hemisphere than in the Southern Hemisphere, within the Northern Hemisphere, values are greater in the mid-latitudes compared to the low and high latitudes. However, the estimation results of various algorithms are different in the statistical distribution value. (2) Comparing to 106 measured values, the mean value of the result estimated by RUSLE2-K is the closest to the measured K factor, which is related to the comprehensive consideration of soil property factors in RUSLE2-K algorithm, and the modification of soil texture and soil structure index algorithms by RUSLE2-K algorithm. This is followed by the USLE-K algorithm and the EPIC-K algorithm, while the estimated K by Dg-K algorithm is quite different from the measured K factor. (3) The "hotspot" areas (HH type) with high K-factor values are concentrated in regions such as China, Russia, India, Germany, the United Kingdom, and Sweden, while the "coldspot" areas (LL type) with low K-factor values are concentrated in Brazil, Mexico, the Republic of the Congo, Zambia, Australia, and other locations.(4) Based on the importance of various soil attributes to K-factor values obtained through random forest regression, it was found that silt content has the greatest influence on the K-factor, followed by organic matter content, clay content, and structural class, whereas sand content and textural class have relatively minor effects on the K-factor. (5) The presence of rock fragment in the soil profile increased the global soil erodibility factor by 2.84%. The rock fragment on the soil surface of the mountain land and desert/Gobi reduced soil erodibility by 18.7%, the combined effect reduced soil erodibility by 6.98%. The dampening effect of rock fragment on K primarily occurs in mountainous areas with weak soil development and more rock fragment cover, as well as in soil types characterized by higher rock fragment cover. This study made the calculation of K more complete and accurate, and is of great significance for improving the accuracy of regional soil erosion estimation and promoting the scientific level of global soil erosion mapping. An earlier version of this research data was made available to the FAO Global Soil Erosion Mapping Group in 2019, and the K-factor data product, which is continuously revised based on the revision of the calculated parameters, is also available for related studies.

# Gully runoff is the primary factor triggering gravity erosion: A case study in the Top Ten Tributaries Watershed, China

**Taoyan Dai [1*], Xiangzhou Xu [2]**

[1] *School of Infrastructure Engineering, Dalian University of Technology, Dalian, 116024, China*

*E-mail Address of Presenting Author

daitaoyan@mail.dlut.edu.cn

**ABSTRACT**

Clarifying the effects of rainfall and runoff on the types and scales of gravity erosion in gullies is fundamental to establishing soil erosion control measures in compound erosion areas. Based on field observations in the North Second Gully of Baijiaqu (NSGB), the types and scales of gravity erosion in gullies and their correlations with rainfall and runoff in the hilly region of The Top Ten Tributaries Watershed (TTTW) were analyzed. (1) Gully runoff was the primary factor triggering newly occurred gravity erosion in 2025. Among the 25 newly occurred gravity erosion events observed that year, 24 events were triggered by gully runoff. (2) Gravity erosion induced by gully runoff primarily occurred as translational landslides. Among these gravity erosion events, 14 events were identified as translational landslides. (3) The main runoff direction of gully runoff influences the development types of gravity erosion. Collapses frequently occur on concave banks directly facing the runoff, while landslides are more likely on convex banks oriented away from the runoff. In the study area, gully runoff is not only the main driver for triggering gravity erosion but also a key factor in shaping its spatial distribution and types. It is recommended to strengthen runoff regulation in gullies of the TTTW to mitigate gravity erosion risks on gully sidewalls during extreme rainfall.

*chenshuai@cau.edu.cn

**ABSTRACT**

Maize row planting creates distinct intra- and inter-row zones with horizontally varying rainfall and root distributions. How such variability impacts horizontal distributions of water erosion remains unclear. This study examined horizontal distributions of rainfall, soil erosion, and runoff in intra- and inter-row zones through simulated rainfall experiments on sloping maize farmland during the period of full canopy development in the black soil region of Northeast China. Intra-row zones received more rainwater (averaging 60.5% of total rainfall, comprising 43.5% stemflow and 17.0% throughfall) than inter-row zones (receiving only 31.2% throughfall). Nevertheless, intra-row erosion comprised 11.7–27.0% of total sediment loss, whereas inter-row zones generated 73.0–88.3%. Runoff depth did not differ significantly between zones, but intra-row runoff coefficients were markedly lower (mean = 0.35) than inter-row coefficients (mean = 0.68). Net rainfall drove intra-row erosion, with stemflow explaining significantly more variability ($R^2$ = 0.53) than throughfall ($R^2$ = 0.07). However, inter-row rainfall erosivity originated solely from throughfall and was stronger than intra-row rainfall erosivity. Soil erosion resistance did not differ significantly between zones, indicating the erosivity of redistributed rainfall, not inherent soil erodibility, drove horizontal variation in erosion. Intra-row soil infiltration and saturated hydraulic conductivity were significantly higher and associated with greater root mass density, which promoted rainwater infiltration and reduced runoff conversion. These findings confirm inter-row zones as hotspots for water erosion owing to their higher redistributed rainfall erosivity and lower soil infiltration capacity. Targeted conservation measures, e.g., improving infiltration or applying inter-row ground cover, are crucial for reducing water erosion in sloping maize farmland.

## ABSTRACT

Soil organic carbon is known to enhance the stability of aggregates against slaking, slumping and erosion, but quantitative measures of hydromechanical drivers at aggregate scale are lacking. Using hydrological and mechanical measurements at raindrop size, this study quantified erosion and structure collapse mechanisms. It used a sandy loam soil from a >10-year-old field experiment that received either no organic amendment (control) or 200 t $ha^{-1}$ compost. Erosion properties were measured over 30 and 60 minutes of simulated rainfall events on soil cores filled only with undisturbed soil aggregates 5mm in diameter. X-ray µCT quantified structure collapse and porosity changes. On aggregates and the surface of the packed cores, mechanical measurements of hardness and elasticity were obtained with a 3 mm spherical loading indenter. With the same samples, hydrological measurements of water sorptivity and repellency used a miniaturized infiltrometer device with a 1.2-mm tip radius. Carbon amendement did not affect water stable aggregates. However, the underpinning mechanical and hydrological drivers of soil stability differed. The aggregates used to the pack the cores had 14% greater ethanol sorpitivity and 17% greater repellency for compost compared to control treatments. At airdry aggregates the compost reduced soil hardness and elasticity by 52% and 56%, respectively. Under fast vetting-moisutre level, compost resulted 32% greater hardness then control.After 60 minutes simuilated rainfall, control soils exhibited 32% greater surface slumping and a 29% greater reduction in total porosity than compost-amended soils. Infiltration of the rainfall was similar between treatments after 30 minutes but was slightly increased in compost-amended soil after 60 minutes. The marked structural collapse observed in the control soil coincided with pore network degradation and surface aggregate dispersion-sedimentation, reflecting reduced aggregate stability and diminished water infiltration under erosive stress. Splash sediment and surface roughness was similar between treatments at post 30- and 60-minutes rainfall. Soil mechanical properties were driven by organic carbon and very sensitive to moisture levels. Soil hardness and elasticity were significantly higher at airdry moisture level but under fast vetting-moisture level the values changed, and compost-amended soil was harder than control which exhibit greater resistance to deformation. The findings confirm that compost-derived carbon resisted erosion by mechanical stabilization, decreasing pore structure collapse at the aggregate scale under rainfall erosive stress. These first ever raindrop scale hydrological and mechanical measurements demonstrate the fundamental role of organic carbon in maintaining aggregate structural resistance against erosion.

**ABSTRACT**

**S**oil **e**rosion **m**apping (SEM) is both a critical methodology and a core topic in the field of regional soil erosion research. From the mid-1920s to the late 1990s, a period referred to here as the "pre-GIS era", when remote sensing and GIS technologies were not yet widely used in SEM, a number of countries and international organizations carried out systematic researches and mapping practices on soil erosion surveys and mapping at national and even global scales. They included the United States, the former Soviet Union, China, Australia, FAO, etc. These efforts led to the development of soil erosion classification systems. The resulting soil erosion maps established an ontological framework for large-area soil erosion studies, provided valuable historical baseline and contextual information for research on dynamic processes of regional soil erosion, and laid the foundation for classical paradigms in regional soil erosion mapping. Furthermore, these cartographic achievements have exerted a profound historical influence and continue to have a sustained practical significance in various aspects. These include legislation, the institutional development of soil and water conservation, the establishment of regional or national soil erosion monitoring systems, and the advancement of global soil and water conservation initiatives. Nevertheless, these pioneering studies and map products have received less attention recently and are increasingly at risk of being overlooked, becoming "a Sleeping Beauty". This paper focuses on major achievements in soil erosion surveying and mapping during the pre-GIS era. It examines representative cases and historical contexts, summarizes their scientific contributions and societal impacts, and explores their implications for the development of contemporary digital soil erosion mapping, with the aim of promoting continued innovation and academic continuity in this field.

**ABSTRACT**

On the slopes of the loess hilly region, the interaction between vegetation coverage and spatial distribution dominates hydrological connectivity, thereby altering the runoff and sediment yield threshold and the balance process of infiltration-runoff partitioning, and ultimately affecting the erosion reduction efficiency of vegetation configuration projects in this area. Although there is a consensus on the enhancing effect of vegetation on the hydrodynamic threshold of soil erosion, previous studies have mostly regarded vegetation as a homogeneous coverage factor, ignoring the key role of its spatial pattern. Based on in-situ controlled runoff scouring experiments in runoff plots of the Chaigou Watershed on the Loess Plateau, this study aims to reveal the regulatory mechanism of vegetation spatial configuration on soil erosion and sediment yield on hilly-gully complex slopes. The erosion responses under different vegetation coverage (25%, 50%, 75%) and three typical vegetation distribution patterns (vegetation located on the upper, middle, and lower parts of the hilly slope) were systematically quantified at multiple flow rates (12, 16, 20 L/min). Firstly, the piecewise regression model was used to accurately identify the critical hydrodynamic threshold where the soil erosion rate undergoes an abrupt change. Secondly, the theories of energy dissipation and entropy change were introduced to clarify how different vegetation patterns alter the flow energy structure. Finally, the Generalized Additive Model (GAM) combined with SHAP (SHapley Additive exPlanations) interpretability analysis was used to quantitatively analyze the nonlinear effects and relative contributions of vegetation coverage, spatial distribution, and runoff intensity on erosion and sediment yield. The results showed that there is a critical abrupt threshold driven by hydrodynamic conditions in the erosion process of the complex slopes in the loess hilly region. When the Reynolds number (Re) and runoff depth of the runoff exceed 428.84 and 1.05 cm, respectively, the slope sediment yield rate increases sharply. Meanwhile, the specific conditions triggering the threshold exhibit a strong dependence on the vegetation spatial pattern: under high coverage (75%), the critical flow shear stress (τ) required for sediment initiation on the complex slope reaches its peak when vegetation is arranged on the upper part of the hilly slope, while the critical Froude number (Fr) and runoff depth (FD) decrease from the top to the bottom of the slope. The spatial differentiation of the above thresholds originates from the difference in energy dissipation mechanisms: vegetation arranged on the upper part of the hilly slope exhibits an effective source blocking effect, maintaining the low-entropy ordered state of the complex slope; however, under extreme hydrodynamic conditions, the single arrangement of vegetation on the lower part of the hilly slope leads to high system entropy in the medium to high vegetation coverage range (50%-75%). Therefore, the erosion stability of the hilly-gully complex slope is dominated by the vegetation layout at key slope positions. Identifying and optimizing the vegetation configuration at key nodes is conducive to the precision scientific regulation of soil and water conservation projects in arid and semi-arid regions.

# Coupled Wind-Rain Forcing Alters Runoff Generation and Soil Loss Dynamics Across Soil Surface Conditions

## ABSTRACT

Soil erosion results from complex interactions among climatic drivers and soil surface properties, yet erosion processes are commonly assessed under rainfall-only and wind-only conditions. In particular, the role of wind–rain coupling and its interaction with soil surface roughness remains poorly represented in erosion studies and predictive frameworks. This study examines how wind-driven rain modifies hydrological response and soil detachment processes under contrasting soil surface roughness conditions.

Controlled experiments were conducted using a coupled rainfall-wind simulation system to apply windless and wind-driven rainfall events at increasing wind velocities on sandy loam soils. Rainfall characteristics were measured under both calm and windy conditions. Time-to-runoff, time-to-infiltrate, runoff and infiltrate volumes, splash erosion, and sediment transport were quantified on initially smooth and rough surfaces under windless and wind-driven rainfall conditions. Changes in soil surface morphology were assessed before and after each rainfall event to evaluate surface feedback induced by wind-rain forcing.

Results show that wind-driven rain fundamentally alters runoff and soil loss mechanisms by increasing rainfall kinetic energy, accelerating runoff onset, and amplifying soil loss compared to windless rainfall. While rough soil surfaces moderated runoff and sediment export at lower wind velocities, their buffering capacity diminished under stronger wind velocity, leading to soil and water losses comparable to or exceeding those observed under windless rainfall. In addition, wind-driven rain amplified soil surface roughness changes, increasing roughness on initially smooth surfaces while reducing roughness on pre-roughened soils, thereby extending these contrasting roughness responses previously observed under rainfall-only conditions (Bahddou et al., 2023).

These findings demonstrate that erosion response is governed not only by rainfall characteristics but also by the interaction between wind velocity and initial soil surface condition. Incorporating wind-rain coupling and dynamic soil surface states into erosion assessments is therefore essential for improving erosion prediction and for designing effective soil and water conservation strategies under changing climatic conditions.

**ABSTRACT**

Understanding the dynamics of soil organic carbon (SOC) loss in eroding slope is essential for assessing the role of soil erosion in the terrestrial carbon cycle. However, a systematic theoretical framework explaining how erosion processes influence SOC loss is still lacking. This study integrates $^{7}$Be tracer technology, in-situ runoff plot monitoring, and field/laboratory simulated rainfall experiments to examine variations in SOC content, enrichment, and fractionation within sediments produced by splash, inter-rill, and rill erosion, as well as in surface soils at the erosion interface. Key controlling factors—including slope gradient, slope length, vegetation cover, and rainfall characteristics—were evaluated to identify determinants of SOC dynamics and to elucidate the response mechanisms of slope SOC loss to soil detachment, transport, and deposition. Results indicate that mineral-associated organic carbon (MOC) is the dominant form of SOC loss across all erosion stages, substantially exceeding particulate organic carbon (POC) losses. Elevated loss rates occurred under high rainfall intensity (120 mm·h$^{-1}$, 20° slope), high raindrop kinetic energy (>168.4 J·hm$^{-2}$), longer slopes (>14 m), low vegetation cover (<35%), and extreme rainfall events. Fine particles, particularly clay and silt, were identified as the primary carriers of MOC. As rainfall intensity, slope gradient, length, and energy increase, fine particles migrate increasingly as aggregates, altering the distribution of SOC fractions and enhancing MOC accumulation. In contrast, vegetation cover reduces clay enrichment in sediments, indirectly attenuating MOC loss. Rainfall (intensity and kinetic energy) and topography (gradient and length) regulate erosion intensity (sediment yield), drive particle sorting (enrichment of fines), and ultimately govern the preferential transport and enrichment of MOC. Vegetation counteracts this process via physical interception and improved soil stability, thereby mitigating SOC loss. These findings provide a basis for further mechanistic studies on slope SOC loss and clarify the effects of erosion on soil carbon stock dynamics, carbon budgeting, and the development of process-based carbon cycling models.

**ABSTRACT**

Vegetation restoration is an important measure for controlling soil and water loss on the Loess Plateau. However, within the typical ridge-gully slope system, the interactive response mechanisms of runoff and sediment processes to natural rainfall characteristics and vegetation spatial patterns remain to be systematically elucidated. Based on ten in-situ runoff plots established in a representative small watershed of the Loess Hilly-Gully Region, long-term monitoring of erosive rainfall events was conducted, and the soil and water conservation benefits of nine vegetation configuration schemes (20%, 50%, and 75% coverage combined with upper, middle, and lower slope positions) were systematically evaluated relative to bare slopes. The results indicate that erosive rainfall in the study area can be classified into three types. Among them, Type II rainfall (high volume, long duration, low intensity) is the primary contributor to soil and water loss, accounting for 61.58% and 64.97% of total runoff and sediment yields, respectively, and exhibiting erosion characteristics dominated by total runoff volume. In contrast, Type I rainfall (short duration, high intensity) triggers the most intense erosion processes, with the highest average sediment concentration, representing a mode dominated by erosion intensity. Overall, the sediment reduction efficiency of vegetation measures (up to 68.59%) is significantly higher than their runoff reduction efficiency (up to 40.44%). Moreover, vegetation spatial configuration exerts a significant influence on regulation effectiveness, with configurations located on the lower ridge-gully slope demonstrating superior soil and water conservation functions. Under Type II rainfall conditions, which contribute most to erosion, the configuration with 75% vegetation coverage on the lower slope reduced runoff and sediment by 59.1% and 79.8%, respectively, compared with bare slopes. In addition, with increasing vegetation coverage, the sediment-runoff relationship gradually shifts from a linear form to a nonlinear form with a power exponent greater than 1, indicating that vegetation plays an important role in regulating the slope erosion resistance threshold. These findings provide a quantitative basis for the coordinated optimization of vegetation structure and function in restoration practices on the Loess Plateau.

**ABSTRACT**

**【Background and Significance】** Soil erosion has long been a persistent problem and will continue to be a major global ecological and environmental issue, posing a serious threat to sustainable economic development, ecosystem integrity, and global food security. A global inventory of soil erosion has been produced through the Global Assessment of Soil Degradation (GLASOD) launched in 1987 under the United Nations Environment Program. However, over recent decades, global climate warming and increasingly intensive human activities have substantially altered both the severity and spatial distribution of soil erosion worldwide. To support the 2030 United Nations Sustainable Development Goals (SDGs) and reduce information disparities among countries, the Food and Agriculture Organization (FAO) initiated the country-driven Global Soil Erosion Map (GSERmap) project, aiming to update the global soil erosion inventory using the most recent data and appropriate models and methodologies.

**【Objectives】**The objectives of the GSERmap project are to: (1) develop a relatively harmonized and integrated technical framework for global soil erosion investigation, assessment and mapping；(2) produce a series of global soil erosion maps and databases covering water erosion, wind erosion, and tillage erosion；(3) establish a foundation for long-term, dynamic monitoring and mapping of global soil erosion; and(4) enhance capacity for soil erosion monitoring, assessment, and decision-making at both global and national levels, particularly in developing countries.

**【Implement Procedures】** The GSERmap project will be implemented through international collaboration with peer experts, adopting a country-driven approach. The project will be carried out in three phases. Phase I will focus on integrating the technical system for global soil erosion mapping and establishing an information-sharing platform. During this phase, the *Technical Specifications and National Guidelines* will be developed and refined through pilot studies on soil erosion surveys and mapping in selected countries, and a basic global database of biophysical soil erosion factors will be established. Phase II will emphasize the collection of human-induced erosion factors using "sampling survey" techniques, integrating high-resolution remote sensing imagery with field investigations. Phase III will concentrate on global soil erosion assessment and mapping using model-based approaches, followed by validation and iterative revision.

**【Acknowledgments】** The authors would like to express their sincere gratitude to contributors from FAO/GSP, China, ERC, the United States, Canada, Italy, Australia and Japan.

**ABSTRACT**

Accurate estimation of global rainfall erosivity is essential for reliable assessments of global soil erosion. The most widely used global rainfall erosivity map was derived from 1–60 minute precipitation records at ~6,000 stations, using a single globally uniform conversion factor to translate coarse to fine temporal resolution data. However, large, spatially variable uncertainties compromise its reliability among regions, due to the highly uneven distribution of gauges and the scarcity of local validation data. In this study, the existing global map is refined using daily and hourly rainfall datasets from a much denser and more uniform station network. By systematically comparing these daily- and hourly-based estimates with published, high- accuracy regional rainfall erosivity studies, we adjust the global product to better reflect regional conditions. The resulting map provides a more robust basis for global soil erosion assessment and for evaluating the impacts of climate and land-use change on soil degradation.

**ABSTRACT**

Vegetation cover is a key factor regulating soil-erosion processes, and high-precision mapping of vegetation conditions is essential for improving regional soil-erosion assessment. The Universal Soil Loss Equation (USLE) and its revised version (RUSLE) remain the most widely used empirical models for predicting soil-erosion rates at regional and global scales. Within these models, the effect of vegetation on erosion is represented by the cover-management factor for non-agricultural land ($C_{non\text{-}crop}$ factor). This study presents an optimized computational procedure for estimating and mapping $C_{non\text{-}crop}$ within the Google Earth Engine (GEE) cloud-computing platform using multi-source satellite and climatological datasets.

Fractional vegetation cover (FVC) was first derived from NDVI, and land-use types were classified into forests, grasslands and shrublands, and other categories based on the MOD12Q1 product. Distinct calculation approaches were applied for each land-use class. For deciduous forests, the pixel-trisection model was used to improve the estimation of understory cover, with winter non-photosynthetic vegetation (fNPV) serving as an indicator of understory conditions. For grasslands and shrublands, an empirical formulation was adopted, while other land-use categories were assigned parameter values based on expert knowledge. To improve rainfall-erosivity estimation, three daily precipitation datasets (CHIRPS, ERA5, and PERSIANN-CDR) were evaluated against national meteorological station observations, and rainfall erosivity was calculated for 24 half-month periods.

The $C_{non\text{-}crop}$ factor was then estimated by integrating rainfall erosivity, vegetation cover, and land-use information. Results demonstrate that combining high-resolution Sentinel-2 imagery with 10-m land-use data substantially enhances the accuracy and spatial detail of $C_{non\text{-}crop}$ estimates, enabling a transition from regional-scale to localized assessments. The computational framework developed in this study provides an efficient, scalable approach for soil-erosion monitoring and mapping across diverse river basins and regions, offering valuable support for precision soil-conservation planning and ecological management.

## ABSTRACT

Biochar, as a soil amendment, has been proposed as a promising strategy to mitigate soil erosion. However, long-term effects of biochar application on soil erosion process included rill erosion and interrill erosion remain poorly understood. This study investigated the long-term dynamics of soil erosion in response to biochar amendment under natural rainfall with five slope gradients (2°, 5°, 10°, 15°, and 22°) and six biochar application rates (0, 1%, 2.5%, 4%, 5.5%, and 7%) from 2017 to 2022. The results showed that biochar exhibits a notable temporal effect and mechanistic evolution in regulating soil erosion on the loess slopes. In terms ofrill erosion, during the initial application period (within 3 years), biochar application at 1%~4% reduced rill detachment capacity and erodibility by approximately 35% and 39%, respectively, whereas more than 4% biochar conversely promoted rill erosion.

After 3 years, all biochar application rates shifted to an inhibitory effect, with reductions exceeding 50%, and the reduction increased proportionally with the biochar application rate. This is attributed to the long-term improvement of soil aggregate structure through enhanced organic carbon under biochar influence. The study pioneered the development of a predictive equation for rill erosion parameters based on the soil physicochemical properties under biochar application. Regarding interrill erosion, biochar reduced runoff within the first 3 years but increased it afterward, while the inhibitory effect on erosion caused by biochar persisted for 5 years before turning promotional. At the slope scale, biochar consistently reduced runoff by 28% and soil erosion by 62% across all periods, with effectiveness positively correlated with the application rate. Ultimately, the study reveals that environmental factors such as rainfall and slope gradient exert a more dominant influence on soil erosion processes compared to biochar application rate and duration. Fundamentally, the enhancement of soil quality induced by biochar serves as the key driver regulating soil erosion process. These findings indicate that biochar can serve as an effective short-term soil conservation measure, but its efficacy is highly dependent on application rate, duration since application, rainfall type, and slope gradient.

**ABSTRACT**

Accelerated soil erosion and deposition pose major threats to soil health and ecosystem services in forested landscapes. Clear-cutting, particularly whole-tree harvesting (WTH), in which the stem and crown are removed from the site, intensifies erosion processes. At the Hubbard Brook Experimental Forest (HBEF) in New Hampshire, US, WTH was conducted in Watershed 5 between 1983 and 1985, and several studies have examined its ecological impacts; however, no study has evaluated its effect on soil redistribution. Here, we aimed to 1) quantify erosion and deposition rates along slopes following WTH using $^{239+240}$Pu, 2) evaluate soil morphological changes nearly 40 years after harvesting, and 3) test the suitability of $^{239+240}$Pu as a tracer in acidic sandy soils. The results revealed that WTH increased soil redistribution: mid-backslope soils showed erosion (−6.8 ± 3.33 t/ha/y), toeslope soils showed deposition (2.06 ± 2.56 t/ha/y), and upslope soils displayed values near zero. Our findings also indicate that a portion of the eroded material was exported out of the watershed, representing a direct pathway for soil carbon loss. Thinner organic horizons were the only remaining morphological sign of disturbance, indicating incomplete forest-floor recovery. $^{239+240}$Pu depth profiles showed strong near-surface retention with only limited lateral subsurface migration, confirming the suitability of $^{239+240}$Pu for tracing erosion processes in northern hardwood soils. These findings evidenced that WTH leaves a long-term geomorphic imprint and that soil redistribution play a key role on soil carbon dynamics, highlighting the need to consider erosion processes for sustainable forest practices, soil management, and carbon storage.

## ABSTRACT

**Background:** Terraces enhance soil conservation ability by modifying micro-topography. Insufficient understanding of the topographic characteristics of terraced watersheds may significantly compromise the accuracy of soil erosion assessments. Digital Elevation Model (DEM) products generated through conventional methods are often constrained by coarse spatial resolution, which limits their capacity to accurately characterize the fine-scale micro-topography of terraced landscapes. Although DEMs derived from emerging Unmanned Aerial Vehicle (UAV) photogrammetry provide enhanced spatial resolution and can effectively capture structural characteristics of terraces, they remain susceptible to elevation biases in densely vegetated regions—particularly in shrub-dominated areas—due to interference from canopy height.

**Methods and Results:** To overcome these limitations, this study selects the Liudaogou Watershed in northern Shaanxi, Loess Plateau, as a representative case study area and proposes a novel method for generating high-resolution DEM specifically tailored to terraced watersheds (technical procedure illustrated in Fig. 1). The proposed approach integrates the complementary advantages of Gaofen-7 satellite-derived DEM and UAV-acquired DEM collected during fallow periods through an adaptive local filtering approach, thereby producing an enhanced DEM with superior spatial fidelity. Comparative evaluation against Gaofen-7-based DEM and UAV-based DEM, as well as field validation data demonstrates that the resulting DEM not only preserves critical structural elements and subtle local terrain variations characteristic of terraces but also significantly reduces vegetation-induced elevation biases, thereby improving overall accuracy and reliability.

**Conclusion:** The proposed method effectively captures the micro-topography of terraced watersheds, enabling more accurate assessment of soil erosion in the Loess Plateau.

yufei970911@163.com

**ABSTRACT**

The loss of soil and water on sloping farmland in the black soil region of northeast China is particularly severe and requires urgent attention. Changes in root characteristics and soil properties induced by different crop types considerably affect soil erosion. The soil anti-scourability index is a key parameter for evaluating soil erosion. However, the effects of crop type on the soil anti-scourability index regarding sloping farmland are not clear. Therefore, this study was conducted to quantify root characteristic effects of alfalfa, soybean, and maize on soil properties at different sampling stages, and to further identify factors influencing the soil anti-scourability index. Specifically, the soil anti-scourability index of alfalfa was significantly higher compared to soybean and maize. Compared with maize, the alfalfa treatment increased the soil anti-scourability index by 139.0% – 349.8%, while the soybean treatment increased the soil anti-scourability index by 19.9% – 37.5%. Structural equation modelling indicated that root characteristics influenced the agglomeration of soil aggregates, which increased both soil aggregate stability and macroaggregate ($WSA_{>0.25}$) abundance, thus ultimately increasing the soil anti-scourability index. Planting alfalfa is a practical and effective method for controlling soil erosion. The research results provide a practical application for improving soil erosion on sloping farmland and adjusting crop type.

## ABSTRACT

***Aims:***Green manure cultivation and tillage management are widely recognized as effective agronomic strategies to reduce soil use intensity, enhance productivity in multiple cropping systems, and mitigate soil erosion. However, under sloping farmland conditions, the combined effects of green manure incorporation and different tillage practices on soil physical structure and the stability of soil organic carbon (SOC) fractions remain poorly understood. This study aimed to systematically evaluate the interactive effects of green manure and tillage practices on soil properties, SOC fraction dynamics, and soil and water conservation in sloping red soils.

***Methods:***A field experiment was conducted in a sloping farmland double-cropping system with three treatments: green manure–maize under reduced tillage, green manure–maize under conventional tillage, and winter fallow–maize under conventional tillage. The effects of green manure combined with different tillage practices on soil physicochemical properties, SOC fractions, microbial biomass and enzyme activities, soil erosion, runoff-induced carbon loss, and maize yield were comprehensively assessed.

***Results:***(1) Compared with winter fallow–maize under conventional tillage, the integration of green manure with tillage significantly improved soil physical structure and nutrient status in sloping croplands, as indicated by a reduction in soil bulk density by 3.20–5.68% and an increase in SOC content by 2.95–11.57%. Among the treatments, the green manure–maize reduced tillage system exhibited more pronounced overall effects on improving soil structure and promoting carbon accumulation.(2) Improvements in soil structure and SOC status significantly enhanced soil and water conservation functions in sloping croplands. Green manure combined with tillage markedly reduced soil erosion intensity and runoff-mediated carbon losses, with runoff losses of total carbon, inorganic carbon, and dissolved organic carbon decreasing by 30.87–38.84%, 36.44–51.46%, and 33.98–51.70%, respectively. These erosion control and carbon retention effects were more evident under reduced tillage conditions.(3) Green manure rotation significantly increased maize yield by 11.54–14.57%, and yield was positively correlated with SOC and its labile fractions ($P < 0.05$), indicating that SOC, particularly the labile carbon pool, serves as a key regulator linking farmland management practices, soil and water conservation, and crop productivity.

***Conclusions:***Green manure incorporation increases organic matter and nutrient inputs and promotes crop growth, thereby improving soil physical structure and microbial activity. These changes enhance microbially mediated carbon transformation and stabilization processes, ultimately reducing the risk of soil and carbon losses through runoff and erosion. Overall, the integration of green manure with reduced tillage represents an effective management strategy that simultaneously improves crop yield and soil and water conservation, providing a sound theoretical basis and technical support for soil conservation practices in sloping farmlands of central Yunnan, China.

**ABSTRACT**

Gully erosion is an important yet often insufficiently represented component of global soil erosion mapping, playing a key role in land degradation and sediment production in many agricultural and semi-arid regions. Despite major advances in high-resolution remote sensing, large-scale gully erosion assessment remains less developed than hillslope-scale studies, mainly due to methodological inconsistency and limited cross-regional comparability. In this study, we present a systematic framework for large-scale gully erosion assessment and examine its applicability using two geomorphologically contrasting regions in China: the Northeast Black Soil Region and the Loess Plateau.

Using sub-meter satellite imagery, Unmanned Aerial Vehicle (UAV) photogrammetry, and extensive field surveys, we compiled a multi-scale gully inventory and assessed its suitability for large-scale mapping. Clear regional differences in gully development were identified. Gully density in the Loess Plateau (4.08 $km \cdot km^{-2}$) is considerably higher than that in the Black Soil Region (1.12 $km \cdot km^{-2}$), while the latter has shown rapid gully expansion over the past 15 years. Gully occurrence is primarily controlled by topographic factors, especially slope gradient and slope length, together with precipitation, and these controls exhibit nonlinear threshold behavior and strong spatial heterogeneity across regions.Comparison with UAV and field observations shows that sub-meter satellite imagery provides a reliable basis for large-scale gully mapping, with gully length identification errors below 6%. On this basis, we developed a predictive framework that combines unequal probability stratified sampling with machine learning to estimate regional gully density, yielding acceptable performance at the large scale (Nash–Sutcliffe Efficiency = 0.6).

The results demonstrate that combining appropriate sampling strategies with data-driven models is essential for advancing large-scale gully erosion mapping within global soil erosion assessments. Future work should focus on dynamic gully monitoring using high-temporal-resolution remote sensing, the development of transferable artificial intelligence methods for gully detection based on high-resolution imagery, and improved approaches for estimating gully depth. The proposed framework offers a practical methodological References for incorporating gully erosion into large-scale soil loss assessments and soil and water conservation planning.

**ABSTRACT**

Predicting soil erodibility in mountain landscapes remains difficult because steep terrain, heterogeneous soils, and strong environmental gradients generate marked spatial variability. This is the case in the Aosta Valley (NW Italian Alps), an alpine region known for its pedological and ecological complexity. In this study, we focused on the topsoil erodibility factor (K) of the USLE, starting from the assumption that—under relatively uniform texture typical of this area—soil organic matter (SOM) would represent the main source of variability in K. We computed K using both USLE (Wischmeier and Smith, 1978) and EPIC (Williams et al., 1983) equations and, for illustrative purposes we extended SOM values beyond the traditional limit of the USLE nomograph to evaluate its behaviour in highly organic alpine soils. To map K across the region, we applied a Digital Soil Mapping (DSM) workflow based on machine-learning models, and we examined field, laboratory data and environmental covariates to better understand how K relates to soil properties. We also derived USLE-based erosion estimates for selected profiles to indirectly evaluate whether the K calculations are consistent with observed soil behaviour. Our results indicate that: (i) the USLE K equation better captures mountain complexity; (ii) SOM significantly reduces K, with stone cover exerting additional influence; (iii) the model identified key regional drivers of K (carbon stock, elevation, pH), producing consistent spatial maps at 40 m resolution; and (iv) K values vary across soil horizons, humus systems, land uses, and soil types. Estimates of erosional denudation further highlight the central importance of SOM in enhancing the resistance of mountain soils. Although part of our modeling approach extends beyond the validated SOM range, we hope this study provides a perspective highlighting that mountain soils may not be inherently as vulnerable as conventionally estimated by standard models, emphasizing the importance of properly accounting for SOM when assessing erodibility in alpine environments.

## ABSTRACT

The Vegas meadows of the sub-Antarctic steppe of Patagonia constitute the main forage for livestock production; the main economic input for Region of Magallanes. This causes overgrazing with a subsequent meadow and soil degradation. Additionally, owing to their high humidity, they must be drained to assess the correct air fraction in the pore system. This management in general causes irreversible settlement, high shrinkage and low swelling capacity as they present a great amount of organic carbon (15-30%). These negative consequences require the development of water conservation practices, such as drainage water management (controlled drainage), that allow the control of the phreatic level, reducing drainage intensity and rates during winter months. This allows water conservation, but also can prevent soil degradation, since appropriate water content allows a more stable soil structure, capable of supporting animal loads without significant negative effects of animal trampling. However, there are very few investigations related to the hydraulic and physical behavior of these ecosystems under drainage and grazing. Therefore, this study aims to determine the influence of drainage on the properties related to the soil structure under Patagonian wetlands meadow (Vegas). To determine this, in a split-split-plot design 3 treatments were established: i) controlled drainage, ii) free drainage, iii) control or non-drained, with two different stocking rate treatments using ewes 1) 1 OE $ha^{-1}$ $year^{-1}$ and 2) 4 EO $ha^{-1}$ $year^{-1}$. Animal entrance:
availability of dry matter between 2,100 and 2,300 kg DM $ha^{-1}$, and the grazing period: one month for all treatments. The CD considers a phreatic level depth between 30 - 50 cm and FD: 100 cm from the soil surface. Before and after the grazing events, undisturbed soil samples were collected from soil surface (0-10 cm). From the samples, the: pore size distribution (PSD) together with air conductivity, precompression stress (Pc), were determined for both animal loads and drainage treatments, were determined in undisturbed soil samples taken from first 10 cm. Generally, both variables influence the investigated properties.
More intensive grazing leads to greater soil degradation, reflected in reduced precompression stress and airflow. Pore size distribution demonstrates its positive distribution from an agricultural perspective, as it increases the soil's water retention capacity. However, if we consider the role of wetlands as water reservoirs, this capacity decreases due to the loss of macropores. For the Patagonian wetlands, these are the first results associated to physical compartment of these ecosystems and can constitute the basis for grazing management, allowing for adjustment of stocking rates to soil moisture (regulated by drainage).

# Spatial Distribution and Erosional Significance of Hollows in Agricultural Landscapes of the European Russia

**Andrei A. Stepanov[1*], Ekaterina A. Eremenko[1], and Valentin N. Golosov[1]**

[1] *Institute of Geography, Russian Academy of Sciences, Moscow, Russia*

*E-mail step.andry@gmail.com

**ABSTRACT**

Hollows (linear depressions belonging to the upper reaches of fluvial network) are among the most common landforms on arable lands in Russia. They concentrate surface runoff on the slopes that promote to soil erosion rate increasing and formation of ephemeral gullies. Also some sections of their bottoms often serve as sediment sink.

Hollows are clearly visible on a ultra-high-resolution satellite images (less than 1 m) due to a darker phototone of their bottoms associated with relatively high water saturation of the surface deposits. Hollows have either a linear or a dendritic pattern in plan view.

The most hollows of central and southern European Russia are Pleistocene relicts (Eremenko & Panin, 2010). Previous studies have identified spatial variations in their patterns across the East European Plain and described their geology. Local assessments have shown an order-of-magnitude increase in soil erosion rates on arable slopes with a network of hollows (Desmet & Govers, 1997; Zhidkin et al., 2025).

In this study, we mapped the hollow network within 18 municipal districts of European Russia with high proportion of cultivated lands. The studied areas differ in their predominant soil types and topography. Spatial variability in hollow density on arable land was assessed by calculating a density metric (the ratio of total thalweg length of hollows to the area of agricultural fields). Several types of dendritic hollow networks were identified based on the results of satellite imagery interpretation. Quantitative assessment showed a clear differentiation: the average hollow density on arable land was more than twice as high in upland areas (1.6 $km^{-1}$, range 0.23–4.58) than in lowlands (0.76 $km^{-1}$, range 0.27–1.25). The completed assessments will allow us to estimate their contribution to the overall soil fertility loss.

## ABSTRACT

Properties of soil cover play a crucial role in controlling natural processes that actively shape and modify landscapes. The project "SOIL SHADES" focused on a multi-scale and multi-analytical approach to enhance understanding of soil characteristics that control the occurrence of shallow landslides by integrating geomorphological, geophysical, and pedological analyses. The research has been carried out in a pilot catchment (Turbolo Stream) of the Calabria region (southern Italy) due to its representativeness of several Mediterranean environments. The basin has an extension of approximately 30 km$^2$ and exhibits an important lithological, geomorphological and pedological variability. Six locations struck by shallow landslides were selected across the catchment because of distinctive parent material and geomorphological features: i) soils developed from Palaeozoic metamorphic rocks on high relief and steep slopes under beech forest, ii) soils from Miocene to Pleistocene clay deposits on hilly morphology, iii) soils from Holocene sand and conglomerates of alluvial terraces in arable lands. On slopes carved into the different lithological types and affected by shallow earth slides (roto-translational movement), multitemporal geomorphological analyses using satellite images, digital elevation models (DEMs) and field surveys allowed detailed mapping of the landslide bodies and related morphological features. Geophysical prospections, using 2D-electrical resistivity tomography (ERT) and electro-magnetic induction (EMI) surveys, were combined to map the soil spatial variability, to provide a comprehensive understanding of geometric features of the landslides, and to identify the depth of possible shallow sliding surfaces, due to the effectiveness of both techniques in the detection of geological and pedological discontinuities.

Six representative soil profiles were analysed across the Turbolo catchment, in the detachment crowns of the main landslides. Soils ranged from highly developed with clay-enriched subsoil (Luvisols) on sand and conglomerate deposits, to vitric (Andosols) on metamorphic rocks, and vertic (Cambisols) soil properties on clay deposits. Consistently, the lowest values of the $Fe_{ox}/Fe_{dith}$ ratio (from 0.3 to 0.11) ($_{ox}$ = oxalate extractable; $_{dith}$ = Na dithionite-citrate-bicarbonate extractable) were measured for the Luvisols, while the highest (0.12 to 0.26) for the Andosols. However, the $Fe_{ox}/Fe_{dith}$ ratio varied along the depth, as well as the Ti/Zr ratio, the clay content, the coarse fragments and the soil organic matter, marking discontinuities potentially acting as sliding surfaces.

# Effects of irrigation timing on early growth of Haloxylon ammodendron seedlings in southern Tajikistan

**Nasreulloi A[1*], Doy Kim[1], Nazarov U[1], and Yowhan Son[1]**

**ABSTRACT**

*Haloxylon ammodendron* is a key afforestation species widely used in arid and desert regions due to its critical role in desert land restoration and erosion control. A five-year field study (2021–2025) was conducted in the desert zone of southern Tajikistan, Shahrituz district (300–350 above sea level; annual precipitation: 166mm; annual temperature: 17.2 °C) to assess the long-term effects of irrigation initiation timing on growth following irrigation cessation. 1–year–old *H. ammodendron* seedlings were established at a spacing of 6 m × 2 m (833 seedlings $ha^{-1}$). Irrigation was applied only during the first year after planting at a rate of 6–8 L per seedling every 35–40 days and the two irrigation regimes—winter and spring irrigation—were compared. In 2025 after 4–5 years without irrigation, winter-irrigated seedlings exhibited greater height (30–180 cm) and root collar diameter (10–41 mm) compared with spring-irrigated seedlings (24–155 cm and 10–35 mm, respectively). Winter irrigation enhances soil moisture infiltration and reduces evaporative losses, enabling effective root development before the onset of the hot season. In contrast, spring irrigation suffers from high evaporation rates, particularly in sandy soils, limiting water availability for seedling establishment. These findings provide long-term field evidence that winter irrigation significantly enhances early root establishment and improves seedling growth, representing a more effective strategy for desert afforestation under arid conditions.

**ABSTRACT**

As the 1st threat to the planet's soil, erosion significantly degrades the soil characteristics, and therefore it is the greatest challenge for sustainable agricultural management. Over the past 30 years, the World is suffering from a serious process of land degradation as a result of global climate change and the increasingly acute conflicts among population, resources and the environment. In order to reverse this trend towards land degradation, many regions and countries have carried out sustained and painstaking initiatives for soil and water conservation, whose results has been monitored using different methodologies. It is urgent to adopt state of the art technologies including the latest earth observation techniques to evaluate global soil erosion status and soil conservation benefit in a standardized way. Accurately achieving the status of global soil erosion and the distribution and types of soil/water conservation measures, will help to illustrate the difference in effectiveness of soil/water conservation practices, improve current technologies, promote soil/water conservation measures, eliminate interregional imbalances and promote the United Nations' Sustainable Development Goals using solid science.

Current methods for conducting national and regional-scale soil erosion evaluations include the following three main categories, depending on the method of data acquisition and analysis: sampling survey method, remote sensing survey method, and grid calculation methods. We briefly describe the data acquisition process, analysis method, and development history of the three methods, and compare their advantage and disadvantage from the perspective of reflecting the real soil erosion status on the ground and the effectiveness of soil/water conservation measures. From the perspectives of the diversity of soil and water conservation measures, the positive effects of controlling erosion processes, and the economy, flexibility and timeliness of global mapping, we believe that planning and deploying reasonable stratified-systematic sampling units globally, and adopting high-accuracy remote sensing imagery for extracting and quantitatively expressing soil/water conservation measures, are the prerequisites and foundation for global soil erosion assessment and mapping with guaranteed accuracy.

**ABSTRACT**

Soil erosion redistributes soils and soil organic carbon (SOC) across landscapes. Vegetation restoration and gully-control engineering, particularly check dams, play crucial roles in mitigating erosion and adapting to climate change. Yet, owing to the efficient representations of cascading dams, the large-scale, spatiotemporal impacts of check dams on eroded SOC yield remain unclear, as do the evolving contributions of rainfall, vegetation, and dams. Using the latest check dams dataset and an improved erosion assessment model, we quantified the spatial and temporal dynamics of eroded SOC yield in the Middle Yellow River Basin from 1970 to 2020. The results show that check dams cumulatively trapped 20.80 TgC of SOC, accounting for 11.07% of the total loss. Within dam-controlled watershed, the relative contribution of check dams to reducing eroded SOC yield decreased from 99.10% in the early restoration period to 30.18% in the later period, while vegetation restoration became the dominant controlling factor in recent decades (75.78%). This study establishes a globally applicable framework for assessing eroded SOC yield, advances the understanding of the synergistic effects between vegetation restoration and check dams, and provides scientific guidance for sustainable erosion control and dam management.

# The efficacy of hedgerow-grass ditch systems in controlling N and P losses in citrus orchards under variable natural rainfall events

**ABSTRACT**

The hedgerow-grass ditch systems (HGDS) is a recognized soil erosion control measure on slopes. However, its efficacy in reducing nitrogen (N) and phosphorus (P) losses across varying rainfall amounts (RM) and vegetation cover remains unclear. In this 3-year field study (2022–2024) in a purple soil citrus orchard, we evaluated six treatments, namely clean-tilled citrus orchard control (CK), *Trifolium repens* L. HGDS in citrus orchard (T1), *Chrysopogon zizanioides* (L.) *Roberty* HGDS in citrus orchard (T2), agroforestry citrus orchard (citrus intercropping with vegetables) (T3), *Trifolium repens* L. HGDS in agroforestry citrus orchard (T4), *Chrysopogon zizanioides* (L.) *Roberty* HGDS in agroforestry citrus orchard (T5), across 26 erosive events spanning four RM categories (moderate rain, heavy rain, rainstorm, and large rainstorm). Runoff depth (RD), sediment yield (SY), and the concentrations and losses of total, dissolved, and particulate N and P (TN, DN, PN, TP, TP, PP) were measured. Surface runoff was initiated at 24-h rainfall above 20 mm. Compared to CK, T1–T5 significantly reduced RD (26–71%), SY (62–89%), TN loss (57–86%), and TP loss (58–81%). Treatment DN comprised 57–75% of TN loss, whilst DP accounted for 43–50% of TP loss. As RM increased from moderate, heavy, rainstorm to large rainstorm, runoff depth rose by 29.3%, 71%, and 75%, respectively; sediment yield increased by 5.4, 5.3, and 22.5 times; TN loss grew by 3.2, 3.8, and 8.8 times; and TP loss was 3.9, 5.4, and 4.8 times higher, respectively. Runoff depth and sediment yield were significantly positively correlated with TN and TP loss, but the magnitude of these responses varies significantly across different treatments, with strong positive correlations observed in CK. These responses were significantly attenuated under HGDS treatments. Based on the results, the effectiveness of HGDS in mitigating nutrient losses in sloping agroforestry systems, supporting its use in sustainable hillslope management.

# Soil and Water Conservation Planning by Estimating Complex Soil Properties from Easily Measurable Soil Properties

**Manmohanjit Singh**

*Dean, College ofAgriculture, Ballowal Saunkhri, Punjab Agricultural University, India*

E-mail:mmjsingh@pau.edu

**ABSTRACT**

Soil erosion by water is one of the most critical environmental concerns and a leading cause of land degradation. The hilly Shiwalik-*Kandi* region of Punjab, India experiences severe soil erosion affecting productivity and soil quality. Understanding soil properties such as aggregate stability and erodibility is essential for soil and water conservation planning. However, direct measurement of these parameters is difficult, costly and time-consuming. Hence the present study explores empirical, statistical and machine learning (ML) approaches for estimating complex soil properties from easily measurable parameters.

The study was conducted in the *Kandi* region of Punjab, India under different land uses – forest, grassland and cultivated lands. Three datasets including soil texture, bulk density, pH, EC, organic carbon, Fe, $CaCO_3$, and cation exchange capacity were used. For each data set, 70% of the data was used for training and 30% for testing. Empirical pedo-transfer functions (PTFs), generalized linear models (GLMs), and artificial neural networks (ANNs) were applied using BigML software to estimate mean weight diameter (MWD), water-stable aggregates (WSA), and soil erodibility (K-factor).

Results indicated significant variations in basic soil properties under different land uses. Organic carbon and aggregate stability were higher in forest and grassland soils. For data sets with fewer variables, GLM provided better results, while ANN outperformed for larger, complex data sets. ANN models captured nonlinear interactions effectively and provided superior prediction accuracy for MWD, WSA and K, confirming their potential for large-scale applications.

The study concludes that machine learning, particularly ANN, offers an efficient, data-driven, and scalable alternative for estimating complex soil properties. Combining traditional, statistical and ML approaches enhance prediction accuracy and supports evidence-based soil and water conservation planning. The integration of artificial intelligence with soil data and remote sensing can revolutionize digital soil mapping and sustainable land management in fragile ecosystems like the *Kandi* region.

# Simulation of Wind Erosion under the Influence of Topography in a Temperate Grassland Landscape

**Zhuodong Zhang***

*State Key Laboratory of Earth Surface Processes and Disaster Risk Reduction, Faculty of Geographical Science, Beijing Normal University, Xinjiekouwai Str. 19, 100875, Beijing, China*

*Presenting author, zzhang@bnu.edu.cn

**ABSTRACT**

Wind highly varies temporally and spatially, resulting in the obvious variation of wind erosion. Such variation has less been considered at the landscape scale. In landscapes with complex topography, wind field is strongly influenced by both terrain and vegetation. This study simulated wind erosion in a temperate grassland landscape by integrating the revised wind erosion equation (RWEQ) and computational fluid dynamics (CFD). Wind field over the landscape was modelled by CFD, which considered both the effects of topography and vegetation. Wind erosion rates were compared with the results based on the fallout radionuclide method, which showed satisfied agreement. The findings demonstrate that both topography and vegetation have vital impacts on wind erosion, and the integration of RWEQ and CFD can effectively improve the simulation of wind erosion at the landscape scale.

**ABSTRACT**

Wind erosion is a major environmental problem contributing to land degradation in arid and semi-arid grassland ecosystems. However, the impacts of vegetation structure on wind erosion remain poorly understood. This study quantified the effects of grass roots, flat residue coverage (90%, 60%, 40%, 25%, and 15%), standing residue and living grass height (30 cm, 15 cm, 5 cm) and coverage (90%, 60%, 40%, 25%, and 15%) on wind erosion using wind-tunnel experiments at different wind speeds (9 and 12 ms-1). Results showed that living grass and dead residue with the same height and coverage has similar wind erosion control effects. The soil loss decreased 16.7%-70.7% grass and residue coverage increased from 15% to 90% at 9 m/s, while it decreased 22.4%-66.5% at 12 m/s. Additionally, the wind erosion rates decreased 46.7%-90.9% with grass and residue heights increased from 3 cm to 30 cm at 9 m/s, while decreased by 40.9%-90.9% at 12 m/s. When residue or grass height was ≥15 cm and cover exceeded 60%, soil loss was reduced by more than 90%. However, grass roots alone without canopy showed weak erosion control effects. The wind erosion rates were 9.5 and 16.1 g $m^{-2}$ $min^{-1}$ with root density varied from 16.7 $gm^{-2}$ to 4.58 $gm^{-2}$, which were only 6.8 and 0.3 g $m^{-2}$ $min^{-1}$ lower compared to the bare-ground values at 9 ms-1. When the coverage of flat residue increased from 15% to 90%, the soil loss by wind decreased 30%–40% compared to the condition having roots only. Further analysis indicated that residue or living grass coverage had the largest contribution for erosion control (contributed 70%-80%) when residue or grass height was >15 cm, while the flat residue coverage had a more significant impact on wind erosion control compared to roots that were very limited in direct wind erosion control. These findings provide quantitative thresholds for vegetation-based wind erosion control and support improvements in wind erosion modelling and grassland management strategies.

# From Aerosols to Soils: A Novel Pedological Framework for Identifying Aeolian Dust Hotspots in Dried Saline Lakebeds

**Hesam Ahmady-Birgani**[1*]

[1] *Faculty of Natural Resources, Urmia University, Urmia, Iran*

h.ahmadybirgani@urmia.ac.ir

**ABSTRACT**

The issue of fast desiccation ofinland hypersaline lakes is one of the most essential, though not elaborated, issues in current soil science. Besides hydrological degradation, lake desiccation is a significant factor that causes alterations in soil physical properties, lake surface crust, as well as soil susceptibility to wind erosion, meaning that soil systems of such lakes change drastically. The problem of aeolian dust emission is considered from a soil perspective. Based on the representative hypersaline lake, Urmia, this study initiates a new conceptual model with "Coldspots," "Hotspots," and "Hottestspots" of dust emissions by employing the joint properties of aerosol optical depth value, frequency, and variability from long-term MAIAC/MODIS satellite observations. Contrary to conventional hotspot mapping, which neither distinguishes actual dust emissions from transported dust clouds nor considers them individually, this model specifically identifies local dust-emitting surfaces in direct connection with soil erodibility classes.

The findings indicate a close relationship between the area development of Hotspots and Hottestspots, and major soil characteristics within the desiccated lake. The finer texture of clay-silt deposition and puffic crusts is prevalent in the southern and central parts, and these are less susceptible to wind erosion, whereas salt-affected and salt- clay crusts in the northern parts are found to be less resistant despite similarity in wind energy. The findings clearly indicate that in desiccated saline environments, wind erosion is not a function of wind energy but is dependent on soil characteristics.

From a pedological perspective, arid hypersaline lake beds are a transitional soil type that lies between the zones of lacustrine soils, saline-sodic soils, and dynamic aeolian features. The soil type is prone to extreme aggregation stability transformations, threshold friction velocity, and surface stability properties affected by climate-induced stress and improper water management. The integration of aerosol algorithms with soil processes makes the proposed work a transferable methodological framework that focuses on soil.

This proposed framework has immediate relevance for soil conservation, desertification studies, and measures for combating dust in arid and semi-arid areas facing intense lake shrinkage. This relevance can now be extended to China, Central Asia, and the drylands of the world. This presentation at the 2026 Meeting of the Chinese Soil Science Congress can thus add a new dimension to the studies of aeolian processes using soil process insights. This can lay the groundwork for international collaboration for soil system management in arid conditions due to climate changes.

# Modeling runoff and soil erosion amounts affected by slope gradient and length in black soil slope farmland of Northeast China based on APSIM

**Cheyu Zhai, Zizhong Li*, Shuming Cao, Shuai Chen**

*Department of Soil and Water Sciences, China Agricultural University, Beijing, P.R.China*

*zizhong@cau.edu.cn

**ABSTRACT**

The black soil region had more ridge cultivation slope farmland, which results in a serious threat of soil erosion caused by water as well as corn yield decreasing. Conservation tillage was beneficial to agriculture production, whereas few study investigated the soil erosion and runoff affected by slope gradient and length under conservation tillage used for Agricultural Production Systems Simulator (APSIM) simulation. In this study, APSIM was calibrated and validated by soil characteristics and corn yield under rotary tillage (RT), no-tillage without straw mulching (NT), no-tillage with straw mulching (NT-SM) and strip tillage with straw mulching in wide rows (ST-SM) treatments, which were used to investigate the regularity of soil erosion and runoff under slope gradient 3°, 6°, 9°, 12°, 15°, 18°, 21°, 24° as well as length 50 m, 100 m, 250 m, 500 m, 750 m, 1000 m, 1250 m under long-term (1981-2023) meteorological data. The result showed APSIM greatly simulated soil erosion amounts, runoff depth and corn yield with normalized root mean square errors (NRMSE) of 48.30-93.25%, 37.41-77.55% and 5.98%, respectively. The simulated soil erosion amounts significantly increased with slope gradient and length, whereas simulated runoff depth increased with no significant difference. Tillage and climate significantly affected simulated soil erosion amounts (0.56 and 0.63, -0.88 and -0.92) and runoff depth (0.14 and 0.15, 0.50 and 0.56). Conservation tillage (NT-SM and ST-SM) significant decreased soil erosion amounts and runoff depth compare with rotary tillage, reduction rate progressively increased with slope length and gradient by more than 96% and 25%, respectively. However, reduction rate of simulated soil erosion amounts and runoff depth of NT treatment relative to rotary tillage progressively decreased with slope gradient by 16.62-15.30% and 14.23-12.89%, and significantly lower than NT-SM and ST-SM treatment. Corn yield was decreased under NT and NT-SM treatments by 3.16% and 7.02% compare with RT treatment, the highest corn yield was found at ST-SM treatment 11.40 t ha-1 (2.89%). In conclusion, APSIM was acceptably applied to simulate soil erosion and runoff in slope farmland, the effect of decreasing soil erosion and runoff of no-straw-mulching practice was insufficiently compared with straw mulching practice in slope farmland. NT-SM treatment was most effective in resisting soil erosion under slopes below 6° and 250 m, ST-SM treatment was more suitable for slopes above 9° and 500 m and increased corn yield.

# Hydrologic regime determines catchment-scale dissolved carbon export patterns

**Xiao Li[1], Jian Wang[1]*, Wei Yin[2], Jianfeng Xu[2], Haibing Xiao[1], Hongying Zhao[1], Yongyong Shi[1], Lei Wang[1], Rui Hao[1], Haiyan Li[3], Yiming Huang[1], Hai Jiang[3], Zhihua Shi[1]**

**ABSTRACT**

Hydrologic regimes are affecting terrestrial carbon transformation, chemical weathering and lateral transport. However, its impacts on dissolved carbon export patterns remains elusive. In this study, we collected a 2-year high-frequency dissolved inorganic (DIC) and organic carbon (DOC) dataset, namely a wet year (Rainfall=1158 mm) and a dry year (Rainfall=603 mm). The results showed that drought led to a significant decrease in dissolved carbon concentration and discharge during the monitoring period. During non-storm periods, DIC and DOC shifted from dilution and chemostatic to enrichment patterns from wet to dry years, respectively. However, the export patterns were reversed during storm periods. DIC and DOC export patterns in wet year were dominated by dilution and chemostatic, respectively, while both patterns were dominated by dilution in dry year. Structural equation models revealed that the aridity index and temperature may affect dissolved carbon export patterns. We further classified storm events into three major types and conceptualized catchment-scale transport mechanisms for dissolved carbon. Dry-AMCs events result in DIC dilution and DOC chemostatic behavior, whereas Wet-AMCs events result in DIC chemostatic and DOC enrichment behavior due to increased hydrological connectivity. The third type corresponds to extreme events, where larger overland flow often results in DIC dilution but DOC enrichment behavior. These findings reveal the predominant role of drought in altering carbon lateral export by decreasing concentrations and fluxes and modifying export patterns.

**ABSTRACT**

Understanding the long-term fate of eroded carbon (C) and nitrogen (N) sequestered behind check dams is crucial for assessing their role in biogeochemical cycling within human-altered landscapes. We characterized the vertical distribution of C and N components, microbial metabolic parameters, and mineralization potentials along a 0-1058 cm sediment profile of a check dam on the Loess Plateau. Sediment burial time and historical sediment yield modulus were determined based on sedimentary couplets. The impact of dam breaching was assessed by comparing sediments exposed for a decade with adjacent buried layers. Soil organic carbon, total nitrogen, dissolved organic carbon, extracellular enzymatic activity, and the mineralization rate of carbon and nitrogen fluctuated with the deposition couplets of the clay/sand layer in the check dam. Soil organic carbon, total nitrogen, carbon nitrogen ratio, dissolved organic carbon, and inorganic nitrogen were higher in check dams than those of the slope in corresponding amounts of 59%, 40%, 18%, 22%, and 327%, respectively. Microbial biomass peaked during the severe erosion stage (1959–1961), while microbial carbon limitation was at its lowest. Microbial phosphorus limitation was lowered throughout the erosion reduction stage (1962–1998) and control stage (1999–2012). While the microbial carbon limitation decreased with the increase in sediment yield modulus, soil organic carbon content and total nitrogen content in the clay layer of the deposition couplets both greatly increase. With an increase in sediment yield modulus, the total nitrogen content of the sand layer increased firstly and then decreased. In comparison to the buried sediment, the exposed sediment had significantly higher soil dissolved organic carbon and inorganic nitrogen, higher soil microbial phosphorus limitation, and lower soil organic carbon mineralization rate, mineralization ratio, and soil metabolic entropy. In conclusion, soil carbon and nitrogen in check dams were more difficult to decompose than those on slopes, and microorganisms were preferred to assimilate carbon rather than release it and this trend increased as burial times increased and after a decade of exposure.

**ABSTRACT**

Vegetation-based approaches are widely applied for runoff and soil erosion control on sloping agricultural land; however, their effectiveness is often evaluated using mean erosion rates without explicit consideration of rainfall regimes or plant root functional traits. This study presents a field evaluation of vegetation with contrasting root traits for runoff and soil erosion control on sloping agricultural land in a humid tropical environment. Root system architecture and mechanical properties of selected plant species were first characterised through controlled support experiments using rhizobox observations and root tensile-strength testing. Field runoff and erosion measurements were carried out on bounded runoff plots under natural rainfall conditions and categorised into wet and dry spells based on rainfall characteristics and antecedent soil moisture. Results showed that vegetation effects on runoff and soil erosion were strongly rainfall-regime dependent. During wet spells characterised by high rainfall intensity and near-saturated soils, deep-rooted vegetation with mechanically strong and vertically extensive root systems substantially reduced runoff coefficients and soil loss. In contrast, shallow-rooted or mat-forming vegetation increased runoff and soil loss relative to the control under saturated conditions, indicating limited infiltration and enhanced surface flow concentration. Vegetation with dense surface cover but limited anchorage provided moderate erosion reduction under wet spells. During dry spells, runoff and soil loss were generally low across treatments, and differences among vegetation types were markedly reduced, reflecting threshold-controlled runoff generation. Only vegetation that enhanced near-surface soil structure and infiltration showed distinct reductions in runoff and erosion under low rainfall intensity. The findings demonstrate that vegetation effectiveness for erosion control is conditional and process-dependent. Evaluation of vegetation-based soil conservation measures without consideration of the rainfall regime may lead to misleading conclusions. A trait-based approach that matches plant root functional traits to dominant erosion processes provides a more robust framework for designing vegetation-based soil and water conservation measures on sloping agricultural land in humid tropical environments.

# Variability of hydraulic characteristics of sediment-laden rill flow under various slopes, water flows and sediment loads

**Chunhong Zhou [1], Nan Shen [1,2,*], Fengbao Zhang [1,2]**

*[1] State Key Laboratory of Soil and Water Conservation and Desertification Control, College of Soil and Water Conservation Science and Engineering (Institute of Soil and Water Conservation), Northwest A&F University, Yangling, Shaanxi 712100, China*

*E-mail Address: shennan@nwafu.edu.cn (Nan Shen)

**ABSTRACT**

During soil erosion, sediment load of rill flow changes dynamically and may affect its hydraulic characteristics. However, current research on hydraulics of sediment-laden rill flow primarily uses river sand/artificial homogeneous materials as sediment, which significantly differ from natural soil, leaving a research gap on how soil quantity impacts rill flow hydraulics. This study uses natural soil in an indoor rill flume simulation experiment to explore how sediment load influences hydraulic characteristics of rill flow, including flow velocity ($V$), Darcy–Weisbach friction coefficient ($f$), Reynolds number ($R_e$), Froude number ($F_r$), and flow depth ($h$). Experiments were conducted under combinations of six different sediment loads, five flow discharges, and five slopes. The results indicated that $V$, $f$, $R_e$, $F_r$ were significantly influenced by sediment concentration. $V$ and $F_r$ show an upward trend as the sediment load increases, while $f$, $R_e$, and $h$ demonstrate a downward trend. The sediment load predominantly influences $V$, $f$, and $F_r$, accounting for contributions of 0.33, 0.49, and 0.39, respectively. The influence of slope gradient on $V$ and $F_r$ intensifies as the sediment load increases, while the impact of flow discharge on $V$, $f$, and $F_r$ diminishes. As flow discharge increases, the effect of sediment load diminishes on $V$ and $F_r$, and that of slope gradient strengthens. Two kinds of prediction equations were developed for estimating the hydraulic parameters of sediment-laden rill flow. The models demonstrate high $R^2$ values (0.74 to 0.98), suggesting strong performance of the prediction equations. These findings lay a foundation for the better development of a physical process-based rill erosion model. Given the differences in the properties of natural soils, which may impact hydraulic characteristics, it is a limitation of this study that it only focuses on a single soil type, and thus future research should explore the effect of sediment properties on hydraulic characteristics.

# Effects of Crop Association on Soil Extracellular Enzyme Stoichiometry in Erosion-Prone Sloping Farmlands in the Rocky Mountainous Region of North China

**Lei Wang, Liang Jin, and Dan Wei***

[1] *Institute of Plant Nutrition, Resources and Environment, Beijing Academy of Agricultural and Forestry Sciences, Beijing 100097, China;*
*wd2087@163.com

**ABSTRACT**

Soil extracellular enzymes—bioactive compounds produced by soil microorganisms, plants, and animals—play a central role in mediating material cycling and energy flow within grassland eco-systems. These enzymes decompose complex organic matter and respond dynamically to environmental perturbations. Their activities and stoichiometric ratios are widely recognized as reliable indicators of soil nutrient limitations. This study identified typical sloping farmland within the Grade I Water Source Protection Area of Taishizhuang Village, Taishitun Town, Miyun District, Beijing, China (117°6′42.08″E, 40°32′22.02″N) and applied in situ field monitoring and laboratory analyses to evaluate four crop association treatments that were based on ecological adaptability, functional complementarity, and economic value: T1 (*Medicago sativa* + *Buchloe dactyloides*), T2 (*Scutellaria baicalensis* + *B. dactyloides*), T3 (*Platycodon grandiflorus* + *Cynodon dactylon*), and CK (bare land control). The objective was to elucidate the effects of plant configuration on soil physicochemical properties, extracellular enzyme activities, and microbial nutrient limitation mechanisms. Key findings were, firstly, that crop association and its interaction with slope position influenced soil particle composition, moisture content, and chemical characteristics ($P < 0.001$), while slope position alone primarily affected clay content and water retention. T1 had the largest soil improvement effect ($P < 0.05$). Secondly, soil enzyme activities were positively correlated with total nitrogen, soil organic carbon (SOC), and soil water content, while sand content and $NO_3^-$–N showed negative correlations. These factors varied spatially by slope position ($P < 0.05$). Sand content was higher on the upper slope (74.8%) than on the lower slope (72.1%), while peak enzyme activity was driven by higher soil organic matter (8.33 g/kg) and clay content (8.8%) on the middle slope. Elevated $NH_4^+$–N levels on the lower slope (11.14 mg/kg) influenced enzyme activity in that zone. Phosphorus limitation was more pronounced than nitrogen limitation throughout the study area. Crop association influenced microbial nutrient limitations by modulating SOC and $NO_3^-$–N concentrations ($P < 0.05$). T1 and T2 notably increased microbial carbon limitation ($P < 0.05$), while T1 also produced lower phosphorus limitation across all slope positions ($P < 0.05$). Thus, the *M. sativa–B. dactyloides* crop association (T1) was most effective in enhancing soil quality and microbial metabolic function in erosion-prone sloping farmlands. These findings provide a foundation for designing crop associations aimed at soil and water conservation in rocky, mountainous regions of North China.

# Influence of land use change and increased rainstorm on shallow landslide sediment connectivity in a small watershed of the Chinese Loess Plateau based on remote sensing

**Bingzhe Tang[1*], Haijun Qiu[2], Pengfei Li[1]**

[1] *College of Geomatics, Xi'an University of Science and Technology, Xi'an, China*

[2] *College of Urban and Environmental Sciences, Northwest University, Xi'an, China*

*bingzhetang@xust.edu.cn

**ABSTRACT**

Shallow landslide, a serious gravity erosion, becomes an important sediment source in the watershed with the increase of rainstorms. Vegetation restoration will reduce sediment transport capacity. With the increasing rainstorm and vegetation restoration in the loess hilly and gully region, the question of whether landslide sediment yield is increasing or decreasing needs to be answered urgently. This study used a Digital Elevation Model (DEM) and a Digital Orthophoto Map (DOM) obtained from remote sensing satellite and UAV photography to interpret the landslide in a small watershed in northern Shaanxi, China. After studying the changes in vegetation and drainage network in 2010, 2015 and 2020, the landslide quantity, area, depth and erosion amount in recent years were explored. The transport of landslide sediment in the watershed is quantified by using the sediment connectivity index, sediment delivery ratio and landslide sediment yield. The results showed that the cropland changed to forest and grassland, and the drainage network continued to shrink with agricultural abandonment. During 2010-2020, the number of landslides increased by 5.88 times and 7.54 times, and the amount of landslide erosion increased by 4.06 times and 4.35 times, but the average area and depth of landslides decreased due to the occurrence of many small landslides on grassland. The sediment connectivity of landslides has been reduced due to the restoration of vegetation and the abandonment of agricultural drainage networks during the conversion of cropland to grassland and forest. Even in the context of increasing landslide erosion, the sediment yield of individual landslides in 2015 and 2020 decreased by 31.43% and 48.37%, respectively. However, the total sediment yield of landslides increased by 3.03 times and 2.89 times in 2015 and 2020, compared with 2010. This study answers the question that landslide sediment yield increases in the loess hilly and gully region under the double background of rainstorm increase and vegetation restoration. This provides a scientific basis for the prevention and control of landslides and the ecological security management of the watershed under the background of climate change.

*202431051003@mail.bnu.edu.cn

**ABSTRACT**

Gully erosion dominates soil degradation in small watersheds. While vegetation mitigates gully development, its effectiveness depends on type, partly through altering soil-root shear strength. Few in-situ studies assess this effect. Hence, this study quantified soil-root shear strength differences between gullies covered by grass versus grass-shrub mixed communities on the Loess Plateau. In-situ shear tests measured peak shear stress (PSS) and displacement, generating shear stress-displacement curves. PSS and strain energy (SE) derived from these curves were calibrated to 15% soil moisture to characterize soil-root shear strength. Results showed the average PSS for grass-covered gullies (9.32 kPa) was significantly higher than for mixed vegetation gullies (6.25 kPa). Shear strength decreased initially then increased with depth. The critical depths for this PSS transition were 20 cm (grass) and 30 cm (mixed). Variations in shear strength with vegetation type and depth were primarily controlled by soil properties and root attributes. PSS exhibited a significant positive association with soil cohesion. SE showed significant positive relationships with root weight mass density and effective root density. Soil organic matter content and aggregate stability enhanced SE through direct and indirect effects. These findings provide insights into the mechanical mechanisms by which vegetation type enhances gully soil strength and controls land degradation in semi-arid regions.

# Response of soil erosion resistance to incorporated straw affected by different microbial inoculants in the black soil region of Northeast China

**Yatong Zhang [1,2*], Guanghui Zhang [1,2] , Ning Zhang [1,2], Shukun Xing [1,2], Yi Zhang [1,2]**

[1] *State Key Laboratory of Earth Surface Processes and Disaster Risk Reduction, Beijing Normal University, Beijing 100875, China*

*yatong@mail.bnu.edu.cn

**ABSTRACT**

Straw incorporation is a widely applied conservation tillage practice that mitigates soil erosion and promotes both the ecological and productive health of the soil. The application of microbial inoculants can stimulate straw decomposition, which benefits soil properties and root traits, and likely further regulates soil erosion resistance, particularly in cold regions. However, the response of soil erosion resistance to straw decomposition influenced by different microbial inoculants remains underexplored. In this study, the flume experiments were conducted to evaluate the influence of straw decomposition on soil erosion resistance under treatments of six microbial inoculants (Chungurun, Fushite, Bangji, Gefu, Hengrun, Lvkang) as well as a control without inoculants in the black soil region of Northeast China. 175 undisturbed soil samples were taken from seven plots and were scoured under five different flow shear stresses. The results demonstrated that microbial inoculants significantly stimulated straw decomposition (15%-36% increase), improved soil cohesion, water stable aggregate, soil organic matter, and root mass density, while reducing penetration resistance. Among six applied microbial inoculants, Lvkang produced the most significant improvements ($p < 0.05$). These improvements contributed to a reduction in soil detachment capacity, ranging from 28.27% to 57.13%. Soil erosion resistance was significantly enhanced ($p < 0.05$). Compared to the control, rill erodibility ($K_r$) decreased by 17.24% to 58.62% and critical shear stress ($\tau_c$) increased by 21.06% to 109.87%. $K_r$ was significantly and negatively correlated to soil cohesion, water stable aggregate, soil organic matter, root mass density and straw decomposition rate ($p < 0.05$), while $\tau_c$ showed no significant correlation with the measured influencing factors. This research provides valuable insights into the application of microbial inoculants for mitigating soil erosion, and offers practical strategies to promote sustainable straw utilization and agricultural management in cold regions.

# Spatial variation of soil erosion resistance impacted by ephemeral gully on long gentle sloping cropland in the Mollisol region of China

**Jun Jing[1*], Guanghui Zhang[2]**

[1] *Affiliation of the Jun Jing (Faculty of Geographical Science, Beijing Normal University, Beijing, China)*

**ABSTRACT**

Ephemeral gully erosion is a primary driver of soil degradation in cropland, significantly impacting soil properties and crop productivity. These alterations, in turn, profoundly modify soil erosion resistance. Despite its importance for soil conservation, the spatial patterns and underlying driving mechanisms of erosion resistance in long, gently sloping cropland under the influence of ephemeral gully erosion remain poorly understood. This study quantified the spatial heterogeneity of soil erosion resistance in a representative Mollisol region of Northeast China, utilizing in-situ field sampling and controlled flume tests. Dominant factors and their interaction mechanisms were identified, and an estimation model for rill erodibility ($K_r$) was established using stepwise regression based on these drivers. Results indicated that soil erosion resistance varied significantly across slope positions, whereas differences between gully positions were less pronounced. Specifically, $K_r$ increased linearly as gully position descended, while critical shear stress ($\tau_c$) exhibited a "decrease-then-increase" trend, with variations ranging from −2.36 to 50.00. Both $K_r$ and $\tau_c$ followed quadratic relationships with slope position: $K_r$ peaked at the middle slope, while $\tau_c$ reached its maximum at the upper slope. The dominant factors influencing $K_r$ were clay and sand content, soil cohesion (Coh), mean weight diameter (MWD), root mass density (RMD), and straw mass density (SMD), which collectively explained 79% of the observed spatial variability. Notably, SMD exerted a significant regulatory effect on Coh, RMD, and MWD, indirectly mitigating $K_r$ through these integrated pathways (standardized path coefficient = −0.263). The proposed estimation model ($K_r = 0.212MWD^{-2.405}RMD^{-0.502}$) demonstrated robust predictive performance ($R^2$ = 0.860; NSE = 0.863), though further field validation is warranted (Jing et al., 2026). These findings provide a theoretical foundation for site-specific erosion control and contribute to the improvement of process-based soil erosion models in Mollisol regions.

## ABSTRACT

**[Objective]** Gully head retreat is one of the primary processes in gully erosion, with the continuous erosion of plunge pools caused by gully head jet flow being an important sub-process. However, the development process and morphological characteristics of plunge pools under different jet flow conditions have been rarely reported and remain to be clarified.

[**Methods**] This study selected dry red soil from the gully development area of Yuanmou Dry-hot valley and established a segmented jet flow scouring flume to systematically simulate the development process and morphological characteristics of plunge pools under 5 inflow rates and 4 slope gradients. The hydraulic parameters influencing the morphological development of plunge pools were further analyzed.

[**Results**] The results showed that, except for average depth, all morphological parameters of plunge pools continuously increased. The development rates of length and width were significantly faster than that of depth. The length-to-width ratio gradually increased, and the shape transformed from circular to elliptical. Among all morphological relationships, the best-fitting performance was observed between area and volume ($R^2$=0.80, $P$<0.01). The jet flow velocity at the gully head brink ($V_{brink}$), into the plunge pool's surface ($V_{pool}$), and the distance between jet flow impinging into pool's surface and gully head ($I_{jet}$) all increased with increasing inflow rate and slope gradient, while the angle of the jet flow impinging the pool ($\beta$) showed an opposite trend. All these parameters were more significantly affected by slope gradient. The development rates of plunge pools exhibited a logarithmic relationship with inflow rate and $\beta$, with inflow rate having a stronger influence. The development rates of average depth and backtracking distance exhibited positive power function relationships with Reynolds number ($Re$), flow shear force ($\omega$) and flow power ($P$), while the others showed positive logarithmic function relationships. The retreat process of plunge pools exhibited a stepwise development pattern. The retreat rate increased significantly with the enhancement of hydraulic action, while $I_{jet}$ also increased notably, and both factors jointly influenced the plunge pool retreat process.

[**Conclusion**] These findings contribute to a better understanding of plunge pool development and provide a basis for improving gully head retreat models.

## ABSTRACT

Water infiltration into soil is a key process in irrigation, erosion and soil/water management studies. In the Peruvian Andes context, soil hydraulic properties are virtually unknown, and their characterization is challenging due to stony soils and steep slopes. Several field methods have been developed including double-ring and single-ring infiltrometers. The Green–Ampt infiltration model [1], derived from Darcy's law, is widely used to simulate infiltration processes. The objective of this study was to calibrate the Green–Ampt model using field infiltration experiments in order to provide parameters suitable for Andean conditions and to evaluate differences in model applicability across land uses. The study was conducted in the community of Yacuy, Huancavelica department (center of Peru). Six land uses were selected: Shrub natural regeneration, two Grazing areas, Irrigated Lucerne, Avocado orchard with cattle grazing, and Natural Forest. For each land use, six single-ring infiltration tests [2] were performed. After the infiltration tests, soil samples were collected to determine bulk density and particle-size distribution. Saturated hydraulic conductivity (*Ks*) was estimated using the Rosetta pedotransfer function [3]. The Green–Ampt model was calibrated by optimizing the matric potential at the wetting front (*hf*) through minimization of the sum of squared logarithmic residuals (SSR) using R software.

Table 1. Green–Ampt model calibration parameters and fit metrics

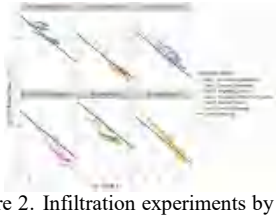

Figure 2. Infiltration experiments by land use

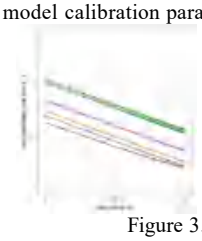

Figure 3. Land-use specific Green–Ampt model calibration

The Green–Ampt model showed a good fit, with SSR values close to zero across land uses. The best performance is observed in Avocado orchard with cattle grazing. A gradient of high calibrated *hf* values was identified. Land uses with low management intensity, such as shrub regeneration and natural forest, exhibited the highest infiltration rates, favoring water redistribution during intense and potentially erosive rainfall events. In contrast, soils under grazing and cattle presence showed the lowest infiltration rates, indicating soil compaction caused by management practices. Overall, the results demonstrate that the Green–Ampt model is a viable tool for studying infiltration processes in Andean environments. However, the scarcity of methodologies adapted to mountainous conditions and the limited availability of reliable soil hydraulic data remain major challenges for hydrological studies in the region.

**ABSTRACT**

The Grain-for-Green Program (GFGP) has significantly enhanced ecosystem service values by changing land use and vegetation cover characteristics, such as reducing soil erosion and increasing soil carbon sequestration. These benefits of the GFGP primarily occur within the topsoil layer, and are not entirely independent, as they can mutually reinforce each other through coupled interactions. However, in the present researches, the processes and mechanisms influencing the soil organic carbon pool by the erosion reduction effect of the GFGP remain unclear. Therefore, cultivated land, land where the GFGP has implemented for 25 and 50 years (GFGP25 and GFGP50), and forest land in purple soil areas were selected to investigate the impacts of the GFGP on soil erosion and SOC dynamics via combined application of 137Cs and 210Pbex in the Sichuan Basin, Southwest China. Compared to lands before GFGP implementation, the soil erosion rates were significantly reduced by 72.50% to 327.18% and 88.66% to 540.35% in GFGP25 and GFGP50, respectively. Compared to cultivated land, GFGP50 and forested land significantly increased the average SOC content, with increases of 59.47% and 101.42%, respectively. Meanwhile, the GFGP could significantly increase the macroaggregate SOC. Moreover, the GFGP can also significantly increase the POC and MAOC content in the surface soil, with a notably higher increase in POC. Compared to cultivated land, the POC contents in the surface soil of GFGP50 and forested land increased by an average of 317.65% to 499.66%, with an average increase in POC/MAOC of 285.71% to 385.71%. Erosion reduction via GFGP could significantly enhance soil carbon sequestration in the eroded zones. In lands of GFGP, soil erosion processes explained 12.16% of the variation in SOC and its physical fraction stock in the surface soil. Carbon sequestration processes were significantly different between erosion and sedimentation zones. Microaggregate organic carbon (MIC) could significantly influence POC content in erosion zones, but its effects on both POC and MAOC were insignificant in sedimentation zones.

# A Dynamic Gully Erosion Risk Assessment Framework Considering Rainfall Regime Shift in the Songnen Typical Black Soil Region

**Dengnan Luo[1], Yun Xie[1], and Jie Tang[2*]**

[1] *Beijing Normal University (Department of Geography, College of Arts and Sciences, Zhuhai, China)*

[2] *Beijing Normal University (Guangdong Provincial Key Laboratory of Wastewater Information Analysis and Early Warning, Advanced Interdisciplinary Institute of Environment and Ecology, Zhuhai, China)*

**ABSTRACT**

Soil erosion is the dominant form of land degradation in the Songnen typical black soil region. Specifically, gully erosion, as the most severe form of water erosion, has emerged as a critical bottleneck constraining sustainable agriculture, posing a serious threat to regional food security and ecological stability. Nevertheless, current gully erosion risk assessments remain predominantly confined to static susceptibility mapping. Crucially, these approaches fail to account for the dynamic variations in erosion thresholds driven by rising erosive rainfall events and annual precipitation under climate change, leading to significant biases with reality. Leveraging 2010 and 2020 Google Earth imagery coupled with field surveys, we constructed two datasets: historical gullies, reflecting long-term morphological evolution, and newly formed gullies, capturing decadal-scale erosion driven by climate change. We then evaluated the predictive performance of six machine learning models (GBDT, XGB, RF, KNN, MLP, and LR) and two Stacking ensemble models for gully erosion risk assessment. By integrating the optimal model with the two datasets, we developed a novel gully erosion risk assessment framework. This framework was utilized to characterize the spatial heterogeneity of gully erosion risks and driving factors in the Songnen typical black soil region. The results demonstrated that: (1) The Random Forest (RF) model outperformed other algorithms in assessing both gully erosion susceptibility and potential, with AUC values reaching 0.975 and 0.979, respectively; (2) The Quantile method emerged as the optimal classification approach, while the Natural Breaks method offered superior stability. Notably, 61.45% of the study area is classified as high-risk or higher, highlighting an urgent need for erosion control measures; (3) SHAP analysis revealed that Mean Annual Precipitation (MAP) and Stream Power Index (SPI) co-dominate gully erosion risk, exhibiting distinct threshold effects. Notably, the relative importance of Topographic Position Index (TPI) and Human Footprint (HFP) was significantly higher for gully erosion potential than for susceptibility. This suggests that topographic transitions and anthropogenic disturbances amplify the erosive impact of rainfall pulses. These findings not only deepen our understanding of gully erosion dynamics in the Songnen black soil region but also provide a scientific basis for the precise allocation of regional soil and water conservation measures.

# Effects of Farmland Shelterbelt Distribution on Wind-Water Compound Erosion in the Northeast Black Soil Region of China

**Hanquan Cheng[1], Yun Xie[1*], Jie Tang[2*]**

*[1] Department of Geographic Science, Faculty of Arts and Sciences, Beijing Normal University at Zhuhai, Guangdong Zhuhai, 519087, P.R. China;*

*[2] School of Technology for Sustainability, Beijing Normal University at Zhuhai, Zhuhai, Guangdong Zhuhai, 519087, P.R. China*

*202431051012@mail.bnu.edu.cn

**ABSTRACT**

Severe soil degradation resulting from wind-water compound erosion poses a significant challenge to food security. Although farmland shelterbelts were originally established to reduce wind erosion, the influence of their spatial layout on the effectiveness of a windbreak requires further evaluation. More importantly, with variations in topography, how the direction of shelterbelts affects soil water erosion processes remains unclear. To address these issues, in this study, the effects of shelterbelt arrangements on wind and water erosion in the typical black soil region of northeastern China were systematically assessed through a sampling survey and remote sensing image interpretation combined with meteorological data and topographic information. The results revealed that the wind erosion intensity increased from northeast to southwest across the region. Shelterbelts effectively control wind erosion, with particularly better effects in areas experiencing severe wind erosion, but its orientation on sloping croplands often constrains ridge direction. In the northern region, most shelterbelts were aligned parallel or perpendicular to the hillslope, whereas in the south, the shelterbelt layout generally disregarded topographic conditions. Under the influence of established shelterbelts, the direction of the ridge tillage was mainly parallel or perpendicular to the shelterbelts. This configuration promotes cross-slope and up-and-down slope ridge tillage, both of which significantly intensify rill/inter-rill erosion and gully erosion. In addition, snowmelt runoff is a major driver of water erosion in high-latitude regions. Shelterbelts influence snow redistribution patterns, thereby modifying snowmelt-driven runoff and soil erosion processes. Gullies affected by shelterbelt-induced snow redistribution exhibited area expansion rates approximately 1.6 times higher than those unaffected. The research results indicated that the layout of farmland shelterbelts in the typical Northeast Black Soil Region may exacerbate water erosion on sloped farmland, providing new guidance and References for shelterbelt restoration and gully management.

# Changes in soil aggregates, pore characteristics, and their relationships with soil erodibility in periodically submerged soils. A case of the Water Level Fluctuation Zone in the Three Gorges Reservoir, China

**Gratien Nsabimana[1,2,3*], Yuhai Bao[1], Xiubin He[1] and Jean de Dieu Nambajimana[3]**

## ABSTRACT

Regulation of the water level fluctuation in the Three Gorges Reservoir (TGR) can critically affect ecological degradation, particularly soil health through its direct impacts on aggregates and indirectly due to erosion. Over the last two decades, distinct elevations in this region experienced different levels of water residence time and intensity, which could be based on to understand the effects of hydrological alterations on soil structural properties. This study has relied on long-term monitoring data of the hydrological alterations in the TGR to evaluate the impacts of water level fluctuations on soil aggregate stability, pore number, porosity, and erodibility. The study has further assessed how soil aggregate stability influence soil erosion and pore characteristics in periodically flooded soils. Samples from different elevations (155 m, 160 m, 163 m, 166 m, 172 m, and 180 m) in the water level fluctuation zone (WLFZ) were exposed to continuous wet-shaking for 3, 9, 27, 54, and 81 minutes resulted to different WLF intensity accordingly. The results showed a remarkable difference between aggregates size before and after the experiment due to the observed increase in micro-aggregates (<0.25 mm) and decrease in large macro-aggregates (>5mm and 2-5mm), respectively. High proportions of micro-aggregates gradually reduced along the elevations, suggesting the capability of soil aggregates from higher and control elevations to withstand stress. The mean weight diameter (MWD) was significantly lower in the lower (2.4–3.7 mm) compared to upper (5.3–6.0 mm) elevations. The exponential prediction proved that aggregate stability decreased with the increase of WLF intensity, insisting the effects of continuous hydrological stress to aggregate break-down. The Disintegration rate (Dr) and soil erodibility (k) showed a positive relationship, $R^2 = 0.73$ ($p < 0.05$). The soil properties decreasing Dr similarly decreased soil erodibility in the study area. Predominant distribution of macropores was recorded in lower elevations, while micropores were widely distributed in the upper elevations. The increase in MWD has increased the proportion of micropores, with $R^2 = 0.59$. This could suggest that the decrease in flooding intensity can create favorable conditions for plant roots growth. The strong flooding stress in lower elevations accelerated the disintegration of soil aggregates and considerably increased the formation of macropores due to slaking and cracking. Relying on the present findings, environmental problems mostly soil erosion in the TGR could be linked to excessive destabilization of soil aggregates. Therefore, the results of this study emphasize the need to restore degraded soils in periodically submerged environments by implementing vegetation restoration measures. This could enhance and sustain aggregate stability, which was also proved to increase functional pores and minimizes soil erosion under hydrological alteration conditions.

# Technical Feasibility of Biomass Buffer Strips for Capturing Excess Nutrients from Agricultural Runoff

**Tianying Li[1*], Ogochukwu Udume[1], Mahendra Thimmanagari[2], Rafael M. Santos[1], and Emily Yi Wai Chiang[1]**

*tianying@uoguelph.ca

## ABSTRACT

Buffer strips are widely recognized as effective landscape measures for intercepting nutrient losses from agricultural fields, thereby enhancing ecosystem protection [1]. However, conventional riparian buffers are spatially restricted, with land-use competition and maintenance demands hindering their broader adoption. To address these limitations, this study introduces the innovative concept of biomass buffer strips, which extend the principle of phytoremediation by employing perennial vegetation to actively capture and utilize excess nutrients for plant growth while producing renewable biomass with economic value through their marketing potential. Thus, biomass buffer strips represent an approach that offers both environmental and economic benefits and can also be implemented along upland field margins that are not directly adjacent to water bodies. This study aims to evaluate the technical feasibility of perennial biomass buffer strips in agricultural fields to mitigate phosphorus (P) losses via surface runoff and subsurface flow, thereby preventing eutrophication of water bodies. To achieve this goal, the study follows a two-pronged approach: the uptake rate of P by biomass vegetation, including switchgrass and miscanthus, is quantified through greenhouse column experiments (Fig. 1); and the relationship between plant-available P retained in soil and dissolved reactive phosphorus (DRP) transported by surface runoff is determined through field trials that incorporate relevant environmental covariates. These approaches quantify the retention and transformation of excess P at different experimental scales, providing empirical evidence for the potential of biomass vegetation to intercept and utilize excess P before its transport to downstream waters.

This study closely aligns with the conference theme by demonstrating a nature-based solution for reducing nutrient pollution from agricultural lands. The findings highlight nutrient interception and transformation within biomass buffer systems, demonstrating their multifunctional role in coupling nutrient recovery with renewable biomass utilization and ultimately promoting the wider adoption among stakeholders.

# Management-Induced Changes in SOM Composition Control Soil Wettability and Hydrological Function

**Felix A. Ogunmokun[1]*, Dorcas Kayode[1], Mercy Ayodele[1] & Samson Oladeji[1]**

[1] *Department of Environmental Sciences, Tennessee State University, Nashville, TN 37209, USA*

*fogunmok@tnstate.edu

**ABSTRACT**

Soil health is functionally governed by soil organic matter (SOM), yet the composition of SOM, not just its total quantity, dictates key soil physical properties and hydrological processes. A critical knowledge gap exists in quantitatively linking agronomic management to specific SOM chemical compositions and, in turn, to soil hydrological functionality (e.g., infiltration and water retention). This study investigated these linkages in a long-term agricultural experiment in a humid-temperate ecosystem (Tennessee, USA).

We collected surface soils (0–5 cm) from six contrasting management regimes, including conventional tillage (CT), no-till (NT), cover crops (CC), and poultry litter (PL) applications. We evaluated soil physical functionality by measuring wettability (Water Drop Penetration Time - WDPT, contact angles) and linked these physical properties to SOM quantity and chemical composition (particulate vs. mineral-associated fractions).

Our preliminary results demonstrate that management is the dominant control on soil wettability. We found that management systems with high biological inputs (e.g., NT + CC + PL) fostered the accumulation of hydrophobic SOM compounds, resulting in water repellent soils (WDPT > 5s) with high contact angles. This physical state promotes rapid, non-uniform infiltration. Conversely, conventionally tilled systems with limited organic input exhibited no hydrophobicity but had slower infiltration.

This work provides direct evidence linking specific management practices to distinct SOM chemical signatures, which in turn control fundamental soil physical properties. This mechanism is a key driver of the soil's hydrological functionality and its subsequent ability to capture and store plant-available water.

# From Soil Morphology to Depression Hydrology: Diagnostic Criteria and Predictive Patterns in the Oka-Don Lowland

**M.A. Smirnova [1,2]*, A.I. Kornilova [1,2], and P.P. Fill[1]**

[1] *Dokuchaev Soil Science Institute, Moscow, Russia*

[2] *Faculty of Geography, Lomonosov Moscow State University, Moscow, Russia*

*summerija@yandex.ru

**ABSTRACT**

Hydrological processes organize the soil cover of the Oka-Don Lowland, where a depression microrelief creates a unique mosaic of soil-vegetation complexes. While similar landscapes exist in the Canadian Pothole Region and Polish lowlands, the distinct moisture and temperature regimes of the Oka-Don region shape unique hydrological processes and pedogenesis.

Depression and inter-depression soils are functionally linked: surface runoff accumulates in depressions, waterlogging their soils, while maintaining optimal moisture in inter-depression spaces. This promotes Chernozem formation in inter-depression areas, while depressions develop waterlogged soils that, despite poor agricultural suitability, perform crucial hydrological functions, serve as biodiversity hotspots, and indicate depression hydrology.

This study developed approaches to reconstruct and predict depression water regimes through integrated analysis of soil morphology and landscape parameters. Objectives included: 1) investigating depression soil morphology; 2) linking soil morphology to water regime characteristics; 3) identifying landscape factors to predict water regimes in unstudied depressions.

Analysis of nine depressions revealed that soils form a genetic sequence reflecting waterlogging source and duration. Gleysols develop under permanent surface and groundwater saturation, Stagnosols form under periodic surface and groundwater influence, while Planosols occur under exclusively surface-driven waterlogging. Waterlogging duration decreases along the sequence: Gleysols → Stagnosols → Planosols.

Simple morphometric parameters (volume, catchment area, depth of depressions) failed to reliably differentiate the depression soils at this key site. However, integrated analysis incorporating precipitation and moisture accumulation data revealed clear patterns. The most waterlogged depressions with Gleysols occupy lower hypsometric positions, characterized by larger diameters and predominantly greater volumes, with strong surface waterlogging (water layer up to 0.3 m) and tall hydrophilic herbaceous plants. Depressions with Stagnosols show intermediate characteristics, supporting distinct vegetation zonation with Cyperaceae in central areas and Salix on slopes. The driest depression with Planosols displays minimal morphometric values and weak surface waterlogging (water layer ≤0.1 m). In these areas, vegetation extracts moisture from surface horizons through herbaceous roots and from deeper layers via woody taproots, enhancing soil desiccation.

The developed approach effectively diagnoses and predicts water regimes in depression landscapes. Quantitative relationships between soil indicators, topography, and vegetation characteristics provide a basis for spatial extrapolation of these patterns.

**ABSTRACT**

Sustainable soil and water management in arid regions requires precise quantification of water fluxes across the soil-plant-atmosphere continuum. This study presents an integrated framework that combines soil moisture-based Evapotranspiration (SMET) modeling, a water-salt-biomass balance approach, sub-surface hydrology sensing, and socio-technical analysis to optimize water use efficiency (WUE) in Utah's agricultural systems. Multi-year field trials evaluated crop-irrigation systems under drought-tolerant genetics, deficit irrigation levels, and conservation practices. The SMET model accurately estimated actual ET ($R^2$ = 0.98-1.0) across management scenarios, identifying low-elevation sprinklers with moderate deficit irrigation as optimal for improving WUE (Singh et al., 2025). A novel water-salt-biomass balance was used to quantify the leaching fraction and deep percolation. The balance links solute transport and biomass accumulation to partition applied water into productive and leaching losses. Field-measured soil moisture and matric potential data were fitted using improved van Genuchten (VG) and Peters-Durner-Iden (PDI) models to refine retention and conductivity parameters, enabling real-time flux estimation via Buckingham-Darcy's law. These coupled modules bridge infiltration, ET, percolation, and recharge to establish a transferable framework for field-scale water accounting. A parallel socio-technical study identified barriers and incentives for sensor adoption, illustrating how integrating biophysical modelling with behavioral insights supports scalable, data-driven irrigation management that enhances groundwater sustainability and agricultural resilience.

**Keywords:** Actual evapotranspiration, soil water retention, deep percolation, groundwater recharge, and sensor adoption.

**ABSTRACT**

Groundwater nitrate concentration constitutes an environmental risk, particularly in regions with significant agricultural activity, livestock production and variable climatic conditions. The Veneto region in northeastern Italy is characterized by high agricultural production and complex hydrogeological systems that could have led to nitrate transport into groundwater. To address concerns about increased nitrate concentrations, the European Union implemented the Nitrates Directive (91/676/EEC), which aims to protect and improve water quality by regulating agricultural practices and designating Nitrate Vulnerable Zones (NVZs). Despite ongoing mitigation efforts under the Nitrates Directive, more advanced tools need to be applied in the Veneto region to understand nitrate variability across different spatial and temporal scales. In response, this study developed a Long Short-Term Memory (LSTM) neural network to predict nitrate concentrations in the groundwater of Veneto. The neural network utilizes a comprehensive dataset spanning 21 years (2003-2023) from 150 wells sampled in the spring and fall of each year. The model integrates an extensive set of predictive variables to capture temporal, spatial, and environmental differences. These include meteorological variables aggregated across 12 time intervals, soil properties at two depths, topographic attributes, soil erosion factors based on the Revised Universal Soil Loss Equation (RUSLE), land use and agricultural land cover within five spatial buffers, nitrogen and irrigation inputs, net primary productivity, population density, and well characteristics. The LSTM was able to capture temporal patterns and interactions among predictor variables to assess how short- and long-term patterns influence nitrate levels. The large, multi-scale dataset could detect seasonal, interannual, and spatial variability specific to the Veneto region. This study demonstrates the potential of machine learning techniques to advance nitrate risk assessment, contribute to data-driven groundwater quality modeling in complex agricultural regions, and aid in site-specific management strategies within the context of the Nitrates Directive.

# Leptosols of Subarctic barrier islands: land – sea interface

**Nikolay S. Sobolev[1,*]**

*M. V. Lomonosov Moscow State University (Faculty of Geography, Moscow, Russia)*
*kolyhome2000@yandex.ru

**ABSTRACT**

The barrier islands in the Northern Okhotsk Sea are unique landscapes, which soils develop on sands and pebble under regular reshaping and addition of marine material by storm surges and tides. These are low, elongated landforms 0-5 m a.s.l. with Calamagrostis-Leymus meadows. The soil profile comprises an organic "dry-peat" horizon merging into pebble interlaced with living and dead roots. Good drainage is provided by marine weakly stratified pebble and despite the periodical ingress of sea waters. Aerated moisture-unstable environment is persistent in these soils. Soil development proceeds slowly and discontinuously, with frequent partial removal of the upper horizons owing to tides and surges. The marine effects on the environment also comprise sea salts emission, and numerous dense seagull colonies are common.

The influence of sea waters on barrier islands does not produce soil hydromorphism, and it creates problems for their classification. The absence of prolonged waterlogging required for peat formation, hence, histic horizon in the WRB system, does not permit to qualify them as Histosols; their topsoil is defined as dry-peat horizon in the Russian classification system. It consists of weakly decomposed plant residues with fibric fabric, abounds in roots and is in agreement with cold, humid, and oxygen-rich environment. It functions as moisture reservoir, maintains vegetation stability and contributes to fixation of sand and pebble brought by surges.

As a result, we have an oxymoron situation: non-hydromorphic soils occur under conditions that are, in fact, strongly hydromorphic. How can we classify them? Depending on the degree of profile development and substrate stabilization, soils were identified as follows: Coarsic Skeletic Eutric Leptosols (Fluvic, Ornithic, Protic) on recently reworked surfaces, Coarsic Skeletofolic Eutric Leptosols (Fluvic, Ornithic) on relatively stabilized material. The most developed soils are Coarsic Skeletofolic Dystric Leptosols (Fluvic, Protospodic). This sequence reflects both the duration of surface stability and the decrease of marine effects.

The studied soils occur at land – sea interface: they are not submerged or anaerobic, but are shaped by coastal processes. Their morphology and genesis demonstrate how pedogenesis proceeds under permanent marine influence and periodical reworking by storms and tides.

The example of these soils extends the concepts of hydromorphic and submerged soils in tidal zones of Subarctic seas.

Figure 1. Coarsic Skeletofolic Dystric Leptosol (Fluvic, Protospodic)

Figure 2. Skeletofolic material (upper picture), protospodic feature on pebble surface (lower picture)

## ABSTRACT

Soil water dynamics in the unsaturated zone are strongly influenced by complex flow phenomena, particularly preferential flow (PF), which can bypass the soil matrix and complicate interpretation of soil water content measured at high temporal resolution. Detecting PF requires alignment between process and observation scales so that predictive models can represent Pedon-scale flow complexity.

For a soil water content data set collected over two years at 10-minute measurement intervals in a humid-temperate Andosol in southern Chile, where PF studies are limited, we applied two PF identification methods, the velocity threshold (VT) and the non-sequential response (NSR), alongside detailed rainfall and wetting-process characterisation. VT and NSR differ in detection sensitivity. Because wetting responses and PF triggers are not unique, we used variable-selection tools: correlation matrices, principal component analysis (PCA), and random forests (RF). We analysed 158 rainfall events (≥2 mm), 95 of which produced wetting responses. These were detected with eight TEROS- 12 sensors at 10, 20, and 60 cm depths (3, 3, 2 replicates). One TEROS-21 sensor per depth monitored the matric potential. In situ hydraulic conductivity was estimated using field dual-porosity van Genuchten parameters.

Correlation matrices revealed an inverse relationship ($r = -0.68$; 20 cm depth) between initial soil water content ($\theta$start) and the time-integrated coefficient of variation (CVint), confirming that dryness dictates heterogeneity. PCA identified three orthogonal factors: rainfall-to-wetting response, soil hydraulic state, and infiltration dynamics. The infiltration velocity (Vinf) was structurally independent of all three. VT indicated PF in 37% of wetting events, whereas NSR detected only two events, proving unsuitable for our dataset. The 6-hour rainfall separation requires reconsideration, as soil water redistribution between events produced false-positive NSR detection. RF regression ($R^2 = 0.93$) showed Vinf was dominated by precipitation rate (Prate), with $\theta$start showing negligible predictive value. RF classification predicting PF occurrence (VTPF) achieved high performance (balanced accuracy = 92.7%). However, the predictive hierarchy reversed: occurrence was best predicted by soil state variables (hydraulic conductivity at 10 and 20 cm depth, and hydraulic gradient), while Prate dropped in rank.

PF occurred most frequently under wetter conditions, primarily governed by rainfall kinetics. Yet, sensor signals appeared largely homogeneous, masking PF occurrence. Conversely, spatial heterogeneity is highest under dry conditions. The NSR method requires detectable heterogeneity and may be better suited for events under dry soil conditions. This highlights the challenge of predicting PF and the need to define PF by both its kinetics (Vinf) and spatial signature (CVint) to identify scalable trends.

# Tree parasitism as a microclimatic amplifier: implications of Viscum album infection for soil moisture and repellency dynamics

**Lizardo Reyna-Bowen[1], Ewa Słowik-Opoka[1], Anna Klamerus-Iwan[1*]**

[1] *Faculty of Forestry, University of Agriculture in Kraków, Kraków, Poland*

*anna.klamerus-iwan@urk.edu.pl

**ABSTRACT**

Mistletoe (*Viscum album sp.*) is a widespread hemiparasitic species whose physiological interactions with host trees can indirectly modify forest microclimates and soil hydrological behavior. This study examined how mistletoe infection affects temperature, soil moisture dynamics, and soil physicochemical properties in Abies and Pinus forest ecosystems.

Measurements conducted between April and August 2025 revealed that in Abies stands, infected trees showed 1.0 - 2.1 °C higher air and soil temperatures and up to 12 % lower mean soil moisture compared to areas under healthy trees. Correlation analysis ($r = 0.62$ for healthy vs. $r = 0.28$ for infected sites) indicated that the presence of mistletoe weakens the coupling between soil temperature and moisture. These conditions may promote temporary soil water repellency and reduced wettability following drying events, especially during low-rainfall periods.

In contrast, Pinus ecosystems exhibited higher hydrological stability, with temperature differences below 0.5 °C and stable volumetric water content ($r > 0.70$). This resilience is likely related to denser ground vegetation and the lower physiological sensitivity of pine species, which buffer microclimatic variation. No immediate degradation of soil health indicators (organic carbon, electrical conductivity, or cation exchange capacity) was detected; however, changes in moisture - temperature interactions suggest potential shifts in infiltration and nutrient mobility over time.

The results indicate that mistletoe presence, while not a direct driver of soil water repellency, acts as a microclimatic amplifier, creating conditions conducive to transient repellency and altered water infiltration in sensitive forest soils. Understanding these host-dependent feedbacks between canopy parasitism, soil water behavior, and nutrient cycling is crucial for predicting long-term forest ecosystem resilience under climate change.

**ABSTRACT**

Soil salinity is a persistent and spatially variable constraint on crop productivity and soil health across the Red River Valley (RRV) and similar landscapes of the Northern Great Plains. Saline soils with electrical conductivity greater than 1.7 dS $m^{-1}$ have been shown to reduce corn yields. Although over 80% of the land in the RRB is dedicated to agricultural production, primarily corn, soybean, small grains, and specialty crops, more than 26% of this region is affected by salinity that limits crop growth. Additionally, the adoption of tile drainage has nearly tripled in the past decade. Despite decades of field trials and remediation efforts, outcomes have been fragmented due to site-specific variability, shallow water tables, complex geology, hydrology, and inconsistent resources.

This work addresses these challenges by using an enhanced modeling framework to integrate long-term field observations and remote sensing data to tile drainage impacts on salt fate, transport, and leaching under diverse soil, landscape, and management conditions. We performed a comprehensive regional assessment of tile drainage-salinity interactions and their potential impacts on crop productivity across the RRV. By linking field-scale processes with watershed-scale responses, the modeling framework provide a decision-support tool for assessing trade-offs between salinity mitigation, crop productivity, and water quality outcomes.

# The influence of selected factors on the various phosphorus compounds in soils with a bog iron ore horizon

**L. Oktaba[1*], D. Kaczorek[1,2] and D. Gozdowski[3]**

[1] *Department of Soil Science, Institute of Agriculture, Warsaw University of Life Sciences - SGGW, Poland*

[3] *Department of Biometry, Institute of Agriculture, Warsaw University of Life Sciences - SGGW, Poland*

*lidia_oktaba@sggw.edu.pl

**ABSTRACT**

Soils containing bog iron horizons occur relatively commonly, although they are usually limited to small areas within river valleys and in the vicinity of water bodies in central and northern Europe. The formation of bog iron is associated with redox processes involving the mobilization and accumulation of iron compounds. These processes are accompanied by the concentration of other elements, including phosphorus. An analysis of the distribution of phosphorus compounds in soils with bog iron horizons (at different stages of development) and in iron-rich soils lacking continuous bog iron layers is of particular interest, as it allows for the assessment of pedogenic processes occurring in these soils.

Total phosphorus ($P_{tot}$) was determined using X-ray fluorescence spectrometry (XRF). Mineral phosphorus forms were analyzed according to the Chang and Jackson (1957) fractionation method, yielding seven fractions associated with iron, aluminum, and calcium compounds. The total phosphorus content in bog iron horizons ranged from 0.58% to 2.43%. A strong positive correlation was observed between $P_{tot}$ and total iron content (Fe), with a correlation coefficient of 0.95.

Occluded phosphorus compounds dominated both the bog iron horizons and the overlying surface horizons, accounting for more than 50% of all mineral phosphorus forms. The content of occluded phosphorus was also correlated with iron, most strongly with the dithionite-extractable iron fraction (Fed), with a correlation coefficient of 0.84. The remaining phosphorus forms were primarily associated with oxalate-extractable iron (Feo), whereas Ca-bound phosphorus (Ca–P) showed a strong correlation with pyrophosphate-extractable iron (Fep), a form linked to soil organic matter ($r = 0.82$). These results indicate highly complex relationships between phosphorus, iron, and other environmental components in soils containing bog iron horizons.

# Occurrence and assessment of water repellency in biochar and biochar-amended soils

**Jiefei Mao[1*], Kun Zhang[2]**

[1] *Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences, Urumqi, China*

[2] *Xinjiang University, Urumqi, China*

*mjf@ms.xjb.ac.cn

**ABSTRACT**

Soil water repellency occurs widely from the nanoscale to the ecosystem scale, is closely associated with soil moisture and its spatial distribution and significantly influences soil hydrological processes. Contact angle (CA) method and water drop penetration time (WDPT) method are commonly used to determine soil water repellency; however, inconsistent results are frequently observed for biochar when using these two methods, reducing the accuracy and comparability of assessments. Moreover, the regulatory effects of biochars with diver structures on soil water repellency lack systematic quantification.

In our study, a series of pure substances were first employed as model materials to establish a new method for evaluating their hydrophobicity. Subsequently, biochars with different feedstock sources and pyrolysis temperatures were compared to characterize surface structural differences. We analyzed the effects on the occurrence and intensity of biochar hydrophobicity and investigated the change of soil water repellency within 90 days after biochar amendment. Based on changes in CA during water droplet spreading within 90 s, a dynamic contact angle (DCA) method was developed, and the concept of "pseudo-hydrophobicity" was proposed for the first time[1]. Application of the DCA method effectively reconciled discrepancies between the CA and WDPT methods in determining the water repellency of biochar and biochar-amended soils. It demonstrated that pyrolysis-induced variations in surface functional groups, specific surface area, and pore size distribution are the key factors controlling biochar hydrophobciity[2]. These structural characteristics exhibited significant negative correlations with water repellency ($p < 0.05$). In biochar–soil incubation experiments, the addition of most biochars increased the contact angle of soil within 90 s, transforming originally hydrophilic soils into a 'pseudo-hydrophobic' state. This study proposes and validates the DCA method as a novel approach for evaluating the water repellency of biochar and biochar-amended soils, providing methodological and technical support for biochar selection and its soil application.

# Characteristics, Driving Mechanisms, and Machine Learning Modeling of Nitrogen Runoff Losses from Chinese Rice Cropping Systems

**Yi Wang[1*], Junjia Qi[2]**

[1] *College of Hydraulic and Civil Engineering, Ludong University, Yantai 264025, China*

**ABSTRACT**

Clarifying the characteristics, mechanisms, and spatial patterns of nitrogen (N) runoff loss in rice cropping systems is crucial for optimizing agricultural N management strategies and controlling non-point source pollution in China. However, the key factors and how they determine N runoff loss in rice cropping systems, remain unclear at a national scale. In this work, we compiled a comprehensive dataset comprising 1,154 records of N runoff losses from Chinese rice cropping systems, synthesized from 141 published studies. Piecewise structural equation modeling (SEM) was first applied to examine the causal linkages among key factors and their effects on N runoff losses in rice cropping systems. Based on the key factors, machine learning models were subsequently developed to simulate N runoff losses across Chinese rice-growing regions. The results showed that the average N runoff loss across the compiled dataset was 9.52 kg N $ha^{-1}$ $season^{-1}$ in Chinese rice cropping systems, with significantly higher N runoff losses observed in the paddy rice system (PRS) than in the paddy rice–upland rotation system (PRURS). Random Forest–based ranking and SHAP (SHapley Additive exPlanations) interpretations of the machine learning model determined that precipitation, N fertilization rate, and total soil N (TSN) were identified as key influencing factors for N runoff loss, and soil elemental stoichiometric ratios (e.g., C:N:P) were negatively correlated with N runoff loss, the later factors highlighted the importance of soil biogeochemical cycling in regulating N runoff loss in the Chinese rice cropping systems. The Piecewise SEM suggested that the pathway effects of the composite variables of N fertilization rate, soil nutrient properties, and soil C:N:P on N runoff loss were ranked as follows: Fertilization (0.52) > Soil nutrient properties (0.29) > Soil C:N:P (-0.14), in the Chinese rice cropping systems. The pathway effects of the three composite variables were ranked as Fertilization (0.52) > Soil nutrient properties (0.38) > Soil C:N:P ratio (-0.19) in the PRS, and Fertilization (0.52) > Soil nutrient properties (0.13) > Soil C:N:P ratio (-0.10) in the PRURS. This indicate that soil nutrient properties and the soil C:N:P ratio exert stronger effects on N runoff loss in the PRS than in the PRURS. The XGBoost model estimated that over the period 2018-2022, the average N runoff loss in Chinese rice cropping systems was 6.64 ± 3.73 kg N $ha^{-1}$ $yr^{-1}$, corresponding to a total runoff load of 228.62 ± 27.43 Gg N $yr^{-1}$. Single- and double-cropping systems exhibited runoff loss intensities of 6.26 ± 3.31 and 11.77 ± 5.07 kg N $ha^{-1}$ $yr^{-1}$, respectively, and the N runoff load of early rice was 1.57 times that of late rice (17.05 ± 1.09 vs. 10.86 ± 2.59 Gg N $yr^{-1}$). High runoff loss intensities were concentrated along the 30°N belt and in southern coastal regions. Hainan Province exhibited the highest intensity (12.02 kg N $ha^{-1}$ $yr^{-1}$), while Hunan and Jiangxi each accounted for more than 10% of the national N runoff loss load. Under a scenario of 15% N reduction, the national N runoff loss intensity and load were projected to decrease by 0.60 kg N $ha^{-1}$ $yr^{-1}$ and 20.45 Gg N $yr^{-1}$, respectively, equivalent to an 8.94% reduction. Early rice showed a higher mitigation potential than late rice (11.03% vs. 7.09%), and provinces with high N fertilizer application rates such as Hubei, Jiangsu, and Shanghai demonstrated more significant reductions. These results provide critical insights into assessing N runoff loss, and offer a robust basis for efficiently mitigating N runoff losses and optimizing N management strategies to control agricultural non-point source pollution in Chinese rice cropping systems.

## ABSTRACT

Identifying the key controlling factors and accurately assessing phosphorus (P) runoff loss and its component fractions—total phosphorus (TP), dissolved phosphorus (DP) and particulate phosphorus (PP)—from rice cropping systems are crucial for controlling agricultural non-point source pollution in China. In this study, we compiled a comprehensive dataset comprising 517 field observations from Chinese rice cropping systems, and developed six machine learning (ML) models to simulate the intensity and load of TP, DP, and PP runoff losses across the China and its six major rice-growing zones (categorized as zone I to VI); especially, a Bayesian correction method combined with Monte Carlo spatial validation was employed to adjust DP and PP estimates to satisfy physical constraints in the ML model. The Pearson correlation analysis demonstrated that TP runoff loss exhibited a significant positive correlation with precipitation and P fertilization rate, while correlations with other factors were generally not significant. However, DP runoff loss was linearly and positively correlated with soil organic carbon (SOC), total soil nitrogen (TSN), and total soil phosphorus (TSP), but negatively correlated with soil C:N and C:P ratios. And PP runoff loss showed linear and negative correlations with SOC and clay content. Among the six ML models, the XGBoost model achieved the highest predictive accuracy for P runoff loss ($R^2$ = 0.76, RMSE = 0.34, MAE = 0.18) and was thus selected for national simulations. Based on SHAP (SHapley Additive exPlanations) interpretation, precipitation, clay content, soil C:P ratio, P fertilization rate, and soil N:P ratio were identified as key factors influencing P runoff loss at the national scale. This suggests that, beyond hydrological drivers, soil texture, and P input, biogeochemical processes (e.g., mineralization, adsorption-desorption, microbial immobilization) are also critical for P runoff loss. The XGBoost-based national simulations indicated that the average TP runoff loss intensity from Chinese rice cropping systems was 0.77 ± 0.35 kg P $ha^{-1}$ $yr^{-1}$, corresponding to an annual total loss load of 26.61 ± 1.67 Gg nationally. DP and PP contributed approximately 49% and 51% to the TP runoff loss, respectively. The higher TP loss observed in the rice-growing region between the Yellow River and the Yangtze River (e.g., North China single-rice cropping zone (IV)) and lower loss in mountainous southwestern areas (e.g., Southwestern plateau single- and double-rice cropping zone (III)). Spatially, DP runoff loss was the dominant P fraction in southern and northeastern rice-growing regions, whereas PP dominated in central and eastern rice-growing areas. Analysis of zonal dominant factors for P runoff loss revealed that precipitation was the primary controlling factor in the South China double-rice cropping zone (I), the Central China double- and single-rice cropping zone (II), and the Southwestern plateau zone (III). Soil pH emerged as the dominant factor in the North China single-rice zone (IV) and the Northwest China dry single-rice cropping zone (VI). TSN was identified as the key factor in the Northeast early maturing single-rice cropping zone (V). These pronounced regional disparities of dominant factors among the six major rice-growing zones underscore the necessity for implementing region-specific mitigation strategies for P runoff losses. Thus, this study provides critical insights for the precise assessment agricultural non-point source P pollution, and guiding the practices of efficient P nutrient management in the China and other similar agricultural regions worldwide.

# Influence of Soil Microstructure on Capillary Rise in Disturbed and Undisturbed Sandy Arid Soils, Oman

**Zainab Al Kindi[1], Afrah Al-Shukaili[1], and Anvar Kacimov[1]**

[1] *Department of Soils, Water and Agricultural Engineering, Sultan Qaboos University, Muscat, Oman*

s128056@student.squ.edu.om or zainabalkindi5@gmail.com

**ABSTRACT**

This study investigates the influence of soil microstructure on capillary rise in sandy soils through experiments conducted in arid dunes, Muscat, Oman. While many previous studies have utilized disturbed samples and treated sandy soils as homogeneous, non-stratified media, this research compares both disturbed and undisturbed samples using direct column tests and indirect methods, including empirical equations and the HYDRUS-1D model (a numerical simulation software for modeling water flow in variably saturated porous media) (Šimůnek et al., 2013). Although the samples exhibited similar soil textures, they differed in particle size distribution, saturated hydraulic conductivity (the rate at which water moves through saturated soil), and capillary behavior (the upward movement of water through soil pores against gravity). Notably, the undisturbed sample exhibited lower capillary rise (60 cm) compared to the disturbed sample (73.5 cm), likely attributable to the complex internal structure of dunes, including stratified sand layers (Al Shukaili, 2018), which obstruct water movement as coarser particles in the upper layers act as a capillary barrier. Theoretical models demonstrated varying accuracy, with some models aligning more closely with the sample data. The findings underscore the significant role of soil microstructure in water movement and emphasize the importance of preserving undisturbed soil conditions for accurate assessments in geotechnical and environmental applications.

**ABSTRACT**

Global climate change is intensifying the imbalance between water supply and demand. Large-scale monoculture rubber plantations in tropical regions have profoundly impacted regional hydrological cycles and soil moisture balance. While rubber agroforestry systems hold potential advantages, their water utilization sources remain poorly understood. This study focuses on monoculture rubber plantations and rubber-*alpinia oxyphylla* agroforestry systems. Based on isotopic data of atmospheric precipitation, soil water, and plant water from 2021 to 2023, along with their monthly and seasonal variation patterns, we quantitatively analyzed the water sources of the two cultivation modes during wet and dry seasons using the IsoSource and MixSIAR models. The results indicate that the isotopic values (δD and $\delta^{18}O$) of atmospheric precipitation were generally enriched during the dry season and gradually depleted during the wet season, with a significant linear relationship observed between δD and $\delta^{18}O$. Soil water content in monoculture rubber systems (XD) was generally higher than that in the agroforestry system (XY), and significant correlations were observed between δD and $\delta^{18}O$ in soil water under both cultivation modes. In both systems, the $\delta^{18}O$ values of rubber trees intersected with the $\delta^{18}O$ curves of soil water at multiple depths, while fewer intersections were observed for *alpinia oxyphylla*. Plants absorbed a higher proportion of shallow soil water during the wet season, while they relied more on intermediate and deep soil water during the dry season. A comparison of the results from the IsoSource and MixSIAR models revealed that the proportions of water uptake from various potential sources by rubber trees and *alpinia oxyphylla* under different cultivation modes calculated by MixSIAR were lower than those estimated by IsoSource. The findings of this study provide a scientific basis for developing rubber plantation models with rational water-use strategies.

## ABSTRACT

In arid and semi-arid regions, salt may precipitate as a crust on the soil surface resulting from strong evaporation and shallow saline groundwater, creating a physical barrier that inhibits the evaporative water loss and heat flow to the external environment (Zhang et al., 2014). However, most existing studies on the processes of water and heat transfer under salt crust have focused on saturated or wet soils (Fujimaki et al., 2006; Li and Wang, 2025), and these processes in drying saline soils remain poorly understood. To address this knowledge gap, we employed soil column experiments in a controlled environment with constant radiation to capture the dynamic evolution of salt crust, while improving one-dimensional transient numerical simulations to investigate the influence of salt crust on water and heat transport. The results revealed that salt crust significantly reduced evaporative water loss, with this inhibitory effect being more pronounced in fine-textured soils. However, when the water content dropped below the critical threshold of 26%, salt domes and fissured structures formed on the surface. As a result, a second peak of water loss rate emerged, and water loss in the near-surface soil layer occurred in four stages. Furthermore, salt precipitation reduced net radiation by 29% by increasing albedo, while concurrently increasing thermal conductivity and heat capacity by retaining soil moisture, resulting in lower temperatures and temperature gradients across the profile in saline soil compared to salt-free soil. These thermal behaviors in coarse-textured soils were more dependent on salt precipitation, which can be attributed to increased pore space allowing for the formation of a larger salt crystal continuum. The findings provide new insights for quantifying water consumption, salt accumulation, and surface heat distribution in saline-alkali soils.

# Optimizing and Validating a Correction Formula for Xylem Water Deuterium Offsets in Field-Grown Apple Trees

**Yining Liu[1], Huijie Li[2*]**

[1] *College of Resources & Environmental Engneering, Ludong University, Yantai, China*

* huijieli88@163.com

**ABSTRACT**

Cryogenic Vacuum Extraction (CVE) has become a key method for determining the hydrogen and oxygen isotopic composition of xylem water in plant water source studies due to its advantages of high extraction volume, efficiency, and operational simplicity. However, existing research indicates that isotopic fractionation biases (e.g., deuterium offset) can occur during cryogenic vacuum extraction, leading to distortion of the xylem water isotopic signal and consequently affecting water source apportionment results. Current understanding of deuterium offsets and their correction formulas under real field conditions remains insufficient.

Therefore, unlike previous rehydration-based approaches, this study focused on apple trees – a typical deep-rooted species used in the afforestation of former cropland on the Loess Plateau. Standardized orchard plots with 0%, 20%, and 40% rain-exclusion treatments were established to simulate no-drought, moderate-drought, and severe-drought climatic conditions, thereby obtaining plant samples spanning a wide range of stem water contents. Continuous sampling was conducted throughout the growing season to observe fluctuations in stem water content and deuterium offset. The main conclusions of this study are as follows:

(1) The stem water content gradients set in rehydration experiments could not cover the actual stem water contents observed in the field. In apple trees on the Loess Plateau, stem water content during the growing season ranged from 0.64 to 1.59 g $g^{-1}$, with the highest values occurring in June and the lowest in October.

(2) Compared with existing correction formulas, the optimized formula proposed in this study improved accuracy by 9% and 6%, respectively.

(3) When stem water content exceeded 1.3 g $g^{-1}$, all three formulas demonstrated good correction performance. Within the stem water content range of 0.6–1.3 g $g^{-1}$, both the He formula and the Chen formula exhibited errors, whereas the optimized formula developed here showed errors only when stem water content fell between 0.6 and 0.9 g $g^{-1}$.

In summary, the optimized correction formula presented in this study offers higher accuracy, a broader applicable range of stem water contents, and can be directly applied to correct deuterium offsets in real field samples.

# Transport Pathways of Nitrate in Stormwater Runoff Inferred from High-frequency Sampling and Stable Water Isotopes

**ABSTRACT**

Storm events can mobilize nitrogen species from landscapes into streams, exacerbating eutrophication and threatening aquatic ecosystems as well as human health. However, the transport pathways and storm responses of different nitrogen forms remain elusive. We used high-frequency chemical and isotopic sampling to partition sources of stormwater runoff and determine transport pathways of multiple nitrogen forms in an agricultural catchment. Bayesian mixing modeling reveals shallow subsurface water as the dominant source of stormwater runoff, contributing 74% of the water flux and 72%, 71%, and 79% of total nitrogen (TN), total dissolved nitrogen (TDN), and nitrate ($NO_3$-N), respectively. Groundwater, by contrast, contributed 11% of stormwater runoff and 21%, 22%, and 17% of TN, TDN, and $NO_3$-N. The remaining 14% of stormwater runoff can be attributed to rainwater, which contains much less TN, TDN and $NO_3$-N. Surprisingly, during storm events the dominant nitrogen form was $NO_3$-N rather than dissolved organic nitrogen. Antecedent conditions and runoff characteristics have an important influence on nitrogen loads during storm events. Our results provide insight into hydrological mechanisms driving nitrogen transport during storm events, and may help in developing catchment management practices for reducing nitrogen pollution in aquatic ecosystems.

# Integrated NP Management for Sustainable Soil Fertility and Crop Productivity

**Muhammad Adnan**

*Department of Agriculture, University of Swabi, Pakistan*

**ABSTRACT**

Integrated Soil Nutrient Management (ISNM) focuses on the judicious integration of organic, inorganic, and biological nutrient sources to sustainably enhance soil fertility and crop productivity. This overview synthesizes findings from a series of field trials conducted across diverse agro-ecological zones, with particular emphasis on the management of nitrogen (N) and phosphorus (P). The trials assessed the combined use of mineral fertilizers with compost, green manures, biofertilizers, biochar, and rock phosphate to evaluate their interactive effects on crop yield, nutrient use efficiency, and soil health indicators. Across locations and seasons, integrated nutrient strategies consistently outperformed sole fertilizer applications by improving nutrient availability, reducing nutrient losses, and sustaining soil organic matter. Overall, the results highlight the effectiveness of ISNM in promoting balanced fertilization, mitigating environmental risks, and strengthening the resilience of farming systems. This synthesis offers valuable guidance for improving nutrient management practices and informing policy initiatives aimed at sustainable agricultural development.

**ABSTRACT**

Water stress poses an escalating threat to wheat (*Triticum aestivum* L.), often inducing oxidative damage in plants and deteriorating soil properties. While organic amendments can mitigate these effects, their comparative efficacy in enhancing drought resilience remains insufficiently explored. A pot experiment was conducted using a completely randomized design under a factorial arrangement (two factors) with three replicates. We evaluated four amendments including farmyard manure, organic waste compost, vermicompost, and biochar under three soil moisture regimes (50%, 75%, and 100% field capacity). Severe water stress (50% FC) significantly reduced soil moisture, root growth, nutrient uptake, and yield. Vermicompost combined with 100% FC emerged as the most effective amendment, enhancing drought resilience through a dual mechanism: it acted as a biostimulant, strengthening the plant's antioxidant defense system to reduce oxidative stress, and as a soil conditioner, improving soil organic matter, water contents and aggerate stability. This synergistic enhancement in soil-plant interaction led to better root growth, nutrient uptake, and yield stability under water stress. Our findings highlight the potential of vermicompost as a promising amendment for developing more drought-resilient wheat cultivation systems, a premise that warrants further validation under field conditions.

**ABSTRACT**

Sugar beet pulp (SBP), a lignocellulosic agricultural waste, holds great potential for bioconversion, but its efficient degradation remains challenging. Our current study investigated the synergistic mechanism of *Klebsiella* sp. HDJT1 and *Pseudomonas* sp. C27 in SBP degradation, focusing on metabolic cross-feeding and quorum sensing (QS) to enhance hydrolysis efficiency and soil-plant-microbe interactions. HDJT1 and C27 exhibit complementary enzymatic profiles: HDJT1 dominated in β-glucosidase activity (11.45 $U \cdot mL^{-1}$), while C27 produced higher endo-β-glucanase (79.43 $U \cdot mL^{-1}$). Their co-culture achieved a 44.05% SBP weight loss in 7 days, outperforming single strains by 13.15–19.60%. C27 recruited diverse microbial communities via QS signaling, optimizing nitrogen (78.4% higher alkaline-hydrolyzable N) and phosphorus cycling core genes such as *phoB* and *phoR*. Meanwhile HDJT1 enhanced cellulose/lignin hydrolysis, reducing lignocellulosic residues to 16.5% after 23 days of in-field degradation. Metabolic cross-feeding between strains enriched rare taxa (e.g., *Pelotalea*, *Desulfovibrio*) and balances N/P cycling, enhancing soil health. This dual-role system (C27 as "ecosystem engineer" and HDJT1 as "metabolic optimizer") advances sustainable agricultural waste management, offering a scalable model for soil fertility improvement through organic waste valorization. Small-molecule carbohydrates released by in-situ degradation of lignocellulose in soil can be used as potential "signal molecules" for underground microbial communication and play an important role in plant-soil feedback.

*alice.boarino@unito.it

**ABSTRACT**

The use of livestock-derived fertilizers in agriculture presents significant agronomic and environmental advantages, like enhancing soil organic matter and decreasing dependence on synthetic mineral fertilizers. However, these organic fertilizers frequently exhibit nutrient imbalances that fail to match crop nutritional requirements, often leading to nutrient surpluses and substantial risks of nitrogen (N) and phosphorus (P) losses to the environment. Such losses, through nitrate leaching, ammonia ($NH_3$) volatilization, nitrous oxide ($N_2O$) emissions, and P runoff, pose major sustainability concerns. This research aims at mitigating nutrient losses from agricultural soils by improving the nutrient balance of livestock-based fertilizers, thereby achieving better alignment between nutrient availability and crop uptake.

In livestock-intensive regions, cattle manure is commonly processed through anaerobic digestion for biogas production. The resulting digestate is usually separated into a N-rich liquid fraction and a P-rich solid fraction, generating a nutrient distribution that poorly corresponds to crop needs. Herein, cattle slurry was pre-treated using hydrodynamic cavitation coupled with enzymatic hydrolysis (employing phytase and a mixture of cellulase, hemicellulase, and pectinase) before anaerobic digestion. This process allowed to increase biogas yield while promoting P solubilization and its transfer from the solid to the liquid phase. Consequently, ammonium and phosphate were effectively recovered from the digestate liquid fraction in form of struvite, a slow-release fertilizer, while the N:P ratio of the solid fraction improved from 6.4 to 9.6, better matching with plant nutrient demands.

The resulting materials were tested on A-horizon soils from two Regosols with comparable low N and P contents but differing in texture and pH. A greenhouse experiment with *Lolium multiflorum* Lam compared conventional fertilization with partial or full substitution by pre-treated and untreated digestate solid fractions and recovered struvite. All treatments efficiently supported plant growth while substantially reducing N losses and P runoff as a function of texture and soil pH. This approach can therefore have strong potential to mitigate nutrient losses from soils, while reducing our dependance on synthetic fertilizers. The study also highlights how soil properties can influence the effectiveness of pollution mitigation using bio-based fertilizers.

**ABSTRACT**

Continuous addition of inorganic fertilizer and farm yard manure (FYM) alone or in combination is necessary to assess the changes in yield and soil properties. Therefore, a study was conducted at the experimental farm of Department of Soil Science and Water Management, Dr. Y. S. Parmar University of Horticulture and Forestry Nauni, Solan (HP) for consecutive two years (2019-2021) to access the effect of nutrient management on sustainable yield, soil fertility, and carbon stock in a Cauliflower–Capsicum cropping sequence of the northwestern Himalayan region. The experiment was laid out in Randomized Block Design having crops *in rabi* and *Kharif* season comprises of nine treatments viz. $T_1$- control, $T_2$-100% FYM (N equivalent basis), $T_3$-100% N, $T_4$-100% NP, $T_5$-100% NK, $T_6$-100% PK, $T_7$-100% NPK, $T_8$-100% NPK+ FYM (recommended Practice) and T9- 150% NPK+ FYM. Results showed that the addition of farm yard manure alone or in a combination with chemical fertilizers contributed to higher soil organic stock and soil carbon sequestration rate. The highest maximum water holding capacity (MWHC) and mean weighted diameter (MWD) were recorded under $T_9$ (47.5 % and 1.39 mm, respectively) and lowest were under control (41.0 %) and $T_3$ (0.66 mm), respectively. The maximum saturated hydraulic conductivity was recorded with treatment $T_2$ (10.6 cm $hr^{-1}$) and minimum was under control (5.9 cm $hr^{-1}$). The maximum CEC was recorded under $T_2$ (14.82 cmol ($p^+$) $kg^{-1}$), whereas minimum was recorded under control (10.49 cmol($p^+$) $kg^{-1}$). Treatment $T_9$ was recorded with highest SOC content (15.2 g $kg^{-1}$), available N (380.5 kg $ha^{-1}$), available P (133.3 kg $ha^{-1}$) and available K (557.7 kg $ha^{-1}$) and the respective parameters were lowest under control (11.7 g $kg^{-1}$, 314.8 kg $ha^{-1}$, 82.9 kg $ha^{-1}$, 453.5 kg $ha^{-1}$), respectively. Application of 150% NPK + FYM improved the SYI of system by 49.4% over a control. This treatment increases soil carbon stock by 12.5% from 25.9 Mg ha−1 to 29.6 Mg ha−1 and recorded with maximum soil carbon sequestration rate, i.e. 2.21 Mg C m−3 year−1 over the 2 years. Thus, balanced fertilization of NPK and FYM is beneficial for the maintenance of soil physical health, improving CEC and macro and micronutrient levels.

# Conservation Agriculture Impacts Soil Organic Carbon Sequestration, GHG reduction and Sustainable Crop Production

**M. Jahiruddin* and M. M. R. Jahangir**

*Department of Soil Science, Bangladesh Agricultural University, Mymensingh, Bangladesh*

*E-mail Address: m_jahiruddin@yahoo.com

**ABSTRACT**

Agriculture is the mainstay of Bangladesh's economy, accounting 11.6% of GDP where the crops sub-sector contributes 7.25%. Recently Bangladesh has paid good attention to bio-farming aiming at achieving food security including safe and nutritious food while minimizing environmental degradation. This approach discourages use of chemical fertilizers & pesticides and instead encourages the use of organic and bio-fertilizers. Organic fertilizer (e.g., compost, vermi-compost, tricho-compost, biochar) use is especially important to produce fruits and vegetables. Conservation agriculture (CA) in this country is an emerging sustainable approach which helps soil organic carbon sequestration, GHG reduction, and decreased cost of production (fuel, labor & irrigation).

We had a 20-year study until recent on CA practice which encompasses minimal soil disturbance (zero tillage, strip tillage, bed planting), crop residue retention and legume-based crop rotation. This practice (CA) is found more suitable for dryland crops like wheat, mustard & pulses and less for wetland rice. It contributes to C stock in soil at a rate of 0.5-1 t $ha^{-1}$ $yr^{-1}$ depending on the duration of CA practice, amount of residue retention and crop diversification. CA shows 24.5% less carbon footprint and 28.5% less emission intensity or global warming potential than conventional practice. Reduced or zero tillage reduces the mixing of crop residues in the soil thereby resulting in lower decomposition rates and $CO_2$ emissions.

It was observed that bed planting improved seed placement, reduced irrigation needs and increased yields by 15–20% for mustard, wheat, and maize. Strip tillage (ST) in mustard, lentil, and potato cultivation demonstrated good economic returns, better yields, and significantly reduced fuel use and thus $CO_2$ emissions. For example, mustard (var. BARI Sarisha-17) under ST yielded 1.77 t/ha with 66% lower $CO_2$ emissions than the broadcast method of sowing. Zero tillage trials in coastal and lowland areas showed higher crop yields, lower labor and fuel cost, reduced salinity effects, and improved soil health through mulching.

Conservation agriculture is a sustainable farming practice that influences soil organic carbon sequestration, reduces GHG emissions and produces sustainable crop yield.

# Short-term interaction between earthworms, compost and biochar on GHG emissions and N mineralization

**Thiago Inagaki[1], Junbin Zhao [1], Claire Douheret [1], Pierre-Adrien Rivier [1], Jihong Liu Clarke [1], Nicholas Clarke [1]**

[1] Dep. Biogeochemistry and Soil Quality, Norwegian Institute of Bioeconomy Research, Ås, Norway

[2] École supérieure d'agricultures d'Angers, Angers, France

thiago.inagaki@nibio.no

## ABSTRACT

Earthworms enhance compost mineralization, improving its fertilizer value and soil quality (biological activity, structure). However, they often increase greenhouse gas (GHG) emissions, particularly nitrous oxide ($N_2O$), via nitrogen mineralization. Combining biochar with compost may mitigate these emissions while further boosting soil benefits alongside earthworm activity. We present preliminary results from a soil incubation (2 months) experiment testing this synergy. Using a Norwegian loam Cambisol, a 2x2x2 factorial design (four replicates) assessed the presence/absence of earthworms (Lumbricus terrestris - 10 adults/jar), compost (manure/food waste - 60 Mg $ha^{-1}$ equivalent), and rice-straw biochar (700°C pyrolyzed - 20 Mg $ha^{-1}$ equivalent). We hypothesized that earthworm and compost addition may present synergistic effects in improving N mineralization with consequent enhanced GHG emissions. We expect that biochar may counteract these emissions and potentially present positive effects for soil quality. The goal was to develop a biochar-compost-earthworm system creating a fertilizer with higher nutrient availability and lower GHG emissions. In the first week of the incubation, we found that higher $CO_2$ and $N_2O$ productions were associated with the presence of compost. Earthworms could further enhance the carbon decomposition but appeared to mitigate CH4 production. Further analysis will be carried out with a focus on GHG emissions ($CO_2$, $CH_4$, $N_2O$) and nitrogen mineralization dynamics.

**ABSTRACT**

The rising cost of synthetic fertilizers coupled with their adverse effects on the soil led to the emergence of biofertilizers as sustainable alternatives. However, the low potassium (K) content of compost biofertilizers often fails to meet the demand of crops. Meanwhile, K-rich minerals, such as feldspar, are underutilized, due to their relative recalcitrance. Against this backdrop, K-solubilizing bacteria are being utilized to mobilize mineral K from such sources. However, a research gap exists regarding using PSB to release K from feldspar and hence improve compost biofertilizers. This study aimed to bridge that gap by using *Bacillus megaterium* S2-4a1 to solubilize potassium in compost-feldspar mixtures. A Completely Randomized Design (CRD) comprising five treatments (T1 — compost control; T2 — compost + *B. megaterium*; T3 to T5: compost + *B. megaterium* + feldspar + rock phosphate at rates of 2.5, 5.0 and 10.0g, respectively) of three replicates each was used to quantify how *B. megaterium* (S2-4a1) solubilizes total and exchangeable potassium in a feldspar-compost biofertilizer mixture during a 60-day incubation period. The results indicated that *B. megaterium* treatments produced higher total and exchangeable K ($p < 0.01$ and $p = 0.0004$, respectively) than the compost control. Meanwhile, the highest exchangeable K was observed in T5 at 15 and 60 days (0.2559% and 0.3082%, respectively), however, these values were not significantly different from those of the T4 treatment (0.2543% and 0.2851%, respectively). On the whole, combining *B. megaterium* S2-4a1 with moderate amount of feldspar (5g) appears to be the most cost-effective treatment for substantially enhancing exchangeable K to improve compost biofertilizers within 15 days. Further studies to elucidate the K-solubilization mechanisms and optimize substrate:inoculum ratios are necessary before devising scalable field strategies employing this K-solubilzing bacterium to mobilize K from feldspar and other minerals towards enhanced soil and agricultural sustainability.

# Innovative Nutrient Recycling through Black Soldier Fly (Hermetia illucens) Rearing: Comparison of three Organic Waste Substrates—Food Waste, Bread, and their Mixture.

**Moussa Bouray[1*], Sanaa Miftah[2]**

[1] *Agricultural Innovation and Technology Transfer Center (AITTC), College of Agriculture and Environmental Sciences, Mohammed VI Polytechnic University (UM6P), Benguerir, 43150, Morocco*

[2] *Faculty of Sciences, Chouaïb Doukkali University, Av. Jabrane Khalil Jabrane, B.P. 299, 24000 El Jadida, Morocco.*

*Moussa.Bouray@um6p.ma

**ABSTRACT**

Optimized management of organic waste is essential to limit resource losses and reduce greenhouse gas emissions. The present study evaluated the efficiency of organic waste valorisation through insect farming, especially *Hermetia illucens* (black soldier fly) larvae, feed with three distinct feedstocks: food waste, bread, and a mixture of the two (70%+30%, respectively).

The results show that the mixed substrate promotes optimal larval growth, high efficiency in converting waste into biomass, and a balanced larval composition in terms of protein and lipid content. The frass derived from the mixed substrate also exhibited interesting properties for use as a soil amendment and fertilizer, particularly in terms of total nitrogen and sulfur contents. Conversely, frass obtained solely from food waste shows superior characteristics in terms of potassium, total calcium, and micronutrients — specifically Fe, Zn, Mn, and Cu — compared to the other two feedstocks.

Frass pH measurements indicate that the food waste substrate generates a significantly higher pH (around 7.2), followed by the bread substrate, while the frass from the mixed substrate presents a lower pH (~ 6.2). Regarding electrical conductivity (EC), the frass from food waste showed the lowest value, suggesting low accumulation of soluble salts, whereas no significant difference was observed between the bread and mixed substrates, both showing higher EC values (~ 10 ms/cm), almost double that of food waste.

We have also conducted a phytotoxicity test (germination test) using rye grass seeds treated with different concentration of frass extracts (0, 20%, 60% and 100%). We found that all frass-based treatments enabled the germination of ryegrass, with varying germination indices depending on the concentration applied and the type of frass used. At a 20% concentration, frass derived from the bread and food waste substrates showed germination indices above 100%, indicating potential phytostimulant activity. In contrast, frass from the mixed substrate exhibited, at the same concentration, a slightly lower germination index (around 60%), suggesting moderate phytotoxicity. At higher concentrations (60% and 100%), frass from the bread and mixed substrates showed indices below 60%, indicating high phytotoxicity. The frass obtained from the food waste substrate, however, showed no notable phytotoxicity at 60% concentration and only moderate phytotoxicity at the maximum concentration of 100%.

Principal Component Analysis (PCA) clearly reveals distinct profiles depending on the substrate used, highlighting the major impact of waste type on the nutritional and agronomic quality of the products obtained from larval composting. This work thus confirms the relevance of the black soldier fly as an attractive and innovative solution for sustainable organic waste management within a circular economy model, with significant implications for improving soil fertility and health.

## ABSTRACT

Enhancing soil organic carbon (C) sequestration is critical for improving soil health and mitigating climate change. This study explores an innovative strategy of co-composting clay materials with food waste to enhance organic C stability and reduce $CO_2$ emissions in soil. Bentonite (B) and kaolinite (K) clays were co-composted with food waste (FW), followed by a soil incubation experiment under controlled conditions. Treatments included unamended compost (FW0), bentonite-amended compost (FWB), and kaolinite-amended compost (FWK).

Results showed that clay amendments significantly reduced dissolved organic carbon (DOC) in the soil. FW0 resulted in the highest DOC, which declined in FWB and FWK after 56 days of incubation, confirming enhanced C stabilisation in clay-amended treatments. Microbial biomass carbon (MBC) was higher in FWB (~2200 mg C $kg^{-1}$) and FWK (~1350 mg C $kg^{-1}$) compared to FW0 (~750 mg C $kg^{-1}$), indicating improved microbial activity in clay-amended soils. $CO_2$ respiration rates were lower in FWB and FWK (150-160 µg $CO_2$-C $kg^{-1}$ $day^{-1}$) compared to FW0 (~207 µg $CO_2$-C $kg^{-1}$ $day^{-1}$), reflecting reduced microbial decomposition and enhanced C protection in clay-amended soils. Clay amendments also influenced nitrogen dynamics; $NH_4^+$ concentrations were elevated in soils amended with FWB and FWK, indicative of enhanced nutrient mineralisation and retention. However, $NO_3^-$ levels were not significantly influenced by clay type, highlighting a stronger influence of clay on $NH_4^+$ stability rather than $NO_3^-$ production. Soil pH was positively affected, with clay amendments (particularly FWB) increasing pH (7-8) compared to the consistently acidic FW0 treatment (4-5), suggesting improved conditions for microbial activity and nutrient availability.

Overall, clay incorporation in composts significantly enhances organic C stability by reducing DOC lability, elevating $NH_4^+$ availability, and improving soil chemical conditions, thus creating a favourable environment for microbial activity. These findings confirm the potential of clay in co-composts as effective amendments for long-term carbon sequestration, improved nutrient dynamics, and sustainable soil management.

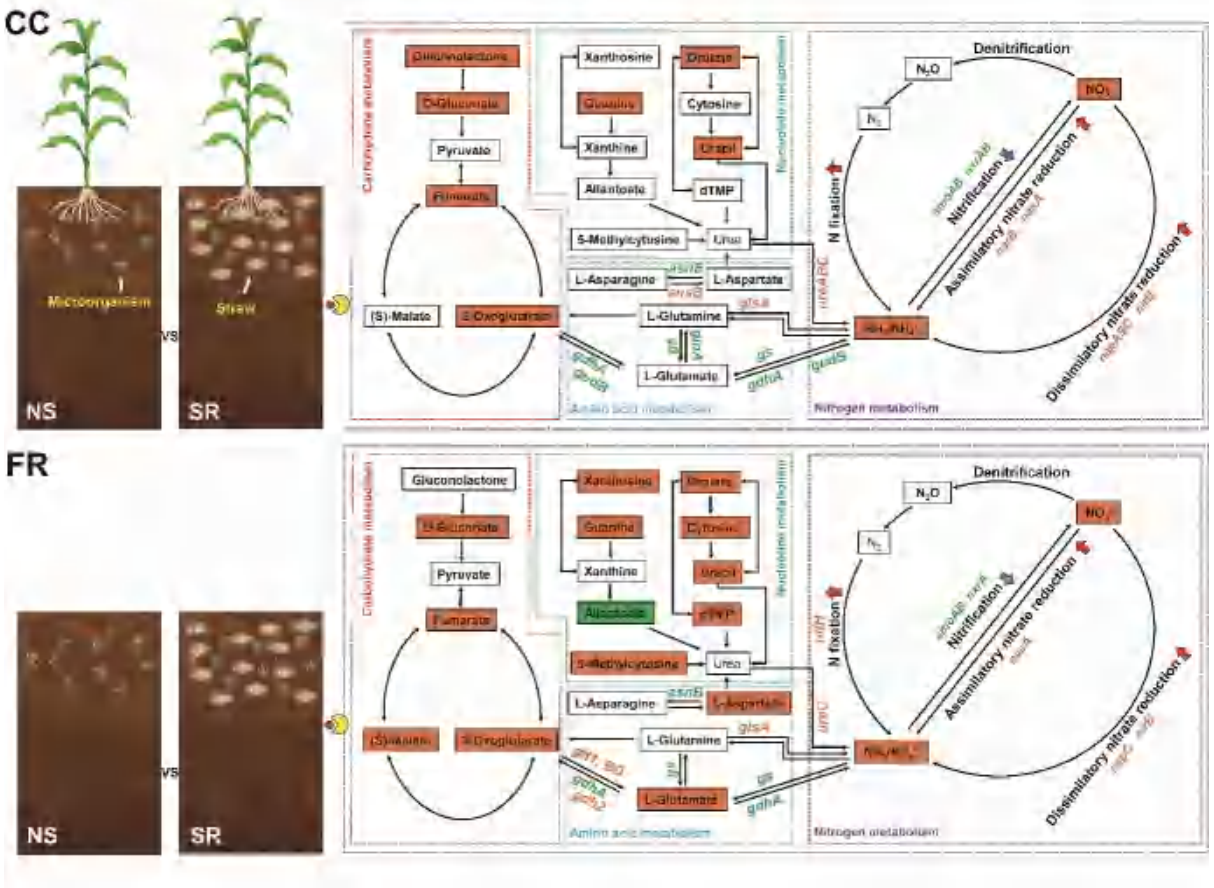
# Straw return facilitates the availability of soil nitrogen by altering the metabolic distribution and nitrogen cycling processes



**Yu Gao[1], Shihao Fu[1], Xiaotong Liu[1], Xiaomin Kang[1], Mingyue Li[1], and Chao Yan[1*]**

## ABSTRACT

Straw return (SR) has been extensively utilized to enhance soil organic carbon (SOC) levels and soil fertility in agroecosystems. However, the impact of SR on soil nitrogen (N) dynamics, microbial communities, metabolic processes, and the underlying mechanisms remains largely unexplored. Through a multi-year manipulation of SR under continuous corn cropping (CC) and fallow (FR), we demonstrate that SR promotes N availability by altering soil microbial metabolism. Moreover, SR facilitated N turnover by enhancing metabolic pathways, including arginine biosynthesis, alanine, aspartate, and glutamate metabolism, as well as glycine, serine, and threonine metabolism, and pyrimidine and purine metabolism. Additionally, SR resulted in a significant increase in the abundance of microorganisms and functional genes involved in mineralization (*glsA* and *ureC*), N fixation (*Bradyrhizobium*, *Altererythrobacter*), dissimilatory nitrate reduction to ammonium (DNRA, *Sorangium*, *napC*, and *nirB*), and assimilatory nitrate reduction to ammonium (ANRA, *nasA*). However, despite a reduction in the relative abundance of nitrification microbes and functional genes (e.g., *Nitrososphaerag*, *Nitrospira*, *Sphingomonas*, *amoAB*, *nxrA*), SR enhanced the content of extractable inorganic N and organic N in the soil. Therefore, SR represents an effective strategy to promote N dynamics and accelerate the restoration of soil fertility. Our results demonstrated that SR alters N cycling processes by modifying microbial community structure and metabolite distribution, thereby increasing soil N availability.

# Effects of straw incorporation on soil carbon and nitrogen sequestration in fallow and continuous maize cropping systems in Northeast China

**Qijian Zhang[1*], Mingxue Ye[1], Jinman Mei[1], Shuangshuang Yan[1], Xulang Zhang[1], Chao Yan[1], Chunmei Ma[1], and Zhenping Gong[1]**

[1] *College of Agriculture, Northeast Agricultural University, Harbin, China*

*zqj20@foxmail.com

**ABSTRACT**

Straw incorporation (SI) increased soil organic carbon (SOC) and total nitrogen (STN). However, the differences in soil responses between maize cropping system and fallow management system under different SI rates in the black soil region of Northeast China remain unclear. In a 6-year experiment, we examined these two systems by using round frames with five annual SI rates (0, 9.2, 18.4, 27.6, and 36.8 Mg $ha^{-1}$) to investigate their effects on soil C and N fractions and storage potential. SI significantly enhanced the SOC and STN concentrations in both maize cropping system and fallow management system. Compared to fallow, continuous maize cropping resulted in higher depletion of oxidizable organic C (EOC) and amino sugar N (ASN) but maintained greater light fraction organic C (LFOC), particle organic C (POC), and hydrolysable unknown N (HUN) concentrations in the 0-15 cm soil layer. Fallow increased the soil C:N ratio and exhibited higher average annual C and N sequestration rates (0.70 and 0.01 Mg $ha^{-1}$ $yr^{-1}$, respectively) compared to the maize cropping system. However, increasing SI rates did not significantly affect the transformation efficiency of straw-derived nutrients. Conventional SI rates in continuous maize cultivation led to soil C and N losses, while higher SI rates and fallow management effectively retained nutrients. Thus, to prevent concurrent losses of soil C and N pools under continuous maize cropping with current soil conditions in the 0-30 cm layer, an annual input of at least 6.8 Mg C $ha^{-1}$ $yr^{-1}$ and 0.2 Mg N $ha^{-1}$ $yr^{-1}$ is recommended.

# Differences in soil organic carbon accumulation caused by microbial-mediated tillage and carbon input

**Ximing Liu[1,2*], Chang Zhang[1,2], Xiaolin Li[2], Song Cheng[2], Jinyao Yan[2], Jingchao Yuan[2], Jianzhao Liu[2], Yao Liang[2],Jingkun Lu[2], Wei Fan[2], Hongguang Cai[2]**

**ABSTRACT**

Tillage and C input are considered to be important management measures to maintain the sustainable production capacity of farmland soil. However, the understanding of the further binding of fungal necromass carbon ( FNC ) and bacterial necromass carbon ( BNC ) to SOC fractions between soil layers is still limited. Therefore, we arranged the same tillage and carbon input treatments in four farmlands in Jilin Province, China, to analyze the difference and mechanism of microbial necromass carbon ( MNC ) to SOC sequestration between topsoil ( 0-20 cm ) and subsoil ( 20-40 cm ). In the topsoil, the increase of carbon input promoted the increase of soil nitrogen content and enzyme activities, and the microbial biomass carbon increased significantly, which promoted the accumulation of FNC and BNC. FNC directly promoted the formation of MAOC, and fungal and BNC together increased POC.The distribution of microorganisms to organic carbon components increased the proportion of POC in SOC, but MAOC still dominated, and SOC content increased by 5.6%, which was not limited by tillage. Different from topsoil, although tillage and carbon input reduced enzyme activity in the subsoil, due to tillage promoted the activity of bacteria such as Proteobacteria and Actinobacteriota and the synergistic decomposition and reuse of enzymes, the FNC content decreased with the increase of C input, resulting in the decrease of POC content dominated by C input. At the same time, the ability of residual carbon to bind to MAOC is weakened due to environmental changes. As a result, SOC decreases with the increase of C input after additional C input. These findings suggest that carbon sequestration in the whole tillage layer is not entirely dependent on C input, but through the comprehensive regulation of tillage, straw and organic fertilizer, higher carbon sequestration benefits of farmland soil can be obtained.

**ABSTRACT**

Biostimulants, including artificial humic acid (A-HA) and microbial inoculants, are gaining attention for enhancing soil fertility and crop growth. This study explores their combined effects on rhizosphere soil organic carbon (SOC) fractions and microbial activity. In this investigation a pot experiment of maize was carried out with six treatments, including the synergistic or independent action of artificial humic acid and microbial agents, and a control. Then soil at various growth stages were collected to determine organic carbon, enzyme activity, microorganism community structure, and the growth of the maize, which has been calculated and analysed by high throughput sequencing, principal component analysis and Shannon index to evaluate the effects of different treatments. A-HA at 200 mg/kg enhances the availability of nutrients, enzyme activity, root development and favors superior growth, better yielding capacity and increasing stability of soil carbon with microbial agents. It increases soil humification, decreases the activity of enzymes for carbon turnover at 400 mg/kg, decreases gene abundance for metabolism of nutrients, increases gene abundance for carbon fixing microbes and gene abundance of stable pathway of carbon so as to increase the active organic carbon to stable organic carbon and elevate the content of overall soil organic matter. The combined application of A-HA and microbial inoculants significantly enhanced SOC fractions and soil nutrient conditions, while stabilizing microbial community abundance in the rhizosphere. This study provides theoretical guidance for improving crop yield through practical application of these soil amendments.

**Keywords:** Artificial humic acid; Rhizosphere soil; Enzyme activities; Microbial community; Soil fertility

A-HA and microbial consortia can both evidently enhance maize growth and finally improved the mature stage yield by changing soil labile organic carbon fractions, soil nutrients and leaf photosynthesis. The results showed that the addition of A-HA and microbial agents as biostimulants in the $H_2M$ treatment group enhanced a signifi- cantly (40.49%) the level of TOC, (19.77%) the level of MBC, and (331.72%) the level of DOC than the control group. As for the content of soil nutrienst, the HM treatment group showed the greatest total nitrogen (13.81%), available phosphorus (11.25%), and available potassium (16.00%), respectively, compared to the control. Additionally, The use of A-HA and microbial consortia as biostimulants which stimulated the multiplication of bacteria with functions on soil carbon cycling, and mineralization, The result showed that, the abundance of *Gemmatimonas* bacteria was highly promoted by the $H_2M$ treatment during the maize plant jointing stage, where increased its abundance by 290.94% compared to (CK). While in the HM treatment it increased by 194.37% compared to (CK), suggesting an activation to a specific bacterial subgroup with particular traits to enhance plant performance and production. Maize Yield: The higher yield at maturity was of 28.00% (indirectly) linked to an increase of Escherichia coli abundance by 41.90%.

**olubunmi.shittu@fuoye.edu.ng*

**ABSTRACT**

Agricultural productivity is severely impeded by soil nutrient leaching, especially in tropical areas like Ado-Ekiti, Nigeria, where intense rainfall promotes nutrient loss. Soil nutrient leaching is a significant environmental and agronomic issue that impacts soil fertility, water quality, and crop yield. This study evaluate the effect of maize stover biochar (MSB) rate on selected macronutrient leaching and investigate the short-term potential impact of MSB on the soil from the Ekiti State University Teaching and Research Farm, Ado-Ekiti (EKSU-TRF), Nigeria. Pyrolyzed MSB was produced at an average of 460 °C and a leaching column experiment was conducted using soil amended with MSB at rates of 0, 2, 4, and 6 ton $ha^{-1}$, simulating rainfall over 90 days. The leachate collected and the soils sampled (before and after the experiment) were analysed to determine the pH, electrical conductivity (EC), phosphorus (P), potassium (K), calcium (Ca) and magnesium (Mg) contents. Result shows that MSB application significantly increased leachate volume, with the highest volume recorded at 6 ton $ha^{-1}$, indicating improved soil porosity and drainage. Leachate analysis revealed elevated pH (7.45-9.41), EC (0.005-0.283 *d*S $m^{-1}$), P (5.09-81.05mg $l^{-1}$), K (107.84-6348.04 mg $l^{-1}$) and Mg (62.50-135.00 mg $l^{-1}$) concentrations, with P and K leaching peaking at 60 days. The leachate volume for Ca reduced with MSB rates. Post-experiment soil analysis shows increased pH (6.20-8.35), EC (0.060-3.090 *d*S $m^{-1}$), total organic carbon (0.49-0.97 g $kg^{-1}$), total N (0.03-0.15 g $kg^{-1}$), available P (4.14-34.40 mg $kg^{-1}$), exchangeable K (0.10-1.89 cmol $kg^{-1}$), Ca (0.85-0.93 cmol $kg^{-1}$), Mg (0.34-0.87 cmol $kg^{-1}$) and water retention (1.99-16.08%) with increasing MSB rates. The MSB improved soil fertility, however, higher application rates increased nutrient leaching risks due to the soil's sandy texture. Long term biochar application on various soil types and economic feasibility is recommended.

# Organic management effect on soil characteristics: a comparison between vineyard and field crop rotation

**M. Giordano[1*], G. Raimondi[1], V. Giannini[1], A. Berti[1], and C. Maucieri[1]**

[1] *Department of Agronomy, Food, Natural Resources, Animals and Environment – DAFNAE, University of Padua, Agripolis Campus, Viale dell'Università 16, Legnaro, PD, Italy*

*maria.giordano@unipd.it

**ABSTRACT**

This study, conducted in the University of Padova experimental farm, investigates and compares the effects of long-term (20 years) organic management in two different cropping systems (vineyard *vs.* field crop rotation - FCR) on soil copper (Cu) and sulphate ($SO_4^{2-}$) accumulation, soil organic carbon (SOC) content, as well as other nutrients content (TKN, P, K, $NO_3^-$, Ca, Mg, $K_{exc}$, $PO_4^{3-}$, Fe) along the 0-40 cm soil profile. In vineyard, the fungal disease control is performed with the use of Cu and sulfur (S), and reduced tillage and inter-row cover are applied. FCR is based on annual moldboard plowing and sporadically used or not at all applied Cu and S treatments. The soil sampling was carried out in 2023 considering an area of approximately 1 ha for each cropping system. Vineyard showed the highest Cu content in both the 0-20 cm (450 kg $ha^{-1}$) and 20-40 cm (300 kg $ha^{-1}$) soil profiles, compared to both FCR layers, for which the Cu content was on average 120 kg $ha^{-1}$. Vineyard showed surface enrichment for $SO_4^{2-}$, too, while FCR soil accumulated $SO_4^{2-}$ in deeper layers, likely due to increased leaching and plow-induced movements. The surface layer of the vineyard was richer in SOC (44.1 Mg $ha^{-1}$) than the deeper layer and both FCR layers (on average 34.1 Mg $ha^{-1}$). Ca, Mg, and Fe were also higher in the top 20 cm of vineyard soil, whereas FCR accumulated higher $PO_4^{3-}$ and had a more homogeneous nitrogen distribution along the entire soil profile. The study highlighted how the two different organic management strategies can influence Cu buildup over time and the interaction with the main crops' nutrients and highlighted the possible implications for environmental sustainability.

**ABSTRACT**

This study examines the effects of various organic waste types on the soil properties in the rhizosphere of Albion strawberry plants (*Fragaria x ananassa Duch.*). Eight organic wastes were tested: Cow Manure (CM), Poultry Manure (PM), Sheep Manure (SM), Vermicompost (VC), Rice Husk (RH), Wheat Straw (WS), Tea Waste (TW), and Hazelnut Husk (HH). These were applied before transplanting the strawberries. Conducted in a controlled greenhouse, the research assessed the impact of 5% organic waste on plant growth and soil characteristics, monitoring soil moisture near field capacity over 61 days. Soil samples were analyzed for microbial biomass carbon (MBC), basal soil respiration, and enzyme activities. Results showed that tea waste significantly enhanced basal soil respiration, while wheat straw increased microbial biomass carbon. Sheep manure notably affected dehydrogenase activity, and poultry manure increased catalase activity. All treatments improved soil organic matter, with sheep manure, cow manure, and vermicompost raising nitrogen levels, while others like tea waste and rice husk decreased it. These findings highlight that diverse organic waste can enhance soil health and strawberry growth, providing valuable insights for sustainable farming practices.

# Regulation of Aggregate Nutrients and Microbial Processes by Organic Materials Incorporation to Enhance Soil Quality and Crop Yield

**Wenxiu Zou** *, Xiaozeng Han, Naiwen Zhang, Zhimin Wu

*Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin 150081, China*

* E-mail: zouwenxiu@iga.ac.cn

**ABSTRACT**

Soil aggregates serve as functional units within soil ecosystems, playing a pivotal role in nutrient storage and cycling. Long-term application of organic materials (including organic manure and crop straw) has been demonstrated to be an effective approach for improving soil structure, enhancing soil quality, strengthening nutrient sequestration, and ultimately increasing crop yield. Based on multiple long-term field experiments, this study systematically investigates the impact of organic materials incorporation on soil physical, chemical, and microbial properties at the aggregate scale, as well as crop yield. Overall, the application of organic amendments (organic manure: 15–22.5 Mg $ha^{-1}$ $y^{-1}$; straw: 2250–15000 kg $ha^{-1}$ $y^{-1}$) significantly promoted the formation and stability of >250 μm aggregates, meanwhile, pore number of >100 μm, porosity of >2 μm, and morphological characteristics (anisotropy, circularity, connectivity and fractal dimension) significantly increased, but the total number of pores significantly decreased ($P$<0.05). Dissolved organic matter concentration in soil aggregates increased by 11.8%–42.7% in organic materials incorporation treatments, and shifted in composition. Fulvic-like and humic-like components increased and protein components decreased, suggesting a transition towards microbial-derived organic matter, enhancing soil humification and bioavailability. Organic materials incorporation also enhanced the complexity of microbial co-occurrence networks within 2000–250 μm aggregate, and alleviated microbial carbon (by 0.93–2.29%) and phosphorus (by 0.80–2.94%) resource limitations. Further analysis revealed organic materials incorporation increased soil quality index in topsoil and subsoil by 18.32%–33.08% and 2.43%–16.99%, respectively. 2000–250 μm aggregates within topsoil and >2000 μm aggregates within the subsoil contributed the most to the soil organic carbon (SOC), total nitrogen (TN), and total phosphorus (TP) storage. The TP content within >2000 μm aggregates was an important predictor influencing soil carbon, nitrogen, and phosphorus stocks. Nitrogen and phosphorus stocks were important predictors influencing soil quality. Consequently, organic amendment incorporation improved the soil quality index by enhancing aggregate structure, chemical properties, and microbial activity, thereby promoting increased crop yield, with aggregates >250 μm primarily influencing this process. These findings provide valuable insights for understanding soil quality improvement at the aggregate scale and exploring effective field management strategies.

# Soil Biogeochemical Responses to Composting and Organic Waste Application Across Agricultural Systems

**Xia Zhu-Barker**

*University of Wisconsin-Madison*

zhubarker@wisc.edu

**ABSTRACT**

Municipal solid waste in the United States exceeds 292 million tons annually, with more than one-third consisting of organic materials such as food and green waste. Yet only ~20 percent of these materials are composted, and most still enter landfills, where they contribute substantially to methane emissions and generate leachates and volatile organic compounds. As state-level restrictions on landfilling organic waste expand, there is growing interest in management strategies that both improve soil function and reduce environmental impacts. However, key uncertainties remain regarding how composting and direct land application of uncomposted organic materials influence nitrogen transformations, nitrous oxide ($N_2O$) emissions, and nitrate leaching across diverse soil conditions.

This study integrates field monitoring, laboratory incubations, and $^{15}N$ tracer experiments to evaluate how composting systems, compost amendments, and uncomposted green-waste applications regulate soil biogeochemical processes. Multi-season observations show that managed composting windrows emit both $CH_4$ and $N_2O$, but at substantially lower greenhouse gas intensities compared with landfilling. Seasonal contrasts highlight the central role of oxygen availability: winter piles with limited aeration generated elevated $CH_4$, whereas summer piles under warm, oxygenated conditions produced more $N_2O$. These patterns underscore the importance of moisture control, feedstock porosity, and turning frequency in mitigating emissions during composting.

Across soil textures and compost types, $^{15}N$ tracer experiments demonstrated that compost amendments consistently reduced cumulative $N_2O$ emissions relative to mineral fertilizer, with the proportional contributions of compost-, soil-, and fertilizer-derived N varying by nitrogen form and texture. In contrast, surface application of uncomposted green waste significantly increased $N_2O$ emissions compared with incorporation, despite similar nitrate leaching responses. Laboratory incubations further revealed that green waste accelerates oxygen consumption, altering $N_2O$:$N_2$ ratios and enhancing gaseous nitrogen losses when left at the soil surface.

Together, these findings highlight organic waste as a valuable but under-utilized resource for improving soil carbon and nutrient cycling, while emphasizing management-dependent tradeoffs for greenhouse gas mitigation. Strategically integrating composting with informed application practices—particularly soil incorporation of uncomposted materials and optimized windrow aeration—advances climate-smart soil management and supports a more circular bioeconomy.

# Partial organic substitution enhances ecosystem services in agricultural soils

**Quan Tang[1*], Jun Shan[2], Yongqiu Xia[2], Chaopu Ti[2] and Xiaoyuan Yan[2]**

[1] *College of Environmental Science and Engineering, Yangzhou University, Yangzhou, China*

[2] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*E-mail: qtang@yzu.edu.cn

## ABSTRACT

Ensuring global food security while minimizing environmental impacts necessitates a transition towards sustainable agricultural practices, such as partially substituting chemical fertilizers with organic amendments. Although numerous studies have documented the effects of partial organic substitution on crop yield, environmental footprints, and microbial community structure, comprehensive assessments of how it influences soil ecosystem multifunctionality and the underlying microbial mechanisms remain limited. Crucially, the temporal dynamics of microbial communities in response to these practices and their role in mediating trade-offs and synergies among ecosystem services are poorly understood.

This study investigated the effects of partial substitution of chemical nitrogen (N) fertilizer with organic amendments in a vegetable production system. Treatments included: zero-nitrogen control, conventional chemical fertilization, and substitutions of 25% or 50% of chemical N with either pig manure or sewage sludge compost. We evaluated impacts on crop yield and quality, soil fertility, greenhouse gas and reactive N (Nr: $NH_3$ volatilization, N leaching and runoff) releases. An economic cost-benefit analysis integrated these aspects to assess overall ecosystem service value.

Key findings revealed that organic substitutions enhanced multiple ecosystem services. It significantly increased vegetable yield by 37.1-47.1% and improved quality, thereby boosting provisioning services. Critically, organic substitutions transformed the system from a carbon source to a sink, enhancing regulating services through a 28.6-43.3% reduction in greenhouse gas emissions and a 19.9-39.8% decrease in Nr losses. Economic analysis demonstrated that despite higher initial input costs, organic substitutions, particularly 50% pig manure, yielded the highest net economic benefit per unit area and yield, largely due to mitigated environmental cost.

The enhanced ecosystem multifunctionality was linked to reshaped soil microbial communities. Organic substitutions significantly increased soil pH, total N, SOC, and extracellular enzyme activities related to C, N, and P cycling. Notably, it elevated the abundance of the $N_2O$-reducing gene more than $N_2O$-producing genes, explaining the reduced $N_2O$ emissions. Microbial communities exhibited significant temporal dynamics, with divergence increasing over time. Ecological network analysis confirmed that organic substitution enhanced the complexity and positive interactions within bacterial-fungal networks. These microbial changes are pivotal mechanisms driving the observed enhancement of soil ecosystem multifunctionality.

This study provided a holistic perspective on recycling organic wastes into agriculture, demonstrating that partial substitution is a strategy capable of synergistically enhance productivity, economic benefits, and environmental performance by fostering a functional and resilient soil microbiome. The research highlights the critical role of managed microbial communities in achieving climate-resilient, circular nutrient economies, aligning with the global need for sustainable soil management.

**ABSTRACT**

Organic farming and the use of organic amendments are widely recognized as sustainable strategies to minimize environmental footprints in agricultural production. However, improving nutrient use efficiency and obtaining higher yields remain key challenges in organic cropping systems. To explore the best practices to optimize the management of organic inputs in organic systems, a long-term experiment CROPSYS, was established in Denmark in 1997. The experiment includes three cropping systems growing similar crops: a conventional rotation (CGL) receiving mineral fertilizers including three cereal crops and lupine-barley intercrop as a grain legume, and two organic rotations with either N-fixing grain legume (OGL), or grass-clover as green manure (OGM). The organic systems were with or without the application of digested manure. The three systems were also designed with and without cover crops. Here, we will present the results from the latest 4-year rotation cycle (2019–2022) together with a historical overview, and share the innovative use of grass-clover-based digestate from biogas production as a renewable green manure in Denmark. The results showed that the inclusion of a green manure crop increased the yields of subsequent crops (spring wheat and winter rye) in organic systems, whereas it had a higher risk of nitrate leaching. Cover crops had slight effects on crop yields but significantly reduced nitrate leaching in both organic and conventional systems. To maximize clover's value, it was used to produce bioenergy (biogas), and the digestate was in turn applied to the field as biofertilizer. By exploring the innovative use of plant-based fertilizer, we are optimizing Danish organic cropping systems to improve nutrient use efficiency and narrow the yield gaps compared to conventional systems, while reducing climate impact.

# Torrefied biomass (biotorr) as soil amendment: insights from multivariate and temporal analysis

**Julia Queiros Vieira[1,2*], Lucas Lesaint[1,3], Maya Kheir[2], Cornelia Rumpel[3] and David Houben[1]**

[1] *AGHYLE UP 2018- C101, UniLaSalle, Beauvais, France*

**ABSTRACT**

Understanding soil-plant nutrient dynamics over time under different management practices is critical for developing sustainable agroecosystems. Torrefied biomass (biotorr), an intermediate thermally treated product between raw straw (RS) and biochar, may combine the advantages of both materials, i.e., stimulate microbial activity while enhancing soil C sequestration. Yet, most studies focus on biochar and RS, and little is known about biotorr effects on plant growth and soil nutrient dynamics. This knowledge gap limits the development of strategies that promote sustainable nutrient management. To address this challenge, we conducted a four-month pot experiment in a greenhouse using Italian ryegrass (*Lolium multiflorum* Lam.) as a test crop. The effects of biotorr on plant growth and nutrient allocation across successive harvests were explored, along with their impacts on soil properties. Treatments included two types of biotorr (230°C and 280°C) and a biochar (400°C), all produced from the same feedstock (rapeseed stalks), as well as RS, mineral fertilizer (NPK), and untreated soil (control). Organic amendments were applied at a rate of 10 t $ha^{-1}$. Plant traits (height, biomass, and shoot concentrations of N, P, and K) were measured and used to calculate nutrient uptake, N use efficiency, and the N/P ratio. Soil properties were assessed at the final harvest and included pH, total N, available P and K, and total organic C concentrations. Multivariate and univariate analyses were applied to capture plant-soil trait interactions and treatment effects. Plant responses were treatment-specific at the first harvest but converged by the final one, with responses more linked to soil chemistry, where soil pH emerged as the most influential factor. Biotorr at 230°C significantly increased soil pH, while biotorr at 280°C enhanced total organic C compared to the control. Both biotorr types and biochar enhanced soil nutrient pools compared with treatments NPK and control. Fertilizer equivalence coefficients indicated biotorr at 230°C and biochar achieved up to 13% and 20% of NPK efficiency in biomass production at maturity, respectively. The results suggested a temporal shift in the drivers of plant-soil nutrient dynamics, implying that strategies targeting nutrient efficiency should prioritize early-season interventions to support growth and late-season adjustments to balance nutrient levels. These findings highlight biotorr's dual role as a complementary amendment to mineral fertilization, enhancing nutrient cycling and improving soil quality.

## ABSTRACT

Tea (*Camellia sinensis*) is a typical leaf-harvested economic crop, its growth and quality are largely determined by nutritional elements and specialized metabolites. Appropriate organic fertilization enhances beneficial microbial recruitment and optimizes rhizosphere microecology by supplying organic carbon and trace elements, thereby improving nutrient transformation and utilization. Tuna meal (TM), a major byproduct of the Japanese seafood processing industry, is rich in proteins and amino acids. After composting or other appropriate treatments, TM can be effectively utilized as a high-quality organic fertilizer in agricultural production. In this study, we examined changes in soil nutrients, rhizosphere bacterial communities, and tea shoot quality under different TM application ratios. Through integrated analyses, we elucidated the soil–microbe–plant interactions underlying the improvement of tea quality induced by TM application.

*Materials and Methods*— Tea seedlings (‘*Yabukita*’) were transplanted into Wagner pots (capacity: 1/5000 a; two plants per pot) and cultivated in a greenhouse at Shizuoka University (Shizuoka, Japan) in March 2025. The soil was reddish loess, and the TM fertilizer was supplied by Izugawa Feed Company (Shizuoka, Japan). The experiment included no-fertilizer and NPK controls, along with 25%, 50%, 75%, and 100% TM treatments, while maintaining equal total nitrogen input across treatments. Samples collected included rhizosphere soil, bulk soil, and new shoots. Soil physicochemical properties and bacterial communities were analyzed, and nutrient compositions in the aboveground tissues (including free amino acids (FAA), catechins, caffeine, and mineral elements) were quantified.

*Results*— (a) Soil nutrient analyses showed that different TM ratios significantly affected rhizosphere soil physicochemical properties. Soil pH remained within the acidic range suitable for tea growth (4.2–4.8) across all treatments. Electrical conductivity (EC) was highest under the 25% TM treatment. Potassium and inorganic nitrogen ($NO_3^-$-N and $NH_4^+$-N) reached their highest levels under the 25% and 50% TM treatments.
(b) Microbial community analysis identified *Proteobacteria*, *Actinobacteria*, *Chloroflexi*, and *Bacteroidota* as dominant bacterial phyla. Redundancy analysis demonstrated that fertilization markedly altered soil properties and bacterial community composition. Key environmental factors associated with bacterial variation included sodium, calcium, magnesium, and nitrate, while potassium and total nitrogen also contributed to community structuring. (c) Tea shoot quality analysis revealed that total FAA and caffeine were highest under the 25% and 50% TM treatments, whereas catechin levels increased progressively with higher TM proportions. Mantel tests further identified significant correlations between soil nutrients and tea shoot quality, between bacterial community structure and FAA, and between bacterial diversity and both caffeine and certain mineral elements.

Overall, moderate TM application enhances soil nutrient status and shapes rhizosphere bacterial communities, thereby promoting the accumulation of quality-related metabolites in tea shoots. These findings provide new insight into the mechanisms through which TM improves tea quality via soil–microbe–plant interactions and support its sustainable use as an organic fertilizer in tea cultivation.

# Fractions of Phosphorus in Broiler Litter and its Fluxes in the Vadose Zone of a Transitioning Organic Farming System

**K* Kpomblekou-A**

Department of Agricultural and Environmental Sciences, Tuskegee University, Tuskegee, AL 36088,

United States

kkpomblekou@tuskegee.edu

**ABSTRACT**

Alabama ranks second in broiler production in the United States, with an estimated annual production of over one billion birds and 1.5 to 2 million tons of broiler litter (BL). This BL (a waste) has been used in organic farming systems to supply phosphorus (P) for plant growth. Continuous applications of BL to soil have contributed to surface and groundwater contamination. Research work conducted in our laboratory has demonstrated that application of BL to soil increases organic and inorganic P contents of soil solutions. Transformations of the added organic P to soil affect P transport in the vadose zone. The objectives of the present studies were to investigate P transformations in BL-amended soils and to assess P fluxes in the vadose zone of a transitioning organic farming system. Suction lysimeters were installed on experimental plots located on a Marvyn sandy loam soil (fine-loamy, kaolinitic, thermic Typic Kanhapludults) at George Washington Agricultural Experiment Station at Tuskegee University with three lysimeters on each experimental unit at 30, 60, and 90 cm depths to allow for periodic water sampling. The pH of the water collected at each sampling occasion was measured and the volume recorded in the field, placed in an icebox, transported to the laboratory, and kept in a freezer until analysis. A portion of the water sample was filtered through a membrane filter (0.45 µm) and an aliquot analyzed for dissolved reactive P by direct colorimetry. Acid-hydrolyzable P following $H_2SO_4$ hydrolysis of the sample was determined in aliquots of filtered and unfiltered samples and total P was determined after ammonium persulfate digestion. Phosphorus in the water sample or in the acid digest was determined by the heteropoly blue colorimetric method as described by Murphy and Riley. Results showed that, before application of the fertilizers, the dissolved reactive P was the most dominant fraction of P in the water samples and varied between 0.05 and 0.28 mg $L^{-1}$ while the dissolved acid-hydrolyzable ranged between 0 and 0.10 mg $L^{-1}$, and the total organic P between 0.02 and 1.65 g $L^{-1}$. Application of fertilizers changed P dynamics in soil water solution, but inorganic P remained an important fraction of P found beyond the rooting zone of sweet potato. Understanding P dynamics in the vadose zone is a prerequisite to designing strategies to improve P nutrition and to prevent surface and groundwater pollution.

# Agronomic and Environmental Effects of Straw Incorporation in the Rice–Wheat Rotation Region of the Yangtze River Delta: Research and Application Demonstration

## ABSTRACT

The Yangtze River Delta is a major rice–wheat rotation region in China. Straw incorporation is a critical pathway for the rapid recycling of crop residues, sustained improvement of soil fertility, and regional yield enhancement. Previous studies indicate that long-term straw incorporation increases soil organic matter (SOM) by 14–68%, available phosphorus and potassium by 2–3 times, and inherent soil productivity by 20–34%. However, systematic research is lacking regarding straw decomposition characteristics, SOM accumulation drivers, and environmental risk mitigation across different seasons and regions. The insufficient integration of these key technologies has constrained the large-scale adoption of straw incorporation strategies that balance rapid fertility improvement with environmental protection.

To address this, we established a province-wide monitoring network and clarified that soil, climate, and water resources are the main drivers of the agronomic and environmental responses to straw incorporation. We quantified the spatial distribution of straw under different incorporation modes, developed biological products to accelerate straw decomposition, elucidated the mechanisms of bioaugmentation-enhanced humification, and developed an integrated model for constructing a fertile plow layer via straw incorporation at optimal depths.

The results are as follows: Straw incorporation—particularly deep plowing—showed clear yield-increasing potential. In the wheat season, deep plowing significantly increased grain yield by 5–14%. Compared to rotary tillage and straw removal, deep plowing increased the tillage layer depth by 6–8 cm and SOM storage by approximately 26.5 t $ha^{-1}$, demonstrating a substantial advantage in building soil organic carbon stocks. Deep straw incorporation markedly promoted wheat root development, enhanced tolerance to drought and cold, and led to an additional average yield increase of over 8%. Furthermore, it significantly reduced the risk of non-point source pollution from surface runoff, decreased greenhouse gas emissions by 12.6%, and markedly lowered the incidence of pests, diseases, and weeds compared to rotary tillage.

Overall, deep straw incorporation in both seasons is the optimal practice. However, considering the tight turnaround time between wheat harvest and rice transplanting, potential delays caused by deep plowing, and increased equipment costs, we propose region-specific incorporation strategies. These comprise three modes: eco-economic balance, priority on carbon sequestration and soil improvement, and priority on environmental protection. Large-scale demonstration zones have been established for each mode.

# The Influence of Organomineral Fertilizers and Biopreparations on Yield, Fruit Quality, and Soil Microbiological Properties under Golden Delicious Apple Orchards in Irrigated Light Chestnut Soils of Southeastern Kazakhstan

**Aigul Zhapparova[1], Maira Kussainova[1,2,3]*, Saule Maulenova[1], Khaiyrnisa Aisakulova[4]**

**ABSTRACT**

This study investigates the effects of mineral and organomineral fertilization systems on the yield, fruit quality, and soil microbiological properties of Malus domestica cv. Golden Delicious grown in irrigated light chestnut soils of southeastern Kazakhstan (Omasheva et al., 2018). Field trials (2021–2025) were conducted on 3–4-year-old trees grafted on MM106 and M9 rootstocks. The experimental design included a control (no fertilizers), a mineral background ($N_{90}P_{90}K_{90}$) (Yefremova et al., 2023), and combinations of NPK with biopreparations (Agroflorin, Al Karal, BioSok Energy Plus) and vermicompost (Nasiyev et al., 2022; Maulenova et al., 2025).

Organomineral treatments increased yields by 39–64% relative to the control. The highest productivity (up to 295 c/ha) and longest storage life (up to 6 months) were achieved with NPK + vermicompost and NPK + BioSok Energy Plus. Fruit quality improved substantially: sugar content increased by 0.5–1.9%, and dry matter by 0.8–1.5%, compared with the control.

Rhizosphere microbiological analyses showed notable increases in ammonifying and nitrogen-fixing bacteria (Azotobacter), Pseudomonas spp., amylolytic forms, and microscopic fungi under organomineral treatments. These shifts indicate enhanced soil biological activity, improved nutrient cycling, and greater biological fertility.

The results demonstrate that organomineral fertilizer systems combined with biopreparations effectively enhance productivity and fruit quality in Golden Delicious orchards while strengthening soil microbiological functioning in irrigated light chestnut soils. Such systems represent a promising strategy for biologized and sustainable orchard management in arid and semi-arid regions of Kazakhstan.

## ABSTRACT

Various organic fertilizers have been widely applied in tea gardens in recent years, which could mitigate soil acidification and other negative effects caused by chemical fertilizer overuse. However, this remains an empirical agricultural practice, and there are still many unknowns about the actual effects including soil microbial ecosystems. In this study, we investigated the dynamics of soil microbial community and tea quality in tea gardens under long-term rapeseed cake and cow manure fertilization.

Three treatments were applied: (1) conventional fertilization (CK; 40 g $N \cdot m^{-2} \cdot yr^{-1}$), (2) organic fertilization with cow manure and rapeseed cake at a standard nitrogen rate (OF1; 40 g $N \cdot m^{-2} \cdot yr^{-1}$), and (3) organic fertilization with a higher nitrogen input (OF2; 56 g $N \cdot m^{-2} \cdot yr^{-1}$). Soil and leaf samples were collected over five consecutive months (December to April next year). This phase of the study builds on eight years of continuous field trials with fixed-position fertilization at our research site.

The results showed that organic fertilization significantly increased soil pH, total carbon, total nitrogen, exchangeable $Ca^{2+}$ and $Mg^{2+}$, demonstrating its ability in mitigating soil acidification and improving soil fertility. Organic fertilization also significantly altered soil microbial communities. Soil bacterial diversity was significantly higher than under conventional fertilization, while fungal diversity was lower. Meanwhile, for soil bacteria, soil pH and some exchange cations (K+, Mg2+, Ca2+) were positively related to the bacterial diversity and the abundance of soil phyla Bacteroidota, Patescibacteria, and Gemmatimonadota. For soil fungi, soil pH, NH4+-N, AP, Exch-Ca2+, and Exch-K+ were negatively related to the fungal diversity and phylum Ascomycota. Besides, a total of 8 phyla and 38 families were identified as key bacterial communities, and 8 families were identified as key fungal communities. About co-occurrence networks, the soil bacterial networks exhibited greater complexity, and the associations among soil bacteria were more interconnected under organic fertilization than in the fungal networks. In addition, the content of total FAAs in OF1 and OF2 was significantly higher than that in CK, and the content of total catechins in OF1 was significantly higher than that in OF2 and CK. In mature leaves, the mineral contents were influenced by both fertilizer management and sampling month. These findings suggest that organic fertilization can effectively mitigate soil acidification and improve tea quality by regulating soil microbial communities.

# The stability of softwood biochars and their impact on nitrogen retention in contrasting boreal soils over 14 years

## ABSTRACT

Biochars as soil amendments have been reported to fix carbon and, in some cases, also improve soil ammonium ($NH^{4+}$) and nitrate ($NO^{3-}$) retention. However, biochar added to fields undergoes physicochemical changes and spatial migration under long-term environmental influences. Knowledge gaps remain regarding how biochar's nitrogen retention capacity changes over time and its migration patterns in the soil profile. We targeted these gaps by studying two long-term biochar field experiments in Finland where biochar was applied to soils (Stagnosol and Umbrisol) in 2010 and 2011, respectively. Firstly, we studied whether biochar was moving downwards in the soil profiles, from the 0-10 cm depth where it was originally applied to, and whether this movement was related to the soil type. Secondly, we tested whether the migrated biochar contents could explain N (especially $NO^{3-}$) contents across the soil profiles and thus provide $NO^{3-}$ retention capacity even in deeper soil layers long time after soil biochar soil application. We analyzed soil samples collected from 0–50 cm depth and divided these into 10 cm deep layers for analysis.

Results showed that in the Stagnosol field, the mean $NO^{3-}$ retention content in biochar-treated samples (9.16 mg $kg^{-1}$) was higher than that in control samples (7.14 mg $kg^{-1}$) at 10–20 cm depth, suggesting a trend toward a persistent effect of biochar on $NO^{3-}$ retention 14 years after application. Further characterization of biochar content and properties using benzene polycarboxylic acid (BPCA) molecular markers revealed that biochar remained present in soil after 14 years. In both fields, black carbon exhibited a downward leaching trend after 14 years. However, the downward migration extent of biochar varied between the two soil types. In the Stagnosol soil, the biochar content in the treated soil had migrated down to 30 cm depth, and the concentration at this depth remained significantly higher than the control. In contrast, in the Umbrisol soil, the difference in BC content between the treated and control groups became non-significant below the 20 cm depth. In the Stagnosol soil, clay content was significantly negatively correlated with biochar content ($p$=0.018), while no such correlation was found in Umbrisol soil. This suggests a contrast in retention mechanisms in both soils. In the Stagnosol soil, the clay fraction failed to provide effective stabilization and protection for BC in the main retention zone. Conversely, in the Umbrisol soil, BC retention is more likely governed by binding into stable aggregates with other soil components, which is independent of clay content. The study demonstrates that biochar can be preserved long-term in soil while maintaining $NO^{3-}$ retention capacity, reducing nitrogen loss, which has important implications for sustainable nitrogen fertilizer management.

# Effect of Biochar from Spent Media Growth on Kimchi Cabbage Cultivation in Upland Area

## ABSTRACT

The expansion of greenhouse horticulture and the advancement of controlled environment agriculture, including smart farming systems, have increased the generation of by-products and spent growing media in South Korea. This study evaluated the feasibility of converting these discarded media into biochar for use as an organic fertilizer. Spent growing media collected from a smart farm were dried and pyrolyzed at 400°C for 2 hours to produce spent growing media biochar (SGMB). The SGMB exhibited the following chemical characteristics: pH 10.2, total nitrogen (T-N) 1.24%, and total phosphorus (T-P) 0.33%. A cultivation experiment using kimchi cabbage (*Brassica rapa var*. glabra) was conducted under a randomized complete block design with four treatments and three replications. The treatments included a control (CN), inorganic fertilizer (IF; N–P–K = 300–78–198 kg ha$^{-1}$), and two biochar treatments, SGMB3 (3 t ha$^{-1}$) and SGMB5 (5 t ha$^{-1}$). The highest plant height was observed in SGMB3 (21.4 cm plant$^{-1}$) and SGMB5 (21.3 cm plant$^{-1}$), while the greatest leaf width, head diameter, and fresh weight were recorded in IF (12.5 cm plant$^{-1}$, 38.0 cm plant$^{-1}$, and 1453 g plant$^{-1}$, respectively). Although overall kimchi cabbage growth in SGMB treatments was slightly lower than that in IF, nitrogen use efficiency and soil chemical properties improved, and nitrous oxide emissions decreased. These results indicate that SGMB can enhance soil fertility and contribute to sustainable crop production as an organic fertilizer. Further studies should assess the long-term effects and optimal application rates of SGMB on crop performance and environmental outcomes.

*kangsw@scnu.ac.kr

**ABSTRACT**

This study investigated the effects of chicken manure biochar (CMBC) application on the growth of kimchi cabbage (*Brassica rapa ssp*. pekinensis), nitrogen use efficiency (AE_N, agronomic efficiency of nitrogen; ARF_N, apparent recovery fraction of nitrogen), and nitrous oxide ($N_2O$) emissions in upland soil. Chicken manure and woody biomass were mixed at a ratio of 80:20 (w/w) and pyrolyzed at 400°C for 2 hours to produce CMBC. The experimental treatments consisted of a control (CN), an inorganic fertilizer treatment (IF; N 320 kg $ha^{-1}$, P 78 kg $ha^{-1}$, K 198 kg $ha^{-1}$), and three biochar treatments with CMBC applied at 3, 5, and 7 t $ha^{-1}$ (CMBC3, CMBC5, and CMBC7, respectively). Increasing CMBC application generally improved soil pH, electrical conductivity (EC), organic matter (OM), available phosphorus (Avail. $P_2O_5$), total nitrogen (TN), and cation exchange capacity (CEC). Kimchi cabbage growth also responded positively to CMBC, with fresh weight progressively increasing from 904 to 1,244 g $plant^{-1}$ for CMBC3 to CMBC7. The highest head height (23.2 cm $plant^{-1}$) was observed in CMBC7, and the overall growth performance followed the order IF > CMBC7 > CMBC5 > CMBC3 > CN. Nitrogen uptake increased with higher nitrogen inputs, with the highest uptake in IF (8.82 g $m^{-2}$), followed by CMBC7, CMBC5, CMBC3, and CN. Among the biochar treatments, CMBC7 achieved the greatest nitrogen use efficiency, with AE_N of 8.88 kg N $ha^{-1}$ and ARF_N of 26%. Both CMBC3 and CMBC5 showed higher nitrogen use efficiency than IF, indicating that CMBC enhanced nitrogen use by the crop. $N_2O$ emissions were highest in IF, decreased by 72.1%, 63.6%, and 59.2% in CMBC3, CMBC5, and CMBC7, respectively, with lower nitrogen application rates associated with reduced $N_2O$ release. Overall, CMBC application improved soil fertility, enhanced nitrogen use efficiency, and mitigated $N_2O$ emissions during kimchi cabbage cultivation. The optimal response was observed at 7 t $ha^{-1}$, suggesting that CMBC represents a promising organic amendment for sustainable crop production. Further research is needed to assess higher application levels and the long-term environmental implications of CMBC use in upland agroecosystems.

**ABSTRACT**

The circular economy is presented as a production and consumption model that involves sharing, renting, reuse, repair, and renewal. In the sisal sector, approximately 4% is used for the commercialization of the fiber (currently the main product sold), while the remaining 96% are byproducts characterized as defibration residues with 15% mucilage (cuticle + palisade and parenchymatous tissue), 1% sponge (short fibers), and 81% juice. These data demonstrate a potential utilization of 96% of the byproducts derived from sisal fiber production (Ferraz-Almeida et al. 2025). This study developed tests with the organic substrate "AgaveFert," based on sisal waste, for the production of sisal seedlings at the State University of Bahia. The system was established in a randomized block design, using 5 replications with 6 treatments: 2, 4, 6, 8 and 10 liters of substrate, and the control (without residue). Residues derived from sisal were collected in the Conceição do Coité region, on 10 different properties with varying soil management practices, to understand the quality of the residues for mixture formation. Results showed that plant mass of the aerial and root parts was greater with the application of sisal solid residues, comparing all doses with the control. The control presented a total plant mass (aerial and root) of 29.7 g/plant, as well as an average root and aerial system mass of 25.4 g/plant and 4.3 g/plant, respectively. The highest average total plant mass (aerial and root) was observed with the application of 12 liters of solid sisal waste, with an average of 247 g/plant, as well as with the application of 4 and 8 liters of solid sisal waste, with averages of 209.0 and 206.9 g/plant, respectively. The application of sisal solid waste promoted the aerial and root development of sisal plants, compared to soil without the application of sisal waste. Among the doses, it was not possible to identify the optimal dose, with a high variation between the doses of sisal solid waste, without a clear linear or quadratic behavior and an $R^2$ value less than 70%. This result indicates that there was no clear increase in plant production (linear or quadratic) with the application of sisal solid waste. Based on the results, it is concluded that the application of sisal solid waste is indicated, increasing the production of leaves and roots of sisal seedlings. Future studies are recommended with a greater variation of high and low doses to better identify the effect of solid waste on the development of sisal seedlings.

## ABSTRACT

**Background:** Long-term evaluation of soil nutrient dynamics under organic management is essential for understanding how sustained amendments influence crop performance, soil fertility, and agroecosystem resilience. In paddy soils, where anaerobic conditions, organic inputs, and nitrogen transformations interact in complex ways, monitoring multi-year changes provides critical insights into nutrient availability and the sustainability of rice production systems. For understanding long-term organic manure application on rice growth, this study investigates eight years of rice biomass production, soil organic carbon (SOC), total nitrogen (TN), and the carbon-to-nitrogen (C/N) ratio changes, a pot experiment with precise management was conducted at Tsuruoka campus, Faculty of Agriculture, Yamagata University, Japan, spanning from 2018 to 2025.

**Material and Method:** The experimental soil was collected from a long-term organic manure field in the Takasaka University Farm, Yamagata University, Japan. The field was applied heavy organic manure at 40 t $ha^{-1}$ more than 20 years. Four treatments were set up in this pot experiment. 1. Continued application organic manure at 40 t $ha^{-1}$ (40T); 2. Decreased the organic manure to the half at 20 t $ha^{-1}$ (20T); 3. Stop organic manure application (0T) and 4. No rice growth and no organic manure application (NP). Each treatment had 4 replications. The rice (Haenuki) was transplanting in the treatment pots excepted NP on end of May and harvested on the end of September, every year. Small size of soil samples also taken from the pots every year after harvest.

**Result:** As the results show, ear and aboveground biomass were highest in 2018, followed by a sharp decline in 2019, after which they remained low and relatively stable from 2020. Throughout most years, the 0T treatment produced higher rice biomass than the 20T and 40T manure treatments. This pattern is attributed to early-stage nitrogen immobilization, where microbes decomposing manure temporarily reduced plant-available nitrogen. Aboveground biomass showed a sharp decline after the high initial values in 2018, with all treatments dropping by 2019 and remaining low in 2020-2023. By 2024–2025, manure treatments, especially 40T, continued to show gradual improvement, where 0T consistently stayed lower, showing a long-term transition from early nitrogen immobilization to more favourable nitrogen mineralization in later years. Similarly, the harvest index was highest in 2018 across all treatments, followed by a decrease in 2019–2020. From 2024 to 2025, the harvest index remained relatively stable, with modest differences among treatments, showing that the balance between grain yield and aboveground biomass became more consistent as the system stabilized over time. Soil depth also decreased across treatments from 2018 to 2020, with 40T, 20T, 0T, and NP each showing a sharp drop after the initial year. In 2022, 40T and 0T showed slight increases in soil depth, while 20T and NP remained lower, reflecting differences in soil settling and the stabilizing effects of organic inputs. From 2023 to 2025, soil depth gradually stabilized, with 40T maintaining the greatest depth, 20T showing moderate recovery, 0T continuing a mild decline, and NP remaining the lowest, indicating that higher manure rates helped preserve soil volume over time.

**Conclusion:** Overall, the 0T treatment produced the highest aboveground biomass and often the highest harvest index, manure levels of 20T and 40T frequently resulted in lower early-year values, likely due to nitrogen immobilization during initial years of organic input. Despite these fluctuations, long-term trends show gradual improvement in both biomass and harvest index toward the later years of the experiment. The SOC and TN results will be shown in the congress presentation.

**ABSTRACT**

Poor soil fertility is a major constraint to food production in Nigeria. The use of agro-waste as organic amendment is sustainable, and a panacea to improving soil fertility and crop yield. This work was carried out in 2024 and 2025 to evaluate the characteristics of fermented saw dust-bokashi (SDB) and its effects on soil properties and the performance of pepper. The fermentation process lasted for 12 days, during which, temperature, pH, moisture, and bulk density were monitored. Fermented SDB was applied on day 13. Six pot treatments were tested: control, 0.8 t $ha^{-1}$ NPK, and bokashi at 15, 18, 21, and 24 t $ha^{-1}$. The treatments were arranged in a completely randomized design (CRD), with three replications. Chemical properties of fermented SDB, as well as pre and post-planting soil attributes, were analyzed. Growth and yield parameters of pepper were measured. The data generated from the effects of the various treatments on soil and plant performance were analyzed using Analyses of Variance (ANOVA) while those from fermented and unfermented bokashi were analyzed using T-test. Significant means were separated using LSD at 5% probability. Results revealed changes in temperature (30.38°C to 51.79°C), pH (7.00 - 9.12), and moisture (27.00% to 57.00%) during fermentation. 12 weeks after treatment application, results showed that the application of bokashi significantly improved soil pH (5.45 to 6.65), organic carbon (0.96% to 2.94%), total nitrogen (0.19% to 0.26%), and available phosphorus (20.58 $mgkg^{-1}$ (control) to 38.66 mg $kg^{-1}$ in 24 t $ha^{-1}$ bokashi. Exchangeable calcium (Ca), magnesium (Mg), potassium (K), and sodium (Na) also increased significantly across treatments, with the highest values observed at the 24 t $ha^{-1}$ bokashi rate. Between 2 and 4 weeks after transplanting (WAT), the unfertilized soils had significant higher plant growth parameters. From 8 WAT onward, bokashi-treated soils generally produced the highest growth parameters with 15 t $ha^{-1}$ and 21 $tha^{-1}$ bokashi rates giving the best performance. The highest number of pepper fruits was also recorded in 15 and 21 t $ha^{-1}$ bokashi rates. The study showed that amending degraded soil with bokashi improved the soil pH, fertility, growth and yield of pepper and these improvements manifested more when 15 $tha^{-1}$, 21 t $ha^{-1}$ and 24 t $ha^{-1}$ were applied. In addition, the study revealed the potential of SDB as a superior alternative to conventional fertilizer.

**ABSTRACT**

Viticultural waste streams, such as grape marc and vineyard prunings, pose ongoing environmental and economic challenges for New Zealand's wine industry. Transforming these waste materials into compost or biochar offers a promising circular solution that can simultaneously reduce waste volumes and provide valuable soil amendments. Our research sought to test the potential of compost and biochar produced from organic vineyard waste to improve clay soil properties and support the establishment of native plants in New Zealand.

We established a field trial at a vineyard in the Waipara wine-producing region in April 2025, with application rates of 2 % and 4.8 % for biochar and compost, respectively. Topsoil samples were collected three weeks after application, using 7.5 × 7.5 cm cores for physicochemical characterisation. We found that both biochar and compost substantially decreased soil bulk density from 1.19 to roughly 0.96 g $cm^{-3}$ and increased soil pH from 5.82 to 6.02 and 6.58, respectively. The biochar amendments also enhanced soil water holding capacity at −10 kPa, however, gas diffusivity has so far remained unchanged. We also report longer-term outcomes on soil carbon sequestration and fertility, as well as effects on plant biomass and nutrient uptake. Our findings will help inform the broader agronomic and environmental value of integrating these amendments into vineyard waste and soil management practices.

**ABSTRACT**

To assess methods to reduce nitrogen waste, a survey of farming practices was conducted in Darusa village, Bangladesh. A total of 100 households were surveyed to determine demographic and agricultural information. Four clusters of farms were identified and nine households randomly selected from each. Detailed surveys on cropping and livestock, and nitrogen contents of imported and exported products were used to estimate nitrogen waste on these 36 farms. Clusters of farms were (cluster-1) high irrigation / high livestock, (cluster-2) low irrigation / low livestock, (cluster-3) low irrigation / high livestock and (cluster-4) medium irrigation / low livestock. Nitrogen waste across crops and livestock in Darusa village reveals substantial inefficiencies in nutrient management. *Nitrogen waste from wheat and lentils* was lower than other crops, while from early kharif (summer-monsoon) rice and rabi (winter) potatoes and onions, waste was significantly higher, indicating clear opportunities for reducing fertilizer inputs in these crops. Nitrogen waste was lowest on farms with low livestock, particularly those with only poultry and ducks. It was significantly higher on farms with cattle and buffaloes reflecting the likely use of cattle and buffalo manure as fuel. The findings suggest that reduced nitrogen waste could be achieved by (1) reducing nitrogen inputs to kharif-rice and rabi-potatoes, (2) reducing number of livestock or improving use of manure and urine to improve soil fertility and (3) increasing recycling of other organic residues to crops. The average savings in synthetic fertilizers across the village highlight a substantial reduction in synthetic fertilizer requirements when manure is effectively utilized. This indicates that using manure not only reduces dependence on synthetic fertilizers but also lowers production costs.

## ABSTRACT

Exporting manure from large dairies and utilization as an organic amendment is a viable pathway for reducing potential on-site nutrient overloading, mitigating greenhouse gas (GHG) emissions, and efficient provisioning of nutrients for crop uptake. Such synergies can arise between industries to meet sustainability and economic goals which can support a circular nutrient economy. However, utilization of dairy manure compost (DMC) in conventional commercial almond orchards and its impact on soil health and biogeochemical cycling is not yet fully understood. Unravelling key factors that underlie mechanisms of emissions mitigations and effects on yield is critical to effective management and broader adoption. To investigate how DMC derived carbon, in tandem with fertigation, affect the microbial community's processing of nitrogen (N), its resulting control on attributable emissions of nitrous oxide ($N_2O$), and soil health response an orchard with microsprinkler fertigation-irrigation was divided into four blocks. Each has established a control of no DMC/fertigation (0C, 0N), DMC only (+C, 0N), fertigation only (0C, +N), and DMC + fertigation (+C, +N). DMC soils had 8 metric tons dry weight per hectare (ha) applied. Soils that received synthetic N had 100 kg N/ha applied over three applications. Yearly DMC application is targeted during Fall after harvest from 2021 through 2024. To assess interactive effects of DMC/fertigation on soil health/physicochemical properties event related soil samples (topsoil 0 - 15 cm, 1-m cores), GHG flux via LI-COR TGA system, hydraulic conductivity, and yield data were collected. $N_2O$ fluxes observed were largely event driven, though a significant reduction was observed for +C,+N relative to 0C,+N during and after fertigation. Soil inorganic N between treatments show no significant difference, though dissolved organic carbon and nitrogen were significantly higher in DMC soils. To explore mechanistic processes a $^{15}N$ isotope dilution via mineralization-immobilization turnover was conducted in-field along with a $^{15}N$ tracer experiment. Tracer gas samples were analyzed for $N_2O/N_2$. In addition, the potential of natural abundance $N_2O$ isotopomer ratios for predicting dominant microbial nitrogen processes was evaluated. Significant differences in site pReferences between treatments before and after fertigation were found. Almond yield in +C,+N treatments were consistently higher than 0C,+N. In addition, GHG reductions were achieved without lowering N inputs while co-benefits such as improved soil structure and tree vigor were measured. Work in progress involves identifying N genes via metagenomics and community identification via 16s sequencing.

**ABSTRACT**

Despite several alternatives to rice residue management have been proposed, there remains a notable gap in understanding how these practices, particularly the use of microbial decomposers and residue management affect soil phosphorus (P) fractions and related biological properties in a rice-wheat cropping system. Widespread rice-straw burning persists especially in Haryana, western Uttar Pradesh, and Punjab of India because of short sowing windows and limited residue-handling options, leading to nutrient loss, greenhouse gas (GHG) emissions, and soil carbon decline which is essential for soil functioning. Promoting in situ residue incorporation offers a sustainable alternative, and the Pusa Decomposer has emerged as an effective, rapid, and scalable solution for improving straw decomposition and soil health. This fungal consortium comprises efficient lignocellulolytic strains capable of accelerating straw degradation within 20–25 days under field conditions, significantly improving organic matter turnover, nutrient availability and soil health. While the positive effects of Pusa Decomposer on straw decomposition, carbon dynamics and microbial activity have been increasingly recognized, its specific influence on soil P dynamics remains inadequately understood. To address this gap, a three-year field experiment (2021-2024) was laid out in a randomized block design comprising five treatments: full residue burning, full residue retention, full residue incorporation, full residue retention with Pusa Decomposer, and full residue incorporation with Pusa Decomposer, each replicated four times to evaluate the impacts of different rice residue management strategies with and without the application of the Pusa Decomposer on soil P fractions and biological indicators in bulk soils and soil aggregates. Soils sampled were collected at the end of the third year of the experiment from 0-15 and 15-30 cm soil layers and analysed for soil aggregation and P fractions in bulk soils and aggregates. The results showed that the full residue incorporation with Pusa Decomposer treatment significantly increased labile and water soluble P, sorbed P, easily mineralizable organic P and moderately labile P fractions, as well as total P, total inorganic P and enzymatic activities compared to the residue burning treatment in the surface soil layer, with consistently higher values observed in bulk soils than soil aggregates. Full residue incorporation treatment exhibited the highest levels of hydrochloric acid extractable P and residual P which were notably more concentrated in aggregates than in bulk soils. Complete residue incorporation led to the highest accumulation of hydrochloric acidextractable P in macroaggregates, whereas residual P was mostly concentrated in microaggregates. These findings highlight the potential of integrated residue and Pusa Decomposer management strategies, to enhance soil nutrient availability, while reducing reliance on external P inputs in intensive rice based systems. Integrating residue incorporation practices with microbial consortia such as Pusa Decomposer is an effective strategy to enhance soil P availability and stimulate soil biological activity in an intensive rice–wheat system, offering a pathway towards more sustainable nutrient management.

## ABSTRACT

Improving soil fertility can reduce the need for nitrogen (N) fertilizer application and mitigate agricultural N losses to the environment. Crop residue return is one of effective practices to improve soil function on N retention and supply, thereby providing a prerequisite for substantial reductions in N fertilizer application. However, the underlying mechanism of how microorganisms involved in different transformation processes respond to N fertilizer reduction under long term residue return remains largely unknown. Here, a three-year N fertilizer reduction experiment was conducted following nine years of continuous stover mulching in a Mollisol of Northeast China. Metagenomic sequencing was used to investigate the response of key functional genes of microbial N cycling to fertilization regimes. Compared with conventional N fertilization application rate (240 kg N $ha^{-1}$, CK), reducing fertilization rate to 190 kg N $ha^{-1}$ (N190) elevated the abundance of the genes involved in organic N mineralization (UreC and pepA), assimilatory nitrate reduction to ammonium (ANRA, nasA) and dissimilatory nitrate reduction to ammonium (DNRA, napA and nirB), thereby maintaining soil N availability by favoring $NH_4^+$ retention, stabilizing microbial N-cycling networks, and supporting plant N uptake. Further reduction of N application to 135 kg N $ha^{-1}$ (N135) resulted in a slight N deficit on account of N balance in the soil-crop system, while the maize yield remained unchanged throughout the three growing seasons. Under this condition, microbial communities shifted from copiotroph-dominated to oligotroph-dominated, accompanied by a weakened microbial N cycling network, likely reflecting a strategy to reduce their N demand Compared with CK, the higher abundance of genes involved in DNRA and lower abundance of genes involved in denitrification in N135 treatment likely sustained soil $NH_4^+$ concentration for plant uptake, while simultaneously reducing soil $NO_3^-$ concentrations and mitigating N losses. When N fertilizer input was completely ceased (0 kg N $ha^{-1}$), severe N deficiency constrained both microbial proliferation and crop yield. To compete with plant for N, microbes enhanced their ability for N retention by enriching genes involved in DNRA and ANRA at greater extent, and reduced N loss potential by suppressing nitrification and denitrification processes. Overall, our results demonstrated that under conditions of consecutive maize residue return for maintaining C availability, there is substantial potential for N fertilizer reduction in black soil of Northeast China. The study comprehensively improves our understanding of microbially mediated soil N transformation and provides a scientific basis for sustainable agricultural management.

**ABSTRACT**

Water scarcity is the main challenge for crop production under rainfed cropping systems. The present study was undertaken to compare the effectiveness of different organic and inorganic amendments to increase soil water retention and crop yield under rainfed conditions. A field experiment was conducted using different amendments i.e. T1 (control), T2 compost @ 750 kg $ha^{-1}$, T3 biochar @ 1000 kg $ha^{-1}$, T4 gypsum @ 1000 kg $ha^{-1}$, and T5 hydrogel @ 15 kg $ha^{-1}$. Two wheat varieties, Wafaq-2023 (V1), and NARC-Super (V2) were grown till maturity following the recommended agronomic practices. The results indicated that among the amendments, hydrogel was the most effective treatment followed by gypsum, biochar and compost, respectively for increasing grain yield and nutrient uptake by wheat. Under the application of hydrogel, grain yield was increased by 29 and 24%, and straw yield was increased by 28 and 23% in V1 and V2, respectively compared to control. The application of gypsum caused 20 and 14% increase in grain yield, and 19 and 15% increase in straw yield in V1 and V2, respectively. Under the application of hydrogel, Chl-a, Chl-b, relative water contents and stomatal conductance were increased by 55, 56%, 52 and 54% in V1 and by 36, 43, 42 and 43% in V2, respectively as compared to the control treatment. The accumulation of macro and micronutrients was also higher under hydrogel followed by gypsum application. The higher grain yield and nutrient uptake was attributed to better soil properties and soil water retention potential of hydrogel and gypsum as compared to the other amendments. It was concluded that hydrogels and gypsum are promising options along with wheat variety Wafaq-2023 for getting higher crop yield with better nutritional quality under rainfed conditions.

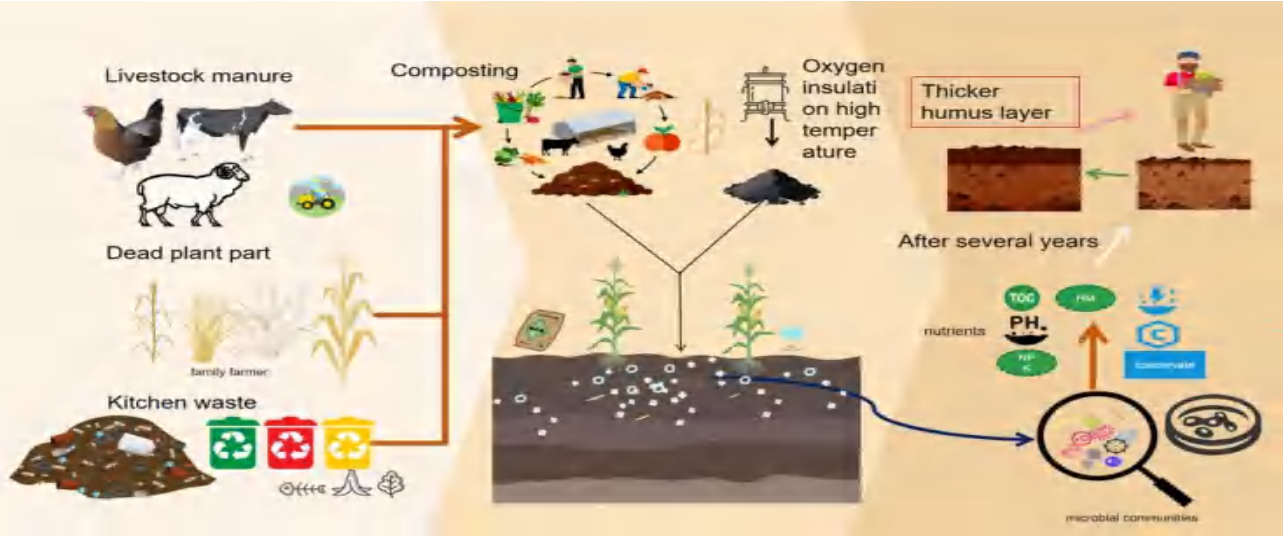
# Study on the Effects of Different Organic Materials on Soil Humus and Nutrients

**Sun Liming[1*], Wu Jinggui[1]**



[1] *College of Resources and Environment, Jilin Agricultural University (Changchun, China)*
wujingguiok@163.com

## ABSTRACT

Based on field experiments, this study explored the effects of different organic materials on soil humus and nutrients, clarified the effects of different organic materials on soil fertility improvement and soil amelioration, so as to provide a scientific basis for optimizing fertilization schemes and improving soil quality.A field experiment was conducted at the Zheng Experimental Base in Nong'an County in 2023. Three types of materials were used in the experiment design, namely kitchen waste (CY), crop straw (JG) and cow manure (NF). Each material was processed into organic fertilizer and biochar, resulting in a total of seven treatment groups:CK (no organic materials added)、CYC (kitchen waste biochar)CYF (kitchen waste organic fertilizer)、JGC (crop straw biochar)、JGF (crop straw organic fertilizer)、NFC (cow manure biochar)、NFF (cow manure organic fertilizer).The effects varied among different organic materials. The NFF treatment increased soil pH. The improvement effect of organic materials on soil nutrients was more significant in the second year after application. Compared with CK, CYC and CYF treatments significantly increased the available nitrogen content by 17.72% and 27% respectively. All organic material treatments significantly increased the available potassium content by 5.02%–19.86%, with the highest content observed in the JGC treatment. Except for NFC, all other treatments significantly increased the available phosphorus content by 10.53%–52.96%. Meanwhile, the available copper content was significantly increased by 19.29%–54.12% in all treated groups, and the soil organic carbon content was also significantly elevated. Specifically, the JGC treatment significantly increased the contents of available zinc, iron and manganese by 73.04%, 19.40% and 10.29% respectively.

In terms of humus components, compared with CK, the NFC treatment significantly increased the fulvic acid (FA) content by 27.90% and also had a significant promoting effect on the water-soluble substance (WSS) content. The NFF treatment increased the humic acid carbon content by 34.30%. The JGF treatment significantly increased the humic acid/fulvic acid ratio and the PQ value of soil, while reducing the HAΔlogK, indicating that the humus tended to be "younger".

In conclusion, different organic materials exert distinct effects on soil properties, and the effects of biochar and organic fertilizer processed from the same raw material also differ. Among all treatments, JGC is conducive to the accumulation of trace elements and available potassium, while NFC and NFF treatments are favorable for the increase of humus carbon components and available phosphorus content.

**ABSTRACT**

Realistic estimation of the effects of organic amendment with compost on yield increase and soil carbon storage in agricultural soils requires long-term field experiments, as the stability of yield and soil organic carbon (SOC) is strongly influenced by spatiotemporal heterogeneity. Based on a long-term field experiment established in Quzhou County, Hebei Province, China in 1993, this study evaluated the dynamic characteristics of wheat and maize yields and soil organic carbon under the application of bio-compost and traditional compost. Over the more than 30-year experimental period, compared with the chemical fertilizer control treatment, the application of high-dose bio-compost showed a significant yield-increasing effect: maize and wheat yields increased by 19.38% and 23.62%, respectively; compared with traditional compost, maize and wheat yields increased by 5.56% and 4.97%, respectively. Compared to chemical fertilization, soil amended with bio-compost and traditional compost exhibited increases in SOC of 95% and 91%, respectively, in 2018. An increasing temporal trend in SOC content was observed under bio-compost application during the first nine years of the experiment. However, this pattern diminished after 2002, as insignificant correlations between SOC and time were found in bulk soil, microaggregates (particle size 53–250 μm), and mineral-associated organic matter (particle size < 53 μm). In contrast, SOC in coarse particle organic matter (particle size > 250 μm) continued to increase over time after 2002, indicating that SOC was persistently stored in macroaggregates (Chen et al., 2024). Between 2002 and 2020, compared with low-dose bio-compost, the high-dose bio-compost mode increased soil organic carbon content by 11.5%-32.6%, with an average annual growth rate of soil organic carbon of approximately 0.34%. This paper will discuss the potential of compost application in improving grain production capacity, mitigating the impacts of global warming, and maintaining long-term soil organic carbon storage.

**ABSTRACT**

Biochar holds great potential for improving soil fertility and enhancing crop yield, but its long-term effects on soil carbon and nitrogen components, microbial activity, and rice yield under continuous nitrogen fertilization remain unclear. A seven-year (2019-2025) field experiment was conducted in the high-fertility rice region of the Jianghan Plain, China, with four treatments: CK (no nitrogen control), CF (conventional nitrogen fertilization), CF+LB (conventional nitrogen plus low-rate biochar, 25 t/ha), and CF+HB (conventional nitrogen plus high-rate biochar, 50 t/ha). Rice yield components and growth indicators were monitored annually, and soil samples from 0-10 cm and 10-20 cm layers were collected in the 2025 harvest season to determine physicochemical properties, catalase activity, total organic carbon (TOC), total nitrogen (TN), and microbial biomass carbon and nitrogen (MBC, MBN).The results showed that, compared with the nitrogen-only treatment (CF), biochar applications (CF+LB and CF+HB) resulted in an average yield increase of 5.8% and 11.0% over seven years. However, the yield enhancement declined in the later years of the experiment. Yield increase was primarily attributed to significant increases in effective panicle number and plant height. Low-rate biochar primarily increased organic carbon in the 0-10 cm soil layer by 38.4%, while high-rate biochar significantly promoted carbon and nitrogen accumulation in the 10-20 cm layer, with TOC and TN increasing by 72.6% and 128.1%, respectively. Moreover, catalase activity was significantly enhanced. Biochar treatments also significantly increased MBC and MBN in both soil layers, with the CF+HB treatment showing the greatest effect. In the 0-10 cm layer, MBC and MBN increased by 21.4-30.1% and 63.7-115.9%, respectively.Structural equation modeling (SEM) analysis indicated that biochar promoted rice yield by increasing soil carbon and nitrogen levels, enhancing microbial biomass and enzyme activity, and improving rice growth indicators and yield components. In conclusion, long-term biochar application, especially at high rates, can synergistically improve soil carbon-nitrogen pools and microbial activity, leading to enhanced rice yield, providing a scientific basis for sustainable agriculture in high-fertility paddy regions.

*yijun@ccnu.edu.cn

**ABSTRACT**

The partial substitution of chemical nitrogen (N) fertilizer with organic fertilizer is a key strategy for reducing chemical fertilizer input and promoting green productivity in rice systems. However, the integrated mechanisms underlying its effects on rice yield enhancement and soil fertility improvement remain unclear. To address this, a seven-year (2019-2025) field experiment was conducted with six N application treatments: no N ( N0), chemical N-only at 60, 120, and 225 kg N $ha^{-1}$ (N60, N120, N225), and two combined treatments: 60 kg N $ha^{-1}$ chemical N+165 kg N $ha^{-1}$ organic N (N60+F165) and 120 kg N $ha^{-1}$ chemical N+105 kg N $ha^{-1}$ organic N (N120+F105). We systematically measured rice yield and its components (effective panicles, filled grain number per panicle, seed setting rate, 1000-grain weight), key growth parameters (tiller number, plant height, LAI, SPAD), soil profile mineral N content, soil physicochemical properties, microbial biomass carbon and nitrogen (MBC, MBN), and activities of four key soil enzymes (catalase, urease, sucrase, and neutral phosphatase). This study investigates the long-term effects and integrated mechanisms of partial organic substitution on rice yield, soil N retention, and fertility enhancement. The results showed that the N120+F105 treatment achieved the highest rice yield, which increased by 3.08%-17.60% compared to the N225 treatment. While maintaining a high leaf area index and tiller number, N120+F105 significantly increased the contents of soil organic matter, total N, available phosphorus, and available potassium in the plow layer. It also enhanced the retention of mineral N within the 0-20 cm soil layer, thereby reducing the risk of leaching into deeper soil. Furthermore, N120+F105 markedly improved soil microbial activity. In the 0-10 cm layer, MBC and MBN increased by an average of 30.3% and 112.0%, respectively, compared to N225. Synchronous increases in MBC and MBN were also observed in the 10-20 cm layer, and the microbial C/N ratio indicated that organic amendment alleviated N limitation in the deeper soil. Structural equation modeling further revealed that the organic substitution treatments primarily enhanced soil fertility and microbial biomass, which consequently improved soil N supply capacity, ultimately promoting rice tillering and effective panicle formation to increase yield. In conclusion, the appropriate partial substitution of chemical fertilizer with organic fertilizer (N120+F105) enhances rice yield and soil health synergistically by boosting soil microbial activity and optimizing soil nitrogen supply.

# Decomposition characteristics of different organic materials and their effects on the carbon fractions of soil organic carbon in arable black soils

**Wanying Lei[1*], Na Li[1]**

[1] *State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin, China*

*leiwanying@iga.ac.cn

**ABSTRACT**

Crop straw, livestock manure, and mushroom bran constitute the major agricultural organic wastes. Their incorporation into soils has been widely recognized as an effective strategy to enhance soil organic carbon (SOC) sequestration and improve soil fertility, thereby supporting sustainable agricultural development. Although numerous studies have examined the decomposition of different organic materials and their effects on soil quality at local or site-specific scales, regional-scale comparisons of decomposition characteristics and associated carbon chemical transformation processes across contrasting organic materials remain limited.

To address this knowledge gap, field decomposition experiments were conducted across five locations distributed along a south–north transect of the typical black soil belt in Northeast China. The dynamic decomposition characteristics of six organic materials—decomposed chicken manure, pig manure, mushroom bran, and soybean, maize, and rice straw—were investigated under equivalent carbon input conditions. Fourier transform infrared spectroscopy (FTIR), solid-state $^{13}C$ nuclear magnetic resonance ($^{13}C$ NMR), UV–visible absorption spectroscopy, and fluorescence spectroscopy were integrated to characterize the chemical transformation of organic materials during decomposition at the regional scale. In parallel, the coupled dynamics between organic material decomposition and changes in SOC quantity, fractions, and chemical structure were systematically analyzed.

This study elucidates the key factors regulating organic material decomposition and their roles in soil fertility enhancement, providing mechanistic insights into the transformation of organic inputs into soil organic matter. The findings offer a theoretical basis for improving the efficient utilization of agricultural organic waste resources and optimizing farmland management practices in the black soil region of Northeast China.

# The influence of organic materials on the chemical structure of humus in salt crust aggregates in the Yellow River Delta

**Zichen Xu[1*], Xiangyun Song[2],Xinwei Liu[3]**

*[1] College of Resources and Environment, Qingdao Agricultural University, Qingdao, PR China*

*1622980791@qq.Com

**ABSTRACT**

To investigate the potential of organic amendments for improving saline-alkali soils in the Yellow River Delta, a field experiment was conducted using saline fluvo-aquic soil in Dongying City. This study systematically compared the effects of biochar and cattle manure, applied individually and in combination, against the application of chemical fertilizer alone. The objective was to assess their efficacy in reducing soil salinity, enhancing soil organic carbon, and modifying the chemical structure of humus. Fourier transform infrared spectroscopy was employed as the principal analytical method to elucidate the mechanisms through which organic materials influence the chemical structure of humus within different particle-size fractions of soil aggregates. The key findings are summarized as follows:

(1) Significant Increase in Humus Components. The application of organic materials markedly promoted the accumulation of humus components across all aggregate size fractions. Specifically, the combined application of biochar and cattle manure (ABM treatment) demonstrated the most pronounced effect compared to the control (CK, no organic materials). In the 2–0.25 mm fraction, the organic carbon content of humic acid (HA), fulvic acid (FA), and humin (HU) increased significantly by 28.83%, 3.73%, and 41.69%, respectively, under ABM treatment relative to CK. Corresponding increases in the 0.25–0.053 mm fraction were 25.63%, 9.78%, and 29.86%. Notably, this enhancing effect persisted even in the <0.053 mm micro-aggregate fraction, with observed increases of 20.13% for HA, 7.92% for FA, and 29.82% for HU.

(2) In the 2–0.25 mm fraction, the application of biochar and cattle manure significantly increased the relative content of aliphatic, aromatic, and polysaccharide compounds in HA and HU, while also enhancing the aliphatic and aromatic characteristics of FA. This trend was consistent in the 0.25–0.053 mm fraction, where HA showed increased relative content of aliphatic, aromatic, and polysaccharide substances, and FA exhibited increased aliphatic and aromatic components. These findings provide a valuable theoretical foundation and practical References for utilizing organic amendments to improve saline-alkali soils, boost soil carbon sequestration, and foster sustainable agriculture in the Yellow River Delta.

# Short-Term Soil Fertility and Crop Yield Responses to Municipal Organic Waste

**Stanko Milic [*1], Tijana Zeremski[1], Snežana Maletic[2], Ivana Bajic[1], Marijana Kragulj Isakovski[2], Nina Djukanovic[2], Irina Jevrosimov[2] Jelena Beljin[2]**

[2] *Faculty of Sciences, Novi Sad, Serbia*

* stanko.milic@ifvcns.ns.ac.rs

**ABSTRACT**

The application of organic waste materials represents an important approach for improving soil fertility while supporting circular economy principles. However, field-scale evidence on the short-term agronomic effects of different organic amendments remains limited, particularly for carbonate, alkaline soils. This study evaluated the first-year effects of sewage sludge, compost derived from sewage sludge, and sewage sludge combined with biochar on soil chemical properties and forage sorghum productivity under field conditions.

A field experiment was established in April 2025 at the Regional Landfill Subotica–Bikovo (Serbia) on a carbonate-rich clay loam soil. The trial included a non-amended control, sewage sludge, compost derived from sewage sludge, and sewage sludge combined with biochar, arranged in a two-factor design with four replicates. Organic amendments were applied at rates of 14 t $ha^{-1}$ for sewage sludge and compost and 12.2 t $ha^{-1}$ for biochar. Forage sorghum was cultivated as an industrial and energy crop, and soil samples were collected from 0–30 and 30–60 cm depths, while aboveground fresh biomass yield was determined at the first harvest.

Organic amendments induced clear treatment-specific changes in soil chemical properties, with responses mainly observed in the 0–30 cm layer during the first growing season. Compost application resulted in a balanced improvement of soil fertility, reflected by increased soil organic carbon and humus content, accompanied by higher availability of phosphorus and potassium and moderate mineral nitrogen levels, consistent with its biologically stabilized nature. In contrast, sewage sludge application substantially increased total and mineral nitrogen as well as available phosphorus, indicating a strong nutrient input but with greater variability compared to compost.

The combined application of sewage sludge and biochar resulted in lower mineral nitrogen and available phosphorus compared to sewage sludge alone, despite comparable levels of soil organic carbon. This response suggests short-term nutrient immobilization or sorption processes associated with biochar addition, likely affecting nitrogen and phosphorus availability in the initial phase after application. As a result, nutrient supply to plants was constrained during the first growing season.

Differences in soil chemical properties were directly reflected in forage sorghum performance. Compost-amended plots achieved the highest aboveground fresh biomass yield, consistent with improved nutrient availability and a balanced soil fertility status. Sewage sludge resulted in intermediate yields, reflecting its high nutrient input but less consistent nutrient availability under field conditions. In contrast, the sewage sludge and biochar treatment produced the lowest biomass yield, confirming that short-term nutrient immobilization can outweigh potential benefits of carbon stabilization during the first year after application.

**Key words:** Soil fertility; Organic amendments; Forage sorghum; Biochar

# Mechanisms of Biochar and Cattle Manure in Regulating the Microstructure of Humic Substances within Saline Fluvo-Aquic Soil Aggregates

**RuiZhang[1*], Xiangyun Song[2] Xinwei Liu[3]**

*[1] College of Resources and Environment, Qingdao Agricultural University, Qingdao, PR China*

*147188107@qq.Com

**ABSTRACT**

This study investigates the effects of individual and combined applications of biochar (AB) and matured cattle manure (M) on the chemical structure of humic substances within soil aggregates in saline fluvo-aquic soil of the Yellow River Delta. A field experiment was established in April 2019, and surface soil samples (0–20 cm depth) were collected in November from Maotuo Village, Dongying City (37°49′15″ N, 118°25′63″ E). Seven treatments were implemented with three replicates each: CK (chemical fertilizer only), AB (20 t·ha$^{-1}$ biochar), M1 (7.5 t·ha$^{-1}$ manure), M2 (15 t·ha$^{-1}$ manure), ABM1 (AB + M1), ABM2 (AB + M2), and 2ABM1 (double AB + M1). Soil aggregates were separated by wet-sieving into three size fractions (2–0.25 mm, 0.25–0.053 mm, and <0.053 mm). Humic substances were fractionated into humic acid (HA), fulvic acid (FA), and humin (HU), and their chemical structures were analyzed using Fourier transform infrared spectroscopy (FTIR).

(1) Analysis of the content of humic substance components indicated that the addition of biochar and cattle manure enhanced the levels of humic fractions within soil aggregates. Treatments receiving biochar and/or manure showed higher organic carbon contents of HA, FA, and HU compared to other treatments. In the 2–0.25 mm aggregate fraction of the ABM2 treatment, HA, FA, and HU increased by 45.73%, 41.26%, and 24.09%, respectively, relative to the control. Corresponding increases in the 0.25–0.053 mm fraction were 44.06%, 34.90%, and 35.03%, while in the <0.053 mm fraction, increases reached 56.38%, 120.31%, and 63.82%, respectively.

(2) FTIR analysis revealed that in the 2–0.25 mm fraction, the application of biochar and manure increased the relative contents of aliphatic, aromatic, and polysaccharide compounds in HA and HU, as well as aliphatic and aromatic components in FA. In the 0.25–0.053 mm fraction, both amendments enhanced the relative contents of aliphatic, aromatic, and polysaccharide substances in HA, and increased aliphatic and aromatic components in FA for both soils studied. In the <0.053 mm fraction, biochar and manure application raised the relative contents of aliphatic and aromatic groups in HA but decreased those in FA.

# The influence of the application of sewage sludge compost on the yield of winter oilseed rape

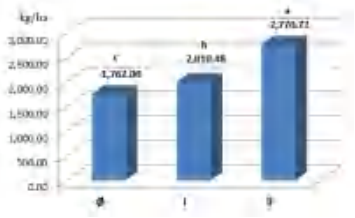
**Jovica Vasin[1*], Stanko Milić[2], Ana Marjanović Jeromela[1], Milorad Živanov[1], Snežana Jakšić[1], Jordana Ninkov[1], Nikolina Dizdar[1]**

*[1] Laboratory for Soil and Agroecology, Institute of Field and Vegetable Crop, Novi Sad, Serbia*

*E-mail Address of Presenting Author: jovica.vasin@ifvcns.ns.ac.rs

**ABSTRACT**

The decline in the content of organic matter in the soils of Vojvodina (the northern part of the Republic of Serbia) represents their most important degradation process. In the absence of organic fertilizers for the soil, the application of various industrial composts is considered as a possible solution to stop this degradation process.



Disposal of sewage sludge in municipal waste landfills is the least favorable option for several reasons (occupation of the capacity of the landfill itself and loss of valuable organic substances found in the sludge). The composting process at the Regional landfill begins with the mixing of sludge created by the purification of wastewater from the city of Subotica and shredded green waste (wooden biomass) collected from public city areas. Compost material goes through a mesophilic phase (25-45 C°), a thermophilic phase (up to 65 C°, with turning and aeration), cooling phase and ripening phase. The tested compost has > 30% organic matter and is free of dangerous and harmful substances.

An agricultural soil of the chernozem type, locality Bikovo, in the area of the Subotica Regional Landfill (N 45°58'37", E 19°47'54") was sampled and tested. All examined soil properties exhibited values typical of this soil type.

An experiment with three variants (Ø – without added compost, I - with 7.5 t/ha of added and plowed compost and II - with 15 t/ha of added and plowed compost) was set up on the plot in four repetitions.

The winter oilseed rape variety Zlatna (group “00”) was used in the trial. Throughout the vegetation period, the plants remained in good condition, with vigorous growth and timely advancement through all phenological stages.

Harvesting was done with a plot combine harvester ZÜRN 150.

Graph 1. Rapeseed yield by varieties of applied compost

The yield of rapeseed on variant II was statistically significantly higher (at the significance level of 0.05) compared to variant I and the control variant (without compost application). Also, the yield of rapeseed on variant I was statistically significantly higher compared to the control variant (graph 1). These differences can be explained by the introduction of nitrogen into the soil originating from the compost, as well as by the partial mineralization of organic matter from the compost.

These results of the experiment indicate the importance of applying compost as a source of nitrogen, which is the bearer of yield. Given that these are one-year data, it is necessary to continue the experiment in the following period.

# The soil rhizosphere metabolome's regulating mechanism on microbial communities depending on straw application depths

**Xiaoyu Li[1*], Hongtao Zou[1]**

[1] *College of Land and Environment, Shenyang Agricultural University, Shenyang, China*

*L_xiaoyu599@163.com

**ABSTRACT**

Rhizosphere metabolites are key drivers in shaping microbial community structure and function. They mostly consist of small-molecule compounds under straw return conditions, such as microbial metabolites, straw degradation products, and root exudates, which act as critical signals and energy sources for soil biochemical processes. The rhizosphere metabolome is influenced by the significantly different soil conditions created by different straw return depths, however it is still unknown how the rhizosphere metabolome regulates microbial communities. In order to examine the regulatory mechanisms of the soil rhizosphere metabolome on microbial communities under varying straw return depths, this study designed a field experiment with four different straw return depths (straw removal, surface mulching, shallow return, and deep return) in combination with 16S rRNA amplicon sequencing and LC-MS/MS untargeted metabolomics. The results showed that the number of rhizosphere soil metabolites was greatly increased by straw return, with surface mulching > deep return > shallow return, reaching 147, 119, and 114 species, respectively. Furthermore, surface mulching increased benzenoids, lipids, and lipid-like metabolites in comparison to straw removal; shallow return increased metabolites of organic heterocyclic compounds; and deep return mainly increased metabolite abundance rather than diversity. Additionally, under varying straw return depths, metabolites may control the composition and abundance of microbial communities, with Actinobacteria and Bacteroidetes dominating surface mulching, Actinobacteria and Gemmatimonadota dominating shallow return, and deep return microbial communities showing increased abundance across phyla under metabolite influence. In conclusion, surface mulching showed the strongest regulating effect with respect to alterations in rhizosphere soil metabolites and microbial populations. This study provides a theoretical basis for understanding rhizosphere microbial activity and improving soil environments.

# Revitalizing Sandy Soils: Organo-Mineral Inputs Enhance Drought Resilience in Wheat and Microbes

**Muhammad Kamran [a], Petra Marschner [a], Thi Hoang Ha Troung [a], Zhe H. Weng [a]**

[a] *The School of Agriculture, Food and Wine, Adelaide University, Waite Campus, Glen Osmond, SA, 5064, Australia.*
*E-mail Address:muhammad.kamran@adelaide.edu.au(Muhammad Kamran)

**ABSTRACT**

Increasing drought conditions severely limit nutrient cycling and wheat production in sandy soils. Organic and mineral amendments such as compost (CM), sheep manure (SM), and bentonite clay (BN) have potential to improve drought resilience. Research on how different rates and types of organo-mineral amendments affect wheat and microbial drought resilience in sandy soils remains limited. We aimed to understand how CM, SM, and BN interact to improve wheat drought resilience in four experiments. **In Experiment I,** three drought-sensitive wheat varieties (Trojan, Cobra, and Gregory) were screened under five drought levels. Based on aboveground and belowground traits, and soil nutrient levels, Trojan, the best performer under drought, was selected for Experiment II. **In Experiment II,** organic amelioration of drought was assessed using CM or SM at three application rates (10, 25, or 40 g $kg^{-1}$) at 75%, 50%, and 25% of water holding capacity (WHC). Under drought (25% and 50%WHC), CM and SM at 25 g $kg^{-1}$ had greatest increase in aboveground (20%), belowground (70%) biomass and photosynthetic rate (42%), but decreased specific root length (34%), relative to the unamended control. Across water levels, CM and SM increased N and P uptake, $NO_3^-$-N, available P, microbial biomass N (MBN) and P (MBP), whilst decreased $NH_4^+$-N and mineral N, with greater effect at 25 g $kg^{-1}$. **In Experiment III,** moderate rate (25 g $kg^{-1}$, eq. 37.5 t $ha^{-1}$) of CM and SM alone (100%CM, 100%SM) or combined (50%CM+50%SM) was applied to assess wheat yield and soil water retention at 75% and 35%WHC during critical vegetative and reproductive growth stages. At 35%WHC, 100%CM and 50%CM+50%SM showed greater increase in yield and physiology during vegetative than reproductive stage. Generally, N uptake, $NO_3^-$-N, and MBN were greater with 100%CM, P uptake, available P, and MBN with 100%SM, and moisture retention and plant available water with 100%SM and 50%CM+50%SM, relative to control. **In Experiment IV,** individual and combined effects of micronized (< 1µm) SM (25 g $kg^{-1}$) and BN (3% w/w) were investigated on soil moisture dynamics, rhizosphere microbial communities, and wheat productivity under 75% and 25%WHC. Synchrotron micro-CT analysis used to visualize and quantify amendment-induced changes in soil porosity and microstructure. We hypothesize that amendment-driven increase in microporosity will enhance water retention in sandy soil, particularly at 35%WHC, leading to improved nutrient availability, microbial activity, and wheat yield. Overall, CM-, SM-, and BN-induced wheat drought resilience was likely due to improved nutrient availability, enhanced water retention capacity, and stimulation of microbial activity in the sandy soil. The moderate rate (25 g $kg^{-1}$, eq. 37.5 t $ha^{-1}$) of CM and SM, alone or combined with BN, could substantially mitigate the negative effects of drought on wheat production, nutrient cycling, moisture retention and microbial dynamics in sandy soils.

# Optimizing Soil Fertilization Processes for Improving 4R Nutrient Stewardship

**Sadia Mahajabin[1*], Tiequan Zhang[2], and Asim Biswas[3]**

*[1,3] School of Environmental Science, University of Guelph, Guelph, ON, Canada*

*[2]Harrow Research and Development Centre, Agriculture and Agri-Food Canada, Harrow, ON, Canada*

E-mail: smahajab@uoguelph.ca

**ABSTRACT**

4R (right rate, right source, right time, right place) Nutrient Stewardship boosts farming profitability and reduces environmental concerns. The current 4R practices were developed using commercial chemical fertilizers (CCF) under field conditions. However, cropping systems that use manure have different management needs than those that use CCF. In manure-intensive regions such as southwest Ontario, manure amendments introduce organic N fractions that may not fully mineralize in the year of application, creating legacy N fertility effects that complicate fertilizer decision-making. Soil texture further influences N availability through its effects on organic matter stabilization, microbial activity, and water retention, yet the combined impacts of manure type, manure form, residual N, and soil texture remain poorly quantified under Ontario conditions. To address the critical research gaps, this study evaluated the first year and residual N availability of pig and cattle manures (solid and liquid forms) compared with CCF across contrasting soil textures. A controlled greenhouse pot experiment using ryegrass was conducted with sandy loam and clay loam soils collected from Essex County, Ontario, followed by calibration and validation under long-term corn–soybean rotation field conditions. Treatments included five N amendments (i.e. chemical fertilizer, solid and liquid pig and cattle manures) applied at four N rates (i.e. zero-N, 0.7×RNR, 1.0×RNR, and 1.3×RNR). The first year and residual N availability of N amendments were calculated using the zero-N treatment as a control. Plant samples were digested after two harvests, and plant biomass, N uptake, nutrient use efficiency (NUE), and soil N and P dynamics were assessed across multiple cuts. Results showed that chemical fertilizers initially increased crop yield and prompted early biomass production compared with manure-based treatments. Solid and composted manures released nutrients slowly and improved nutrient retention, but liquid manures increased biomass production quickly, particularly in sand-textured soils. These findings show that optimal manure management can improve NUE while supporting soil nutrient management, providing insights for integrating organic amendments into 4R nutrient stewardship frameworks.

# Nutrient enriched biochar reduces chemical fertiliser requirements for forestry seedling growth

## ABSTRACT

Nutrient-enriched biochar (NEB) offers a way to turn forestry residues and dairy effluent into a valuable fertiliser product that supports a circular nutrient economy, but its optimal use for plantation seedlings is not yet well understood. This study tested NEB for Eucalyptus nitens seedlings in both a controlled pot trial and a replicated field trial on a Red Ferrosol in Tasmania, Australia. NEB was produced by soaking hardwood timber-residue biochar in dairy effluent washdown liquid and applied either alone at two rates, or in combination with a slow-release mineral fertiliser, alongside an industry-standard fertiliser treatment and an unfertilized control. In the glasshouse, after 140 days, seedlings receiving NEB plus fertiliser or fertiliser alone showed significantly greater stem diameter, shoot biomass, leaf number and branch number compared to the control, whereas NEB on its own did not enhance growth. Similar results were observed in the field, where seedlings receiving NEB plus fertiliser or fertiliser alone were 40 % taller (approx. 0.5 m) than the control after 13 months, again with NEB alone unable to match this growth response. Before transplanting, the NEB–fertiliser mix delivered the same initial ammonium-nitrogen supply as the industry-standard fertiliser despite containing only half the total nitrogen and both treatments slightly increased soil pH. NEB treatments also boosted available potassium and several micronutrients, including boron, zinc and manganese. These initial differences in soil ammonium, potassium and pH were no longer evident after 140 days of seedling growth, indicating active nutrient uptake and redistribution in the system. Overall, NEB, when combined with mineral fertiliser, was able to sustain seedling performance comparable to the industry standard while partially substituting for mineral nitrogen and potassium and contributing useful micronutrients, without negatively affecting soil properties. These findings suggest that NEB can function as a supplementary nutrient source rather than a complete fertiliser replacement for forestry seedlings. Future work should explore higher dairy effluent loadings during NEB production and longer-term trials over 5–15 years to determine whether NEB can reliably support plantation establishment and early growth as part of an integrated fertiliser strategy.

**ABSTRACT**

The resource utilization of organic waste is a crucial pathway for promoting the green transformation of agriculture and synergistically enhancing soil health and the sustainable production capacity of rice.This study presents the results of a long-term field experiment initiated in 2018,focusing on the sustainable recycling of organic waste in typical paddy systems of Suzhou.Through multi-dimensional evaluations,it systematically investigates and assesses the long-term comprehensive effects of applying kitchen waste compost and similar organic amendments on soil health (encompassing physicochemical properties,microbial diversity,biodiversity,and ecosystem functions),as well as on rice yield,quality,and economic viability.The key results are summarized as follows:

(1)Significant improvement in soil physicochemical properties:The application of kitchen waste compost significantly increased soil organic matter content (by up to 18.52%),available nitrogen,phosphorus,and potassium,stabilized soil pH,reduced bulk density and enhanced aggregate stability.The secondary compost treatment showed particularly notable effects,improving aggregate water stability by approximately 19.2–49.3% and markedly optimizing soil structure.

(2)Enhanced soil carbon sequestration capacity:The kitchen waste compost treatment promoted the accumulation of both active and inert organic carbon,particularly increasing carbon storage in the topsoil (0–20 cm) and raising the proportion of mineral-associated organic carbon,contributing to the formation of a stable carbon pool and enhancing long-term soil carbon sequestration potential.

(3)Improved soil microbial diversity and functionality:Long-term application of kitchen waste compost significantly increased soil bacterial α-diversity (e.g.,elevated Shannon index) and enriched beneficial functional microbial communities (such as nitrogen-fixing and organic matter-degrading bacteria).It also enhanced the activity of key soil enzymes,including dehydrogenase and β-glucosidase,thereby strengthening nutrient cycling and pollutant degradation capacity.

(4)Enhanced paddy biodiversity and ecological functions:Organic farming practices helped maintain the stability of weed communities in paddy fields,significantly increased the diversity and niche breadth of natural enemies such as spiders,and improved the natural control of pests like rice planthoppers, promoting the balance of the farmland ecosystem.

(5)Synergistic improvement in rice yield, quality, and economic benefits: Under the premise of ensuring food security, the kitchen waste compost treatment increased rice yield by 0.8–56.9% compared to conventional chemical fertilizer treatments. From an economic perspective, optimized organic rice systems demonstrated a higher net economic value, exceeding conventional rice by up to 5,399.45 CNY/hm².Ecological subsidy policies,such as crop rotation and fallow incentives,further improved economic profitability by approximately 2.7%.Additionally, farmer willingness-to-accept (WTA) compensation for ecological rice cultivation reached up to 14,000 CNY/hm²,indicating strong potential for economic viability and farmer adoption. Importantly, rice quality in terms of taste and appearance met premium standards without introducing heavy metal or salinity risks, achieving multiple objectives of "increased yield, improved quality,and enhanced economic sustainability".

This study confirms that implementing organic waste recycling in Suzhou's paddy systems can synergistically improve soil health through multiple pathways—"physicochemical properties,microorganisms,and biodiversity"—while simultaneously enhancing rice yield and quality.It provides a scientific basis for green rice production and circular agricultural practices in the region.

**ABSTRACT**

Purpose: The objective of this study was to determine how residues from different anatomical parts of the corn plant affect SOC content and the molecular structure of humic acid (HA) in black soil, using long-term incubation and advanced spectroscopic techniques.The study provides new insights into how targeted residue management based on plant anatomy can be leveraged to optimize soil fertility and carbon sequestration strategies in sustainable agriculture.

Methods: This experiment selected 7 different parts of corn plant residues as experimental materials for pot experiments. Through FTIR, Fluorescence spectra and $^{13}C$ CPMAS NMR technology, the changes and characteristics of the ingredient and structure of HA were qualitatively characterized.

Results: The results show that the application of corn plant residues can increase the SOC content and the proportion of humus, Compared with 360d, after 720d of cultivation, the soil organic carbon content in each treatment increased to varying degrees. And compared to CK, the R treatment showed the highest increase in PQ value at 6.45%, while the PB treatment exhibited the smallest increase at 2.67%. The elemental composition and $^{13}C$ CPMAS NMR results demonstrated that the application of corn plant residues enhanced the ratio of H/C and the aliphatic C/aromatic C ratio of HA and reduced the O/C ratio, indicating enhance the aliphaticity of soil HA, reduce the oxidation degree and condensation degree, and rendered HA molecular structure simpler.

Conclusion: The higher the carbon content between different parts of the residues, the more plant parts containing difficult to decompose components (such as lignin and carbon with alkyl structure), the higher the degree of humification. The residues from root and stem bark significantly enhanced humification, promoted the formation of more aliphatic and stable HA structures, and contributed more effectively to SOC buildup compared to leaf and bract residues.

## ABSTRACT

Topsoil removal in the Fukushima Prefecture as response to the radioactive contamination through the Fukushima Daiichi nuclear power plant incident in 2011 led to severely impacted soil. In response, the restoration of the crop soil layer is an important undertaking. The prime focus for the restoration of the soil is the organic content.

In this study, we analyzed the content of soluble organic compounds present in the soil solution of an organically managed field in the Fukushima Prefecture by Liquid Chromatography - Orbitrap mass analysis. We identified several organic acids and amino acids that are abundant in the soil solution samples, and potentially available to plants.

We chose the 10 most abundant organic compounds to test the influence on A. thaliana root growth. Instead of applying high concentrations, we focused on a concentration range that is most commonly associated with High Affinity Transport Systems (HATS). The tested concentrations were mainly in the µM range, with the highest concentration being 1 mM. All tested concentrations were added in addition to MGRL media to see effects that are prominent while the plants have a good nutritional status (as it should be in agricultural applications).

We were able to classify the organic compounds into either no alteration of growth, growth suppression and growth promoting, based on root length, shoot weight and additional photosynthetic measurements. Currently RNA sequencing is ongoing to identify genes responsible for this regulation.

The aim of this study is to identify which organic compounds are released in organically managed fields, that are available to crops. Further, we will develop plants that are better adapted towards growth in these conditions.

# Beyond Porosity: Dual-Mode Nitrogen Fertilizers from Metal-Modified Biochar

**ABSTRACT**

Nitrogen leaching and volatilization represent major challenges in the development of efficient fertilizer. In this work, we explore the development of a chemically modified sawdust biochar able to sorb Green Ammonia (John et al., 2023), aiming at the production of slow-release fertilizers. Biochars were modified with several metals (Mn, Zn, Fe) reaching an increase of up to 65% in nitrogen content compared to the pristine biochar, highlighting the dominance of surface chemistry over pore structure in ammonia retention. To explain the increase in N%, several characterization techniques (XPS, XRD, FT-IR, SEM-EDS) were performed in order to obtain a mechanistic understanding of the sorption process. XPS and XRD revealed a pivotal role of the metals in the sorption process, indicating that ammonia retention is not limited to classical ionic interaction, but involves the formation of crystalline ammonia complexes on the biochar surface. The obtained fertilizers show a dual modal release that combines the fast release typical of physisorption with the slow release obtained by the formation of amidic bonds. These fertilizers show an increase in slow-release ammonia compared to the pristine biochar, reaching 50% of covalently bonded ammonia. Moreover, the selection of the metals was not fortuitous, all those metals are also micronutrients for the plants, enabling the simultaneous delivery of two pivotal elements. This approach lays the basis for a future creation of an “in situ” small implant for the production of fertilizers that allow a fast release before the sowing and a controlled release during the growth.

# Banana growers: Battling with soils for productivity in the Chitwan valley of Nepal

**ABSTRACT**

With the realization that soils of the Chitwan Valley (180 m - 220 m amsl) of Nepal are fertile and resourceful, the government promoted a policy to provide sizeable financial and technical support to the banana growers after the district was categorized as a super-zone (>1000 ha cultivation) of banana. The zonal concept was introduced under the Prime Minister's Agriculture Modernization Project in 2016. After the declaration of the super-zone, the government assumes that agriculture production should be increased in a self-sufficient manner. Paradoxically, a recent transect survey of three banana (dominated by G9 var.) farms from the Padampur, Jagatpur, and Tribeni areas in the East-Rapti River corridor of the Chitwan district revealed that much of the scientific data needed for soil improvement required for commercial production of bananas is lacking. During the survey, farmers reported that their banana super-zones increasingly face soil health challenges mainly due to soil acidity, excessive use of chemicals and pesticides, decreased groundwater tables for irrigation, reduced organic matter, and nutrient depletion in soil. This has resulted in declining banana productivity (approx. 20 Mt to <15 Mt/ha) with time. Over 600 banana growers (registered and unregistered, combined) are likely to suffer from these drivers of soil degradation in the district. Worthy of mention is one example: widespread 'Panama disease' could be suppressed by judicious liming of soils, but it must be verified by farmers' field experimentation. It implies that such investigations should be tailored to the need for periodic soil tests for fertilizer recommendation, residue management, bio-fertilizer promoting healthy soil ecosystems, and assessing lime requirements to bring soil to a desired acidity level. Most farmers have benefited from government subsidies; many are still missing out due to unclear land-use policy hampering the good soil management practices for optimization of banana production in the region. In summary, this quick field survey suggests that while government efforts are somewhat visible, more emphasis should be laid onto integrated nutrient management involving banana farmers and field-based research outcomes.

## ABSTRACT

The management of poultry litter presents a significant environmental challenge due to its high nitrogen content and the risk of gaseous emissions. The composting of poultry litter is a widely recognized organic waste management strategy. However, it is often associated with significant gaseous emissions, including ammonia ($NH_3$), greenhouse gases (GHGs) such as methane ($CH_4$) and nitrous oxide ($N_2O$), and odorous components including volatile organic compounds (VOCs) and hydrogen sulfide ($H_2S$). These emissions contribute to nitrogen loss, environmental pollution, and public health concerns. While previous studies have focused on nutrient retention and GHG mitigation in the composting process, limited research has comprehensively examined odour reduction, which remains a critical concern for farmers. The unpleasant odour generated during composting is a major barrier to its widespread adoption, making odour control an essential aspect of sustainable manure management. This study investigates the potential of lignite granules, a low-rank coal derived carbonous product, as an additive to mitigate gaseous emissions during in-vessel composting of poultry litter. A series of closed laboratory composting reactors were used, each containing 30 L of composting material. Treatments included control (no lignite addition) and different dosages of lignite in both powdered and granulated forms to evaluate their comparative effects. Gas emissions ($NH_3$, $CH_4$, $N_2O$, VOCs, and $H_2S$) were monitored throughout the composting process using advanced analytical instruments, including a Picarro G2508 gas analyzer for $NH_3$ and GHGs, and GC-MS for VOC quantification. Additionally, compost quality parameters such as pH, moisture content, total nitrogen, and carbon retention were assessed to determine lignite's impact on nutrient stabilization.

Preliminary projections based on lignite's physicochemical properties suggest that its addition reduces $NH_3$ emissions by adsorbing ammonium ions and stabilizing nitrogen within the compost matrix. Similarly, its porous structure facilitates VOC and $H_2S$ adsorption, leading to reduced odour emissions. The presence of lignite may also influence microbial activity, potentially modulating $CH_4$, $N_2O$ emissions. Comparative analysis between powdered and granulated lignite highlights the most effective formulation for practical applications.

The findings of this study provide valuable insights into the feasibility of using lignite granules as a sustainable solution for emission control in poultry litter composting. If successful, this approach could enhance compost quality, reduce environmental pollution, and support the broader adoption of composting technology in poultry farming. Future research will focus on scaling up the application of lignite in semi-commercial composting systems and evaluating its long-term agronomic benefits.

**ABSTRACT**

Agricultural production is increasingly constrained by soil degradation, climate change, and the inefficient management of organic residues, while conventional linear farming systems continue to accelerate soil resource depletion and environmental pollution. This presentation introduces biochar-based circular agriculture as an integrated and soil-centered approach to addressing these challenges. It first frames circular agriculture within the context of global agricultural pressures, with particular emphasis on critical soil problems including salinity, acid sulfate soils, land degradation, and desertification, as well as current limitations in managing organic residues from agricultural production. The conversion of these residues into biochar is then presented as a value-added pathway that transforms agricultural waste into a stable, carbon-rich soil amendment. Studies show that biochar can effectively improve soil acidity regulation and nutrient-related properties, with reported improvements in soil pH balance, nutrient retention, and overall fertility commonly reaching 30–50%, depending on soil conditions and biochar characteristics. In contrast, its effects on soil salinity remain inconsistent and highly context-dependent, indicating that biochar does not provide a universal solution to salinity stress. Crop yield responses are therefore shown to depend primarily on the extent to which biochar alleviates dominant soil constraints and matches crop-specific nutrient demands, rather than on biochar application per se. The presentation concludes by proposing a conceptual model of biochar-based circular agriculture that integrates residue recycling, soil restoration, yield improvement, and climate mitigation, positioning biochar not as a standalone yield-enhancing input but as a soil-function-oriented amendment for building healthier and more resilient agricultural systems.

## ABSTRACT

Biochar has been promoted as a soil amendment to enhance soil carbon sequestration and mitigate greenhouse gas emissions. However, biochars derived from different feedstocks exhibit substantial variation in carbon structure and inorganic nutrient composition, which may result in contrasting agronomic functions. In particular, manure-derived biochars with high ash and nutrient contents may act more as nutrient sources than contribute to carbon sequestration, raising questions regarding their sustainable use in agricultural soils. This study evaluated the effects of wood biochar (WB) and chicken manure biochar (CB) on crop yield under contrasting soil fertility conditions.

A two-year field experiment was conducted at two sites: a low-fertility upland soil cultivated with soybean and a high-fertility greenhouse soil cultivated with red pepper. WB and CB were applied at rates of 0, 1, 2, and 4 Mg $ha^{-1}$. To distinguish residual and cumulative effects, each plot was divided into one-year application followed by one-year residual effect (1/2y) and two consecutive applications (2/2y). Physicochemical characterization showed that WB had a well-developed carbon structure with high specific surface area (213 $m^2$ $g^{-1}$) and porosity (0.1295 $cm^3$ $g^{-1}$), whereas CB exhibited low porosity (0.0116 $cm^3$ $g^{-1}$) but contained high concentrations of available inorganic nutrients (citrate-soluble $P_2O_5$: 2.4%, water-soluble $K_2O$: 3.2%) and high electrical conductivity (50.1 dS $m^{-1}$).

Crop yields were evaluated after the second year. In the low-fertility soybean field, the optimum application rate of WB shifted to lower with increasing application frequency (1/2y: 1.83 Mg $ha^{-1}$, 2/2y: 1.06 Mg $ha^{-1}$). In contrast, CB considerably increased soybean yield with increasing application rate, and yield responses were further enhanced under the 2/2y treatment (4-1/2y: 2.9 Mg $ha^{-1}$, 4-2/2y: 4.1 Mg $ha^{-1}$), indicating a strong cumulative fertilizer effect. In the high-fertility red pepper greenhouse, WB showed an optimum application rate of 1-2 Mg $ha^{-1}$ under both application frequencies. CB increased red pepper yield with increasing application rate under the 1/2y treatment (1-1/2y: 5.1 Mg $ha^{-1}$, 4-1/2y: 5.9 Mg $ha^{-1}$); however, under consecutive application (2/2y), yield decreased with increasing application rate (1-2/2y: 6.6 Mg $ha^{-1}$, 4-2/2y: 5.7 Mg $ha^{-1}$). These results suggest potential stress effects related to nutrient accumulation or salinity.

Overall, WB might function as a buffering carbon-based amendment with indirect effects on crop yield, whereas CB acted as a nutrient-rich fertilizer whose agronomic benefits and risks depended on soil fertility and application frequency. These findings emphasize the need for feedstock-specific management strategies for the sustainable use of organic waste-derived biochars in soil fertility management.

**ABSTRACT**

Wood biomass combustion ash (wood ash) has high potassium (K) content, and its reuse as a fertilizer has attracted increasing interest in response to rising fertilizer prices. However, some types of wood ash also contain heavy metals such as Cr, and the behavior of heavy metals in soil after wood ash application remains insufficiently understood. This study aimed to characterize the physicochemical properties of different wood ashes and to evaluate their effects on elemental dynamics in soil solution and crop growth.

Three types of wood ash (A, B, and C) were characterized using X-ray diffraction (XRD), scanning electron microscopy with energy-dispersive spectroscopy (SEM–EDS) and titration test. Chromium speciation in wood ash A was further examined by X-ray absorption near-edge structure (XANES) analysis. A pot experiment was conducted using K-deficient Gray Lowland soil. Komatsuna (*Brassica rapa var. perviridis*) was grown with the application of ammonium sulfate (N: 100 mg), superphosphate ($P_2O_5$: 100 mg) and 1% wood ash. The treatments used NP and NPK fertilizer were conducted as control. Soil solution was collected during cultivation, above-ground dry biomass and elemental concentration in crops was determined following acid digestion and ICP–OES analysis.

The results showed that all wood ash contained abundant carbonate minerals and exhibited strong buffering capacity. XANES analysis indicated that Cr in the wood ash was present as 33% Cr(VI) and 67% Cr(III). Compared with NP treatment, all wood ash treatments increased K concentrations in both soil solution and crops, resulting in a 1.33–1.90-fold increase in above-ground dry biomass, demonstrating the effectiveness of wood ash as a K fertilizer. Concentrations of Cd and Zn in soil solution and crops decreased, with Cd levels reduced to below the Codex limit for leafy vegetables (0.2 mg $kg^{-1}$). The reductions in Cd and Zn were attributable to increased soil pH, which enhanced cation adsorption onto soil particles and promoted precipitation reactions. Although Cu and Cr concentrations increased in soil solution, their concentrations in crops decreased. This trend is consistent with a recent study by the authors (2025), which demonstrated that Cu and Cr form stable complexes with dissolved organic carbon at higher pH, thereby reducing their bioavailability to crops.

This research was supported by the Research and implementation promotion program through open innovation grants (JPJ011937) from the Project of the Bio-oriented Technology Research Advancement Institution (BRAIN). This work was also supported by the Project of Integrated Compost Science (PICS).

# From Waste to Resource: Stabilizing Nitrogen in Broiler Litter Using Granulated Lignite

**Clayton R. Butterly[1*], Brendon Costello[1], and Deli Chen[1]**

*[1] School of Agriculture, Food & Ecosystem Sciences, Faculty of Science, The University of Melbourne, Parkville Campus, Melbourne, Australia* *clayton.butterly@unimelb.edu.au

**ABSTRACT**

The sustainable management of global nutrient cycles is central to the congress theme *Advances in Soil Fertility Management Through the Utilization of Organic Waste*. As global population growth intensifies pressure on food systems, maintaining a livable planet will depend on improving the recovery and reuse of carbon and nutrients from organic waste streams. It is estimated that 2.6 million tonnes of organic waste are generated globally each day, accounting for over 40% of total waste by mass (ISWA, 2020). Rich in organic carbon and essential plant nutrients, these materials represent a critical opportunity to enhance soil health and build climate-resilient cropping systems.

In intensive animal production systems such as broiler housing, more than half of the nitrogen (N) excreted by birds can be lost prior to waste collection, primarily through ammonia ($NH_3$) volatilization. These losses reduce the nutrient density, economic value, and fertilizer potential of broiler litter. In addition, land application of untreated litter can contribute to environmental nitrogen losses via leaching and surface runoff. Stabilizing N in broiler litter is therefore a key prerequisite for developing a circular agricultural waste economy.

Lignite, an abundant and low-cost brown coal resource in south-eastern Australia, has emerged as a promising amendment for sustainable organic waste management. When incorporated into broiler bedding, lignite reduces $NH_3$ volatilization, suppresses microbial activity, slows litter decomposition, and lowers odor emissions. However, conventional run-of-mine lignite is high in moisture content, dusty, bulky, and difficult to distribute, limiting commercial adoption. To overcome these constraints, a granulated lignite formulation has been developed for practical on-farm application.

This presentation reports commercial-scale testing of a lignite granule in broiler housing, compared with powdered lignite and a no-lignite control. We quantify the impact and elucidate the mechanisms underpinning N stabilization in lignite-fortified broiler litter using various techniques ($^{15}N$ tracer, $NH_3$ and greenhouse gas fluxes via Picarro G2509, odor via olfactometry). Results demonstrate enhanced nutrient retention, reduced mass loss and odor emissions, and improved litter quality relative to conventional management. Overall, lignite-fortified waste streams provide a superior feedstock for high-value organo-mineral fertilizers, supporting improved nutrient use efficiency, soil health, and climate-resilient agriculture.

# Regulation of Humification and Nitrogen Retention during Organic Waste Composting by Compound Microbial Agents

**Fan Luo[1*], Zhong-yuan Li[1] and Xing Chen[1]**

*[1] CSCEC 8TH division environmental technology co.,ltd. (Shanghai, China)*

**ABSTRACT**

Compost application of organic waste to soil is an important approach to achieve resource recycling and improve soil fertility. However, low humification efficiency and severe nitrogen loss remain key bottlenecks restricting its high-efficiency utilization. This study used food waste and crop straw as typical raw materials, focusing on the key mechanisms and technical optimization of humification regulation by compound microbial agents, and established an integrated technical system of "raw material pretreatment - targeted inoculation of functional agents - precise regulation of composting process". Through screening brown-rot fungi (BRF) and cellulolytic nitrogen-fixing bacteria (CNFB) to construct a high-efficiency compound microbial community, the effects of key parameters such as microbial agent ratio and carbon-to-nitrogen (C/N) ratio on compost humification process and nitrogen retention efficiency were systematically investigated. Combined with three-dimensional excitation-emission matrix fluorescence spectroscopy (3D-EEM) and functional gene sequencing technologies, the microscopic regulatory mechanisms of the compound microbial agent in promoting Maillard/polyphenol humification pathways and inhibiting denitrification were clarified.

The results showed that the compound microbial agent with optimized ratio could extend the high-temperature phase of composting by 3-4 days and significantly enhance the humification process: the content of humic acid (HA) in the compost product increased by more than 30%, and the humification index (HA/FA) reached above 6.2. Meanwhile, it effectively inhibited nitrogen loss by 20% and increased the available phosphorus content by 15%-25%. Verification by field plot experiments showed that after applying the compost product to farmland, it could significantly improve soil aggregate structure, enhance soil microbial community activity, and promote the absorption of nitrogen and phosphorus nutrients by crops, with the absorption efficiency increased by 12%-18% respectively.

Through the enhancement of microbial functional synergy, this study achieved the organic integration of efficient resource transformation of organic waste and enhancement of soil fertility. The constructed technical process is simple, controllable and easy for short-term transformation, providing a precise technical scheme for the local return of agricultural organic waste to the field and the reduction and substitution of chemical fertilizers. It is of great significance for promoting green and sustainable agricultural development and ensuring soil ecological security.

**ABSTRACT**

Palm Oil Mill Effluent (POME) is an organic liquid effluent generated during the production of Crude Palm Oil (CPO) and Palm Kernel Oil (PKO) in a Palm Oil Mill. In oil palm plantations, POME is applied to the plantation and is able to fully substitute for synthetic fertilizer. This study aimed to compare plant and soil nutrient contents in oil palm plantations with and without the application of POME. The research was conducted on an oil palm plantation on mineral soils in Paser Regency, East Kalimantan, Indonesia, using two treatments: blocks treated with POME (8 blocks) and blocks without POME (8 blocks), where synthetic fertilizers served as the primary nutrient source. Each block covered 30 hectares and had a planting density of 136 trees per hectare, comprising palms planted in 2008 and 2009. Leaf nutrient contents (N, P, K, Ca, Mg) were analyzed annually in 2018, 2019, 2020, 2022, and 2023, while soil analyses were conducted in 2017 and 2022. The nutrient content of POME (pH, P, K, Ca, and Mg) was also analyzed in the laboratory, after the sample was collected from the Contact Pond. Statistical analyses were performed using t-tests or Wilcoxon tests for non-normally distributed data. Results showed that leaf nutrient content in 16- and 17-year-old palms, both with and without POME application, remained within the optimum range. No significant differences were observed in leaf N, K, and Mg contents in 17-year-old palms, nor in soil nutrient status, with acidic soil pH values of 4.58–5.34 and organic carbon contents ranging from 0.80–1.20%. Similarly, in 16-year-old palms, leaf nutrient contents (N, P, K, Ca, Mg) remained optimum with no significant differences between treatments. Soil pH in both treatments was acidic (4.55–5.33), with organic carbon contents of 1.03–1.55%. However, Ca and Mg levels were higher in soils treated with synthetic fertilizers, likely due to the application of dolomite. The nutrient analysis of POME indicates a very high available nutrient content, with available P at 469 ppm and exchangeable K and Ca at 1506 ppm and 149 ppm, respectively. Meanwhile, the pH of POME discharged into palm oil plantations is 8.78. These findings demonstrate that the application of POME in oil palm plantations promotes circular agricultural practices, reduces reliance on synthetic fertilizers, and mitigates greenhouse gas emissions, thereby contributing to sustainable agriculture.

# FUNGAL CONSORTIUM ASSISTED COMPOSTING FOR RAPID STABILIZATION OF POULTRY LITTER

**Thiyageshwari Subramanium [1],* Hemavarshini Muthulakshmi Pandi[2], Selvi Duraisamy [3]and Anandham Rangasamy [4]**

[1,2&3]*Department of Soil Science & Agricultural Chemistry, Tamil Nadu Agricultural University, Coimbatore, India*

[4]*Department of Agricultural Microbiology, Tamil Nadu Agricultural University, Coimbatore, India*

*E-mail: thiyageshwari@tnau.ac.in

**ABSTRACT**

The rapid expansion of the poultry industry has led to the continuous accumulation of poultry litter, a heterogeneous organic residue composed primarily of manure, bedding materials and feed remnants. Inadequate management or disposal of this waste stream can result in nutrient leaching, offensive odour generation and greenhouse gas emissions, thereby posing significant environmental and public health concerns. Aerobic composting is widely regarded as a sustainable strategy for stabilizing poultry litter and converting it into a nutrientrich organic amendment; however, the process is often slow and suboptimal because of the structural complexity and recalcitrant nature of the substrate, poultry liiter. The targeted application of microbial consortia as bioinoculants has therefore emerged as a promising approach to accelerate composting dynamics and improve the quality of the final product.In the present study, three fungal isolates, *Trichoderma* sp., *Phanerochaete* sp. and *Pleurotus* sp., were evaluated for their suitability as composting inoculants. Compatibility testing demonstrated that all three isolates were mutually compatible, thereby enabling their formulation as a single fungal consortium. This consortium was incorporated at 3% (v/w) into freshly collected poultry litter and subjected to aerobic composting for 45 days. Moisture content was maintained within the optimal range, and the composting mass was periodically turned to ensure adequate aeration and sustain microbial activity throughout the process.Composting performance and maturity were assessed using a suite of physicochemical maturity indices and bioassay- based indicators. The E4/E6 absorbance ratio decreased from 4.85 in the uninoculated control to 3.32 in the consortiumtreated compost, signifying accelerated humification and more efficient transformation of organic matter. Maize seed germination assays recorded 100% germination in the consortium treatment, compared with 83.33% in the control, indicating a marked reduction in phytotoxicity and enhanced suitability of the compost for plant growth.Furthermore, starch iodine testing confirmed that the inoculated compost retained the light yellow iodine colour, indicating complete polysaccharide degradation, whereas the immature compost developed a brown colour due to residual carbohydrates.Overall, the findings indicate that a fungal consortium comprising *Trichoderma* sp., *Phanerochaete* sp. and *Pleurotus* sp. can substantially accelerate the composting of poultry litter, promote humic substance formation and yield mature, safe compost within 45 days. This bioaugmentation strategy offers considerable potential for the sustainable management and valorization of poultry waste, with broader implications for improving soil fertility, supporting organic fertilizer production and advancing circular bioeconomy frameworks.

## ABSTRACT

The availability of nutrients from steer manure composts (SMC) for crop growth is a complex interaction of soil environment and biogeochemistry with agricultural management. SMC has been used in both irrigated silage maize and dryland organic wheat systems to supply nutrients and improve soil health in long-term experimental plots in the semi-arid environment of northern Utah, USA. These soils are calcareous with high buffering capacities. The irrigated silage maize study was conducted for a decade comparing N fertility sources using a CRB design with four treatments: control with no N fertilizer, ammonium sulfate at 112 kg N $ha^{-1}$(AS112), at 224 kg N $ha^{-1}$ (AS224) and SMC at 224 kg total N $ha^{-1}$. Fertilizer P and K were applied according to preseason soil testing. Silage corn yield, N uptake, N use efficiency (NUE), N cycling and soil health indicators had variable responses across years emphasizing the importance of multi-season studies. Yield under SMC exhibited a notable 41% increase compared to control but was approximately 31% lower than the average yield under AS treatments. AS112 achieved a yield comparable to AS224 and demonstrated higher NUE. SMC significantly enhanced soil total N and soil organic C by 23%. Repeated applications of SMC decreased need for supplemental NPK fertilizers. While AS fertilizers proved effective in achieving higher silage corn yields and NUE compared to compost treatment, SMC enhanced soil C and N and soil health indicators. Our observations highlight interactions between soil C and N and the responsiveness of active organic matter pools and enzyme activities on nutrient supplies. Farmers are encouraged to adopt a balanced approach, incorporating compost alongside fertilizers and implementing soil health practices for sustainable silage corn systems.

In organic dryland wheat systems, yields are limited by irregular rainfall, low soil organic matter, and minimal nutrient availability. A 30-year field study in Snowville, Utah, USA examined the legacy effects of a single large SMC application (50 Mg $ha^{-1}$) applied once in 1994. Persistent improvements in soil fertility and wheat yield were observed over decades, although we still have a limited understanding of the microbial communities driving these benefits. To better understand the mechanisms underlying these persistent benefits, a complementary experiment was established in 2021 to examine the effects of amendments of varying lignin content and C:N ratio: Hardwood Compost, Softwood Compost, SMC and Wheat straw with and without Feather Meal on wheat yields, NPK and microbial communities. Both nutritive and non-nutritive benefits of the SMC were observed in these dryland organic wheat systems. Understanding the longevity of the benefits of composts applications in these resource limited systems is driven by both the biogeochemistry of the composts themselves and the availability of moisture at critical times in the wheat growth cycle.

# Safeguarding global nitrogen sustainability by managing organic waste throughout the food supply chain

**Jingfang Zhan[1,2*], Yiyang Zou[1,2], Xin Xu[1,2], Baojing Gu[1,2,3]**

**ABSTRACT**

Organic waste generates substantial nutrient losses and reactive nitrogen ($N_r$) emissions, severely undermining global nitrogen sustainability. However, the specific impacts of various organic waste streams across the full food supply chain (FSC) remain poorly characterized. Here, by integrating a Coupled Human and Natural System (CHANS) model with global FSC datasets, we quantify nutrient losses and $N_r$ emissions from organic waste across 159 countries. Our results show that in 2020, global food loss and waste (FLW) resulted in 34.6 Tg N of $N_r$ emissions and 32.5 Tg N of nutrient losses—equivalent to 29% of total food-system $N_r$ emissions and 43.5% of the global food nutrient supply. Other organic wastes (e.g., crop residues, manure, and sewage) totaled 132.1 Tg N, of which 33.0% was managed inefficiently, contributing an additional 4.8 Tg N to $N_r$ emissions. We find that when accounting for the entire FSC, the full-chain nitrogen use efficiency ($NUE_{fc}$) drops to a mere 8% globally, with significant regional heterogeneities driven by agricultural NUE, FLW rates, dietary patterns and trade patterns. Notably, nitrogen losses embedded within the FSC are nearly four times higher than those occurring at the waste management stage, suggesting that improving end-of-pipe treatments alone offers limited mitigation potential (~6.3%). In contrast, an integrated strategy—comprising halving FLW, maximizing resource recovery, adopting plant-based diets, and optimizing trade distributions—could reduce FSC $N_r$ emissions by 26.0 Tg N (~24.8%) and nearly double the $NUE_{fc}$ to 14.7%. These findings highlight the critical need for holistic FSC interventions to safeguard global nitrogen and nutrient sustainability.

# The potential of organic waste recycling to replace mineral fertilizers in EU Member States

**Donghao Xu[1]*, Gerard H. Ros[1], Wim de Vries[1]**

*[1] Wageningen University and Research, Earth Systems and Global Change Group, PO Box 47, 6700AA Wageningen, the Netherlands*

*donghao.xu@wur.nl

**ABSTRACT**

Nitrogen (N), phosphorus (P) and potassium (K) inputs to soil by mineral fertilizers and organic sources (manure, sewage sludge and biowaste) differs among EU member states, ranging from inadequate inputs to deplete the soils to inefficient applications leading to nutrient losses [1]. Besides their supply N, P and K, organic resources also supply carbon and other major nutrients thereby improving soil fertility [2]. European policies thus promote nutrient recycling to decrease the dependency on imported mineral fertilizers produced outside Europe [3]. In addition, the mineral fertilizer supply can be reduced by balancing the nutrient supply to the crop nutrient demand.

Yet the potential of organic waste recycling to replace mineral fertilizers across Europe remains insufficiently quantified. Using country-level statistics on livestock and crop production, human population and biowaste generation, we estimated (i) currently (2020-2022) applied and the potentially recoverable nutrients under existing and improved nutrient recovery technologies in 27+3 member states in Europe, and (ii) the potential of organic waste recycling to replace mineral fertilizers based on crop demand assuming balanced fertilization.

Results show that potential nutrients in : (i) manure are 5525 ktons N, 1375 ktons P and 4737 ktons K, of which 72%, 75% and 70% is currently applied in arable land, respectively (the rest is applied in grassland), (ii) sewage sludge are 2698 ktons N, 523 ktons P and 572 ktons K, of which 5%, 18% and 3% is currently used in agriculture, respectively and (ii) biowaste are 795 ktons N, 159 ktons P and 477 ktons K, of which 51%, 32% and 46% is currently used in agriculture, respectively.

Assuming balanced N, P and K input based on crop demand, while maintaining the current organic nutrient supply already reduced current fertilizer use by 20%, 11% and 14% for N, P and K, respectively. When in the future all new and best treatment nutrient recovery technologies are applied, and all organic nutrients are recycled, then the fertilizer use can be reduced by 49%, 61% and 34% for N, P and K fertilizer, respectively compared to the current use.

Our findings highlight the substantial potential of organic nutrient recycling to reduce mineral fertilizer dependency in Europe, supporting policy development for nutrient circularity while safeguarding soil quality and environmental health.

## ABSTRACT

Recycling organic waste into agricultural soils is a key strategy for circular nutrient management, improved soil fertility, and climate resilience. However, agronomic and environmental outcomes depend strongly on waste processing pathways, soil context, and potential greenhouse gas (GHG) trade-offs. This presentation synthesizes incubation, greenhouse, and field studies to evaluate how organic waste-derived soil amendments regulate nutrient availability, soil biological processes, and nitrous oxide ($N_2O$) emissions across contrasting soils and environmental conditions.

Incubation experiments show that thermochemically processed organic wastes substantially reduce $N_2O$ emissions compared with direct waste application, with effectiveness depending on soil texture and processing conditions, underscoring the need of pre-application screening. Field studies indicate that processed waste-derived amendments can lower $N_2O$ emissions relative to untreated organic waste without compromising crop yield, although whole-season climate metrics may not diverge in short-term assessments. From a soil fertility perspective, untreated organic waste resulted in the highest phosphorus uptake and use efficiency in a greenhouse study, while microbial indicators - particularly fungal and arbuscular mycorrhizal fungi markers - emerged as key drivers of nutrient acquisition. In addition, mineral-rich waste-derived amendments demonstrated potential to enhance crop performance under drought stress, linking organic waste recycling with climate-resilient agroecosystem management.

Overall, effective use of organic waste-derived amendments requires integrating waste processing strategies with soil-specific evaluation of nutrient cycling, biological mediation, and GHG risks to maximize soil fertility benefits while minimizing unintended environmental impacts.

# The effects of different crop straw retention modes and nitrogen fertilizer rates on nitrogen runoff loss, crop yield and soil fertility in rice-wheat cropping systems

**Dejain Wang[1*], Shijie Zhang[2], and Gang Zhang[1]**

[1] *Institute of Soil Science, CAS, Nanjing, China*

*School of Agriculture and Biomanufacturing, Zhengzhou University*

*djwang@issas.ac.cn

**ABSTRACT**

The Crop straw retention has been established as an effective conservation tillage practice for decreasing nitrogen (N) runoff losses and increasing crop production. However, the impacts on N runoff losses from annual rice-wheat rotation are not well understood, which has prevented identification of optimal straw retention practice. Herein, N dynamics and losses in the runoff, crop yields, and soil properties were assessed for two years in a rice-wheat system after implementing straw return for five consecutive years. The field experiment included 7 treatments—N2, WN2, RN2: recommended N application with no straw, wheat straw, and rice straw retained, respectively; and SN0, SN1, SN2, and SN3: both wheat and rice straw return with zero, reduced, recommended, and custom N addition (0, 180, 240, and 300 kgN/ha for rice), respectively. The results showed that total N loss (TN, $P < 0.001$) and mean annual crop yield (rice and wheat, $P < 0.01$) significantly increased as the N fertilizer rate increased. With respect to crop straw retention modes, the cumulative TN loss and mean annual crop yield trends were: N2 > RN2 >WN2 >SN2 ($P < 0.05$) and SN2≥RN2 >WN2≈N2 ($P < 0.05$), respectively. During a one-year rice-wheat rotation cycle, the treatments with simultaneous incorporation of crop residue and N fertilizer reduced N runoff loss by 2.7–20.9% ($P < 0.05$) and increased crop yield by 8.7–16.9% ($P < 0.05$), of which the SN2 treatment was found to be the most effective. The straw-induced reducing effect occurred only during the base and tiller fertilization stages of the rice growing period, which was primarily regulated by soil inorganic nitrogen (SIN), soil organic carbon (SOC), and pH during the rice tiller stage. Structural equation modelling revealed that SIN ($r = 0.53$, $P = 0.007$) had the most direct positive effect on N runoff loss, but the effect was statistically compromised by the overall negative effects of SOC ( $r = -0.33$, $P = 0.034$), pH ($r = -0.15$, $P > 0.05$), and bacterial community composition ($r = -0.10$, $P = 0.041$), and to a less extent by α-diversity ($r = -0.04$, $P > 0.05$). The SOC, TN and available-K content in the RN2 and SN2 treatments were respectively 20.7–24.7% and 16.1–15.7% and 33.3–49.4% higher than those in the N2 treatment ($P < 0.05$). And both SOC and TN also showed an increasing trend as the N fertilizer rate increases. Our findings indicate that straw return decreases N runoff loss by mediating factors in soil and standing water. In order to reduce N runoff loss without jeopardizing crop yield, the practice of double seasons straw retention with recommended N application (SN2) is suggested in the rice-wheat rotation cropping system in southern China.

# Repurposing Lake Sediments as a Sustainable Phosphorus Source for Spring Barley: A Case Study in Denmark

**Andressa Morato Freitas[1*], Antonio M. M. Silva[1], Anna-Marie Klamt[1], Edzard van Santen[2] and Kasper Reitzel[1]**

[1] *University of Southern Denmark (Department of Biology, Odense, Denmark)*

[2] *University of Florida (Agronomy Department, Institute of Food and Agricultural Sciences, Gainesville, United States)*

*andressa@biology.sdu.dk

**ABSTRACT**

Phosphorus (P) scarcity in agriculture and persistent eutrophication of freshwater ecosystems are two interconnected challenges. Lake sediment removal is often required to restore eutrophic lakes, as internal P loading from sediments can delay recovery even after external inputs are reduced. Repurposing dredged lake sediment for agricultural use offers a dual benefit: supporting lake restoration while providing an alternative P source for crop production. In recent years, the use of lake sediments as a soil amendment has increased, driven by sustainability goals and restoration incentives. However, its effectiveness as a fertilizer remains uncertain due to low P solubility and the limited number of field-based studies evaluating its agronomic performance.

Preliminary analyses indicate that a large portion of sediment P is bound to iron (Fe), limiting plant availability. Phosphorus-solubilizing microorganisms (PSMs) have therefore been proposed as a strategy to enhance P availability through the release of organic acids and enzymes that mobilize Fe-bound P. Beyond increasing plant-available P, PSMs may also provide additional benefits, such as promoting root growth, hormone-mediated stimulation, and improved soil structure, potentially enhancing the agronomic value of lake sediment.

This study evaluates the agronomic potential of lake sediment, alone and in combination with PSMs, using spring barley (*Hordeum vulgare* L.) under Danish field conditions as part of a three-year field experiment. Here, we present results from the first growing season. The experiment compares two P application strategies: (i) an annual application of 30 kg P $ha^{-1}$ on a total P basis, and (ii) a single application of 90 kg P $ha^{-1}$ followed by no additional P input for three years, both consistent with regulatory limits. Treatments include lake sediment, triple superphosphate (TSP), and control plots, each applied with or without PSM-coated seeds.

The objectives of the first-year assessment are to (i) evaluate the capacity of lake sediment, with and without PSMs, to function as an effective P fertilizer, (ii) assess the potential role of microorganisms in supporting crop growth and yield, and (iii) compare crop yield responses under different P dosing strategies. These initial results provide insight into the short-term agronomic performance of lake sediment-based fertilizers and inform expectations for subsequent years of the study.

**ABSTRACT**

Nitrogen (N) management remains a critical challenge in rice-based systems, especially across South Asia, where fertilizer use is the highest, yet nitrogen use efficiency (NUE) remains persistently low. This study integrates a comprehensive review of 60 fertilizer management mobile applications (30 from South Asia and 30 beyond South Asia) with a field experiment evaluating app-guided and crop-responsive N strategies in two consecutive seasons of Boro rice cultivation. App profiling revealed the dominance of static calculators and generic advisories, with limited use of real-time diagnostics or crop-stage-specific logic. In contrast, field results showed that dynamic leaf-based tools Leaf Color Chart and SPAD chlorophyll meter achieved comparable yields to conventional and app-based methods, while significantly improving agronomic and recovery efficiencies of N. These tools enable precise, demand-driven N applications and reduce input use without compromising productivity. The findings underscore the crucial need to digitize physiologically aligned decision tools into mobile platforms, enabling real-time, field-specific N recommendations for smallholders. Such innovations can transform N management by enhancing NUE, reducing N losses, and improving environmental sustainability. This study calls for the development of next-generation, image-enabled, crop-stage-responsive N advisory apps tailored to smallholder realities. Policymakers should prioritize the development and dissemination of sensor-integrated fertilizer advisory apps to boost NUE, reduce emissions, and promote sustainable intensification of rice cultivation systems, particularly in high-input, low-efficiency regions like South Asia.

**ABSTRACT**

【Objective】 The overall phosphorus balance in Chinese farmland shows a trend of surplus, which is continuously intensifying. This study aims to investigate the effects of different crop rotation phosphorus fertilizer application ratios, reduction ratios, and reduction methods on phosphorus fertilizer use efficiency and soil quality.【Method】From October 2015 to September 2018, a year-round phosphorus fertilizer optimization experiment was conducted under a wheat–corn rotation system on two selected sites in Dezhou, Shandong Province: one high-phosphorus and one low-phosphorus field. The experiment was designed as a randomized block trial, with five treatments and three replicates. The treatments included: no phosphorus fertilizer throughout the year (P0), two-thirds of the annual phosphorus fertilizer applied during the wheat season and one-third during the corn season (CK), half of the annual phosphorus fertilizer (P0.5), phosphorus fertilizer applied every other year (P biennial), and phosphorus fertilizer applied only during the wheat season (P1). During each wheat and corn harvest season, plant and soil samples were collected to analyze crop phosphorus content, phosphorus fertilizer uptake and utilization, and soil available phosphorus content. Soil available phosphorus content was measured annually at depths of 0–20 cm, 20–40 cm, and 40–60 cm to analyze phosphorus variations across different treatments, soil depths, and rotation years.【Conclusion】 The experimental results indicate: (1) For fields with initially high soil phosphorus content, reduced phosphorus application can meet the phosphorus nutrient requirements of the aboveground parts of crops. A single concentrated fertilization during the wheat season can enhance the annual grain phosphorus uptake in high-phosphorus areas; (2) Compared with conventional phosphorus application, reducing phosphorus by half in high-phosphorus areas can increase phosphorus fertilizer recovery efficiency by 48.21% and phosphorus fertilizer partial productivity by 54.05 kg/kg. Under alternate-year phosphorus application, phosphorus recovery efficiency can be increased by 45.64%, phosphorus fertilizer partial productivity by 41.31 kg/kg, and agronomic efficiency by 1.68 kg/kg. Concentrated phosphorus application during the wheat season can increase the annual phosphorus fertilizer yield contribution rate by 6.13% and improve agronomic efficiency by 3.17 kg/kg; (3) In low-phosphorus areas, reducing phosphorus by half can increase phosphate fertilizer utilization rate by 34.32% and phosphorus fertilizer partial productivity by 35.10 kg/kg. Alternate-year fertilizer application can improve phosphorus recovery efficiency by 30.79% and phosphorus fertilizer partial productivity by 32.18 kg/kg. Concentrated phosphorus application during the wheat season can raise the annual phosphorus fertilizer yield contribution rate by 1.03%; (4) From the perspective of available phosphorus supply in the 0–20 cm plow layer, reducing phosphorus by half, alternate-year application, and concentrated wheat season application in high-phosphorus areas can fully meet nutrient requirements for two rotation cycles. However, a decrease in yield may occur from the third rotation cycle and subsequent maize seasons; (5) In low-phosphorus areas, alternate-year phosphorus application has effects on available phosphorus in the plow layer that are generally consistent with conventional phosphorus application, whereas reducing phosphorus by half or concentrated wheat season application may lead to insufficient soil phosphorus supply during some maize seasons in the rotation cycles.

**ABSTRACT**

The substitution of organic fertilizers for chemical fertilizers has become a pivotal strategy for achieving a balanced nutrient supply and ensuring high, stable yields in maize and other crops. Although this approach has shown marked success in many regions, its long-term effects on soil quality and the mechanisms underlying its enhancement of crop growth remain unclear. Accordingly, a seven-year field experiment (2017-2023) was conducted in a typical subtropical red soil region of China to evaluate the long-term effects of organic fertilizer substitution on soil quality, maize yield, and nutrient use efficiency (NUE and PUE). The experiment applied five treatments: no fertilization (CK), chemical fertilizer (CF), and organic fertilizer substituting 20%, 40%, and 100% of chemical N (COF20%, COF40%, COF100%). The results showed that all fertilized treatments significantly improved the soil quality index (SQI) and maize yield compared with CK. Among these, COF20% and COF40% achieved the highest SQI and yield, increasing SQI by 54.52-115.56% and yield by 329.97-599.15%. From 2022 to 2023, soil properties and crop indices remained relatively stable ($p > 0.05$). Structural equation modeling indicated that improvements in soil organic matter (SOM), total phosphorus (TP), available phosphorus (AP), and hydrolyzable nitrogen (HN) were the main drivers of SQI enhancement and yield increase. These factors also promoted nitrogen and phosphorus utilization efficiency. Overall, partial substitution with organic fertilizer, especially COF20%, robustly enhanced soil fertility, nutrient use efficiency, and maize yield in a cost-effective manner. This strategy provides a viable pathway for fostering sustainable and resilient agricultural systems in upland regions.

# Evolution characteristics of soil phosphorus and its availability under long-term fertilization in black soil region, China

**Xing-zhu Ma*, Xiao-yu Hao, Yue Zhao, and Bao-ku Zhou**

*Heilongjiang Academy of Black Soil Conservation and Utilization (Heilongjiang Academy of Agricultural Sciences, Harbin 150086, China)*

*maxingzhu@163.com

**ABSTRACT**

Based on the long-term fertilizer experiment in Harbin, Heilongjiang Province, China(1979~2021), to study the evolution characteristics and availability changes of phosphorus (P). Contents of soil total phosphorus (TP) and Olsen phosphorus (Olsen-P) and their linear regressions were analyzed and calculated. The results showed that contents of TP and Olsen-P under treatments of phosphorus fertilizers (P, NP, PK, and NPK) increased significantly after 42 years of fertilization, with an average increase of 0.73g/kg and 77.6 mg/kg, respectively, compared to the initial content. While, contents of TP and Olsen-P decreased with the extension of fertilization years under treatments of no P fertilizer (CK, N, K, and NK)(with reductions of 18.3% and 53.6%, respectively). P availability coefficient (PAC) showed yearly declining trends under treatments of no P fertilizer, but had increasing trends with P fertilizer. The PAC of P fertilizer treatments were higher than that under treatments of no fertilizer and no P fertilizer. Soil Olsen-P increment after P application was positively correlated with the accumulated of P. For every P of 100 kg/ha surplus in the soil,Olsen-P increased by 2.34 mg/kg, 2.96 mg/kg, 1.82 mg/kg and 2.89 mg/kg in treatments of P, NP, PK and NPK. When the soil P balance was in deficient, the Olsen-P content under treatments of CK, N, K and NK would be decreased by 1.17 mg/kg, 0.87 mg/kg, 0.83 mg/kg and 1.16 mg/kg for every deficiency of P 100 kg/ha, respectively. In general, the application of P fertilizer could increase contents of soil TP and Olsen-P totally, with PAC being overall higher than treatments of no fertilizer or P fertilizer. Increment of Olsen-P varied closely with the change of soil P balance. The rational application of P fertilizer is of great significance for maintaining soil P surplus and increasing its availability in black soil regions.

# Nutrient status and fertility constraints of highly weathered oil palm-growing soils in Thailand

**Pornpavee Somkiatikul[1*], Daojarus Ketrot[1], and Worachart Wisawapipat[1]**

[1] *Department of Soil Science, Faculty of Agriculture, Kasetsart University, Bangkok 10900, Thailand*

*E-mail Address of Presenting Author: pornpavee.som@ku.th

**ABSTRACT**

Oil palm (*Elaeis guineensis* Jacq.) is a major economic crop, with Indonesia, Malaysia, and Thailand producing 86% of the global supply (FAO, 2023). This study evaluated the nutrient status and main fertility constraints of soils used for mature oil palm plantations (5–17 years old) in Surat Thani province, southern Thailand. Composite surface soils (0–20 cm) from representative Typic Kandiudults (OP1 and OP2), Typic Paleudults (OP3 and OP4), and a Sulfic Endoaquepts (OP5) were analyzed for texture, pH (1:1 $H_2O$), electrical conductivity (ECe), organic matter (OM), cation-exchange capacity (CEC), available P, and extractable K, Ca, Mg, and B using standard methods (Soil Survey Staff, 2014; FAO, 2024).

Soil properties varied markedly across sites. Texture ranged from sandy loam in OP1–OP4 to silty clay in OP5, showing contrasting nutrient-retention capacities. All soils were ultra-acid to very strongly acidic (pH 3.28–4.58), which decreases nutrient availability and promote base-cation leaching. ECe values ranged from 0.43 to 2.31 dS $m^{-1}$, indicating non-saline conditions. OM was low to moderate (7.79–17.8 g $kg^{-1}$) in OP1–OP4 but higher in OP5 (30.8 g $kg^{-1}$), consistent with CEC results, which ranged from very low to moderately low (2.50–7.50 $cmol_c$ $kg^{-1}$) in OP1–OP4 and were substantially higher in OP5 (22.5 $cmol_c$ $kg^{-1}$), reflecting differences in OM content and clay mineralogy. Available P varied widely (16.49–329 mg $kg^{-1}$), with the highest values in OP5, likely influenced by historical fertilizer use and enhanced P retention. Extractable K ranged from 60.8 to 1,096 mg $kg^{-1}$, while Ca (130–701 mg $kg^{-1}$) and Mg (29.3–237 mg $kg^{-1}$) were mostly low in OP1–OP4, indicating substantial leaching losses and base-cation depletion. Extractable B in OP1–OP4 (6.25–16.7 mg $kg^{-1}$) was uniformly high, consistent with soils receiving B fertilization, whereas OP5 showed an exceptionally high concentration (78.2 mg $kg^{-1}$), indicating substantial B accumulation due to heavy or repeated applications. Overall, these findings highlight major fertility constraints in oil-palm-growing soils and emphasize the need for targeted nutrient-management strategies to sustain productivity.

# Fertilizer Use and Nutrient Management in Indian Agriculture

**Suresh Kumar Chaudhari**
*Director General*
*The Fertilizer Association of India, New Delhi, India*
E-mail: dg@faidelhi.org

**ABSTRACT**

Fertilizer is the important component of agricultural development in the world and India is no exception. On all counts, accomplishment on the production of food grain front has paralleled the consumption of fertilizers since the 1960s in India. Government implemented policies from time to time to give impetus to fertilizer use.

Deterioration of soil health is considered as one of the main reasons of declining nutrient use efficiency *vis-à-vis* stagnation of agricultural productivity in tropical regions without exception of India. Post Green Revolution, sharp increase in the use of high analysis fertilizers to meet the nutrient demand of HYVs and decrease in use of organic manure due to shifting of animal-based farming to mechanized agriculture resulted in multi-nutrient deficiencies and deterioration of soil physical and biological health over the years. Organic carbon in soil is on decline. The fertilizer response ratio (kg grain per kg nutrient) decreased from 13.5 in 1960-69 to 5.0 in 2010-17) in irrigated areas of the country.

Systematic analysis of data from long-term fertilizer experiments showed that: complete recommended dose of fertilizers (RDF or 100% NPK) applied to soils initially low in soil organic carbon (SOC) (< 7 g $kg^{-1}$ soil) sustained productivity and significantly improved SOC content, indicating thereby protection to soil health. Contrarily, RDF failed to sustain productivity and SOC of soils initially high in its content (>7 g SOC $kg^{-1}$ soil). Integrated use of organic manures (equivalent to 25-30% of RDF) plus fertilizers (70% to 75% of RDF) raised productivity and level of SOC, irrespective of initial SOC content. Use of vermicompost, FYM and bio-fertilizers improves endophytic bacterial diversity compared to mineral fertilizers. Further, results of long-term experiments conducted from 1972 to 2002 at four locations of 4 states of India demonstrated that integrated use of recommended dose of 100% NPK with 5 MT FYM $ha^{-1}$ is necessary to enhance populations of bacteria, fungi and actinomycetes as the results were observed to be better than control, 100% N, 100% NP and 100% NPK. Balanced NPK was found to be better compared to N or NP.

Use efficiency of applied fertilizers is low. Promotion of better nutrient management strategy among the farmers is vital to improve soil health, farm productivity and to minimize the environmental footprints on sustainable basis. Conservation agriculture with its three basic principles of minimum soil disturbance, permanent soil cover, and crop rotation could be a viable option for meeting the targets of SDGs (Chaudhari et al., 2021).

To mitigate the adverse effect of climate change, Government of India and Indian Council of Agricultural Research (ICAR) has initiated several programs/schemes/research projects. Leveraging digital tools is poised to play a pivotal role in adoption of 4R Stewardship Principle of nutrient management involving application of Right Source, at the Right Rate, at the Right Time, and in the Right Place**.** The soil health & fertility scheme of the Government of India has emerged as a transformative intervention in Indian agriculture, laying the foundation for sustainable soil and nutrient management.

There is no much improvement in NUE in the country. All stakeholders namely the Government, research institutions and fertiliser industry are concerned for the ways and means to improve the NUE. Efforts like use of 100% neem coated urea; promotion of 100% water soluble fertilizers, micronutrients, bio-stimulants, liquid and customized fertilisers; impetus to new formulations; arena of Nano-based fertilizers undergoing rapid expansion through development of Nano urea and Nano DAP; promotion of bio-fertilizers, etc. would go a long way to improve NUE considerably. The country is on forefront to use N-(n-butyl) thiophosphoric triamide – a urease inhibitor, to improve use efficiency of applied urea.

**ABSTRACT**

Over the last century, inorganic fertilizers (also sometimes referred to as mineral or synthetic fertilizers) have played a key role in the food security of billions of people. Fertilizers supplied nutrients to crops on soils with insufficient natural supply and/or where organic fertilizers were not or too little available to sustain crop production. As such, inorganic fertilizers have closed the balance for the nutrients lost from fields as harvested biomass, leaching and emissions. Farmers across the world have therefore relied on fertilizers to increase crop yields over time yet the size of this contribution is uncertain. Quantification of fertilizers' contribution to food production will allow more informed nutrient management as well as identification of food system vulnerabilities to disruptions in the supply of fertilizer.

In this study, we used two approaches of estimating fertilizers contribution to food production worldwide, namely (1) a nutrient supply and (2) an agronomic nutrient use efficiency approach. These approaches were applied to elemental nitrogen (N), phosphorus (P) and potassium (K) in inorganic fertilizer applied to cropland worldwide. The Nutrient Supply approach assessed fertilizers contribution to food based on the share of total nutrient inputs provided as inorganic fertilizer using data from the FAO Cropland Nutrient Balance. The Agronomic efficiency approach used long-term (>5 year duration) experiments to derive the agronomic nutrient use efficiencies (AE; i.e. change in yield from the addition of fertilizer divided by the change in nutrients applied to the fertilized treatment), while accounting for soil legacy effects. The AE values were applied to surveyed data of fertilizer use by crop and country to estimate the additional quantity of crop production resulting from fertilizer. Estimates of crop production from fertilizer were divided by the total quantity of crop production per region to estimate fertilizers' contribution to food.

Using the Nutrient Supply approach we estimated that, on average over the 1961-2022 period, N, P and K fertilizers accounted for 50%, 70% and 40% of the total cropland N, P and K inputs, respectively. Inorganic fertilizer as a share of total inputs increased steadily since 1961, but its share varied widely by countries and regions. The exception to this was for N whose change in share of total inputs plateaued in the last ~ 30 years. Estimates of fertilizers' contribution to food production using the agronomic efficiency approach were generally lower than those estimated using the nutrient supply approach, with the greatest contributions estimated for Asia and the lowest contributions for Africa. Results of our two methods of estimating fertilizers' contribution to food production should be accounted for when policy-makers consider making changes to fertilizer policies.

**ABSTRACT**

Achieving high crop yields requires an adequate supply of essential mineral nutrients, yet global attention and research investment have remained disproportionately focused on nitrogen and phosphorus compared to other macronutrients such as potassium (K) and sulfur (S). Intensification of farming systems, characterized by higher crop yields and depletion of native soil reserves, exacerbate current K and S limitations to crop production. In this study, we assessed the degree of K limitation in major agroecosystems worldwide and investigated the underlying drivers. Our approach integrates global datasets collected after 2000, including soil K measurements (n = 3.6 M), on-farm K balances (n = 111,000), and yield responses to K fertilizer in short -term experiments (n = 66,300), complemented by crop modeling and statistical analysis. Cropping systems were classified into four groups based on K balance status and yield responsiveness to fertilizer. The first group includes systems where K addition is not common, yet crop responsiveness and negative K balances (-39 kg K $ha^{-1}$ $y^{-1}$) are increasing (e.g., South American Pampas and western US Corn Belt). The second includes systems where yield response to K fertilizer is widespread, but K balances remain negative (-27 kg K $ha^{-1}$ $y^{-1}$) due to insufficient fertilization, high cropping intensity, and straw removal (e.g., south and southeast Asia). The third represents systems where soil K supply is insufficient for crop demand, but current K inputs appear sufficient or excessive relative to present yields (e.g., Brazilian Cerrado and China). The last group includes low-input, low-yield regions where K limitation was inconsistent, likely due to limitation by other factors (e.g., Sub-Saharan Africa). The economic analysis shows that K fertilizer application is profitable (285 US$ $ha^{-1}$ $y^{-1}$) in the second and third group (e.g., south and southeast Asia and China). Our study also shows that global K fertilizer requirement will increase from 14 to 24 MMT for a scenario of crop intensification where current crop yields reach 80% of yield potential. Because crop residue removal greatly affects K outputs, the K input needed to sustain attainable yields would increase to 33 MMT if residue removal increases from the current 41% to 75% in the future. Building on the same data-driven analytical framework, we are conducting a parallel global assessment of sulfur limitation. Preliminary S results indicate increasing risk of S deficiency in areas with reduced atmospheric deposition, intensified crop removal, and limited S fertilization. Overall, our findings highlight that soil K and S supply is seldom adequate to sustain current yields, and that closing global yield gaps will require improved K and S management strategies tailored to regional production systems.

**ABSTRACT**

Durian (*Durio zibethinus* Murr.) is one of Thailand's most economically important tropical fruit crops, yet long-term continuous cultivation has raised concerns about soil nutrient imbalance and phosphorus (P) accumulation. This study aimed (1) to assess the soil nutrient status of durian orchards cultivated for more than 25 years under an organic–chemical mixed management system, and (2) to quantify P residues resulting from long-term fertilization. Soil samples were collected from farmer orchards in Thung Bencha Subdistrict, Tha Mai District, Chanthaburi Province, at two depths (0–20 and 20–40 cm) beneath four cultivars (Chanee, Puangmanee, Monthong, and Kanyao). Samples were analyzed for texture, pH, electrical conductivity ($EC_{1:5}$), organic matter (OM), Bray II–extractable P, $NH_4OAc$-extractable K, Ca, and Mg, and DTPA-extractable Fe, Cu, Mn, and Zn (Soil Survey Staff, 2014). Total P (perchloric acid digestion), organic P (ignition method), and inorganic P were determined following Kuo (1996).

The soils were predominantly sandy clay loam and extremely acidic (pH 3.93–4.32), conditions that intensify nutrient limitations and promote cation leaching. $EC_{1:5}$ values were low (0.03–0.07 dS $m^{-1}$), while OM contents were relatively high (29.3–39.8 g $kg^{-1}$). Extractable P levels were extremely high (93.2–210 mg $kg^{-1}$), indicating substantial long-term P accumulation. In contrast, extractable K, Ca, and Mg were low (13.5–33.2 mg $kg^{-1}$; 72.1–183 mg $kg^{-1}$; 13.1–22.9 mg $kg^{-1}$), reflecting severe depletion of base cations under prolonged acidic conditions. Micronutrient concentrations were within moderate to high ranges (Fe: 59.1–152 mg $kg^{-1}$; Cu: 0.50–2.56 mg $kg^{-1}$; Mn: 1.11–2.64 mg $kg^{-1}$; Zn: 0.48–1.99 mg $kg^{-1}$). Most nutrients were significantly more concentrated in the topsoil than in the subsoil ($P < 0.05$), indicating fertilizer-driven nutrient accumulation in the upper horizon. Total soil P was also remarkably high (427–767 mg $kg^{-1}$), dominated by inorganic P (351–649 mg $kg^{-1}$; 77–85%), whereas organic P accounted for only 18–23%, confirming persistent P loading in the soil profile. Overall, these findings reveal a pronounced nutrient imbalance characterized by excessive P accumulation and critical deficiencies of K, Ca, and Mg under long-term organic–chemical durian cultivation. The results highlight the urgent need to reduce P inputs and replenish depleted base cations to sustain soil fertility and maintain long-term orchard productivity in eastern Thailand.

**ABSTRACT**

Cover cropping helps improve soil conditions in *Camellia oleifera* —an important edible oil tree species predominantly grown in hilly red soil regions of southern China. Soil extracellular enzymes play vital roles in nutrient transformations. However, how cover crops influence soil enzymatic stoichiometry and its underlying regulatory mechanisms in *Camellia oleifera* plantations remains unclear. In this study, we examined soil extracellular enzymes, organic carbon composition, and microbial communities across two seasons in a long-term field experiment involving different cover crops: natural grass cover (control), Coreopsis tinctoria (CT), Festuca arundinacea (FA), Trifolium repens (TR), and Cosmos bipinnatus (CB). The results showed that, compared with the control, artificial cover crops significantly improved soil physicochemical properties. During the growth period of *Camellia oleifera* (June), TR and CB significantly increased the contents of ammonium nitrogen, nitrate nitrogen, available phosphorus, soil organic carbon, and particulate and mineral-associated organic carbon. From the growth period to the maturation period (October), soil extracellular enzyme activities generally increased, and microbial nutrient limitation shifted from phosphorus to nitrogen limitation. The decrease in vector length indicated a relief of carbon limitation. Fungi had a more significant impact than bacteria on organic carbon components and enzyme activities, with TR and CB exerting the most pronounced effects on soil organic carbon accumulation and fertility improvement by regulating fungal communities and enzyme activities. This study highlights the role of labile soil organic carbon and fungal communities in regulating enzymatic stoichiometry in *Camellia oleifera* plantations.

*E-mail Address of Presenting Author: Weeraya.le@ku.th

## ABSTRACT

Sugarcane (*Saccharum officinarum* L.) is an economically important crop worldwide, yet increasing yield remains challenging, particularly for ratoon crops. This study investigated the effects of foliar potassium nitrate ($KNO_3$) supplementation on chlorophyll content and nitrogen (N), phosphorus (P), and potassium (K) concentrations in second-ratoon sugarcane (var. Khon Kaen 3). The experiment was conducted at the Department of Soil Science experimental field, Faculty of Agriculture at Kamphaeng Saen, Kasetsart University, using a 4 × 3 factorial arrangement in a randomized complete block design. Treatments consisted of four $KNO_3$ concentrations (0, 1.5, 2.5, and 3.5% w/v) and three spray volumes (667, 1333, and 2000 L $ha^{-1}$), with three replications. Soil-applied NPK fertilizers were applied according to recommended rates for ratoon cane (Department of Agriculture, 2021). Foliar $KNO_3$ was applied when the ratoon cane was 6 months old. Chlorophyll content was measured three weeks after application using a SPAD-502Plus meter, and index-leaf samples were collected for analysis of N, P, and K. Statistical analysis was performed using an F-test, followed by Duncan's Multiple Range Test at the 95% confidence level.

Foliar $KNO_3$ application significantly increased chlorophyll content and leaf N, P, and K concentrations. The highest chlorophyll content occurred with 2.5% $KNO_3$ at 667 L $ha^{-1}$ (SPAD = 45.5), which also produced the highest leaf N and K concentrations (13.5 and 19.79 g $kg^{-1}$, respectively). In contrast, the greatest P concentration (1.65 g $kg^{-1}$) was observed in the treatment receiving 2.5% $KNO_3$ at 2000 L $ha^{-1}$. Foliar $KNO_3$ application enhanced chlorophyll formation and improved leaf N and K nutritional status in second-ratoon sugarcane, likely because the nitrate supplied promoted chlorophyll synthesis and facilitated the mobility of N and K within plant tissues. The variation in P among spray volumes suggests that canopy coverage and solution deposition influence foliar nutrient absorption. Comparison with published sufficiency ranges (McCray & Mylavarapu, 2020) showed that leaf K exceeded the "sufficient plus" category (>16 g $kg^{-1}$), whereas leaf N and P remained below their sufficiency thresholds (N: 20–23 g $kg^{-1}$; P: 2.2–2.6 g $kg^{-1}$). These findings highlight the potential of foliar $KNO_3$ as a supplementary practice in ratoon cane management, while emphasizing the need for improved soil- or foliar-based N and P nutrition strategies.

# The Effect of Nutrient Management on Yield and Fruit Quality of Nam Hom Coconut in Thailand

**Jiraphat Kwansue[1], Wipawan Thaymuang[1*], and Winai Utkhao[2]**

[1] *Department of Soil Science, Faculty of Agriculture at Kamphaeng Saen, Kasetsart University, 73140, Thailand*

[2] *Center for Agricultural Biotechnology, Kasetsart University, Kamphaeng Saen Campus, 73140, Thailand*

*wipawan.t@ku.th

**ABSTRACT**

The Nam Hom coconut (*Cocos nucifera* L.), an aromatic coconut, is frequently harvested every 24-27 days, which can lead to soil nutrient depletion and potentially affect yield and fruit quality over time. This study investigated the effects of different nutrient management on the yield and fruit quality of Nam Hom coconut. The experiment was conducted at a coconut plantation in Ratchaburi Province, Thailand. The soil is derived from alluvial sediments and classified as *Vertic (Aeric) Endoaquepts*. There were four N-P-K fertilizer regimes (T1; 0.8-0-0.9, T2; 0.6-0.2-1.2, T3; 0.6-0.2-0.8, and T4; 0.8-0.2-0.8 kg N-$P_2O_5$-$K_2O$ tree$^{-1}$ year$^{-1}$) were applied based on crop nutrient removal. The fertilizer rate was divided into five equal applications every two to three months. Each treatment consisted of 28 trees, six of which were randomly selected for soil and leaves nutrient analyses, while yield was recorded from all trees and fruit quality from sampled fruits. No significant differences in soil nutrient concentrations were observed among treatments based on every two months monitoring throughout the experiment. However, all treatments showed a continuous increase in soil nutrient levels over the 12-month period. Treatment 3 showed the highest exchangeable K compared with the other treatments, although the difference was not statistically significant. In addition, available P also increased markedly compared with the initial soil condition. For nutrient concentration in leaves, there were not significantly different for nitrogen and phosphorus among treatments, whereas potassium showed significant difference, with Treatments 4 and 3 exhibiting the highest concentrations, respectively ($p<0.01$). The leaves nutrient levels tended to increase during the rainy season (October 2023) and decreased during the cool season (February 2024).

The cumulative yield of Nam Hom coconut increased all treatments, especially treatments 1 and 2 showing the highest yields. These two treatments had the greatest increase in fruit number. For fruit quality, treatment 3 showed the highest sweetness (7.53 °brix) and electrical conductivity of coconut water, with significant differences ($p < 0.05$). High potassium accumulation was also observed in coconut water across treatments. Correlation between nitrogen and potassium in leaves were significantly associated with coconut water sweetness, while flesh thickness was positively correlated only with potassium. These results suggest that N and K are key nutrients influencing fruit quality and yield of coconut productivity.

# Cropland nutrient use efficiency: recent trends and targets for sustainable agriculture

**Achim. Dobermann[1*] and Cropland Nutrient Balance team**

[1] *International Fertilizer Association (IFA), Paris, France*

*adobermann@fertilizer.org

**ABSTRACT**

In cropland, the major inputs of nutrients are mineral fertilizers, manure, biological nitrogen (N) fixation, atmospheric deposition and seed. The primary nutrient output is in the form of the harvested main product. The difference between these inputs and outputs is the nutrient balance, whereas the ratio of outputs/inputs is an indicator of nutrient use efficiency. We present a global database of country-level balance and use efficiency estimates for N, phosphorus (P) and potassium (K) in cropland. The database, disseminated in FAOSTAT, provides a global References, synthesizing and continuously updating the state-of-the-art on this topic. The database covers 205 countries and territories, as well as regional and global aggregates, for the period 1961 to 2023.

Results highlight the wide range in nutrient use and use efficiencies across geographic regions, nutrients, and time. The greatest contributors to nutrient inputs in recent years were synthetic fertilizers, followed by biological N fixation for N, and manure applied to the soil for P and K. The global N surplus on cropland rose from 21 Mt in 1961 to 81 Mt in 1988, but has remained relatively unchanged at about 85 Mt in the past 15 years. Despite rising N inputs, the average global cropland N balance has remained fairly stable at about +50-55 kg $ha^{-1}$ $year^{-1}$ during the past 15 years, which is also reflected in an increase of N use efficiency, from a low of 43% in 1988 to 55% at present. This reflects yield growth, but also progress in adoption more N-efficient practices. However, regional and national trends vary widely, ranging from large N surpluses in Asia, particularly China and India, to long-term nutrient deficits of N, P and K in much of sub-Saharan Africa to. When nutrient removal with crop residue was included in the balance, K balances became negative in many regions, suggesting that K is likely to become a significant limitation to global crop yields.

Indicators such as nutrient balance (N, P, K) and N use efficiency are important for setting realistic, national targets for food security, soil health and environmental impact, and monitoring progress towards achieving them. We highlight several examples for that, discuss data uncertainties and provide priorities for further improvement.

**ABSTRACT**

To investigate the synergistic effects of new mineral fertilizer (main components $K_2SO_4$-$MgSO_4$-$2CaSO_4$-$2H_2O$) and its combined application with bio-organic fertilizer on soil fertility and soil multifunctionality in coffee plantation and the yield and quality of coffee. A seven-year continuous field experiment was conducted in Yunnan, China. Five treatments included no fertilization (CK), two local conventional fertilization (SOP, MOP), mineral fertilizer application (POLY), and mineral fertilizer combined with bio-organic fertilizer (POF) application were set. The soil physical and chemical properties, soil nutrients, soil enzymes activity and coffee fresh fruit yield and quality were analyzed. The differences among treatments were examined using one-way analysis of variance (ANOVA), and the soil multifunctionality was studied with the Average Value Method. The results showed that, the combined application of mineral fertilizer and bio-organic fertilizer (POF) synergistically enhanced soil fertility and soil biological activity, thereby significantly improved soil multifunctionality in coffee plantation. Compared with the conventional fertilization SOP and MOP, POF increased soil fertility comprehensive index (IFI) by 33.3% and 36.1% respectively,the content of soil microbial biomass carbon (MBC) and nitrogen (MBN) increased by 41.46% and 55.01%, and by 15.28% and 16.58%, respectively, while significantly enhanced the activities of urease, sucrase, and β-glucosidase. Consequently, the soil multifunctionality index (SMF) increased 28.2% and 32.1%, respectively. The yield of fresh coffee fruit increased 17.8% and 28.3%, and the green coffee bean quality index (FQI) improved 29.24% and 35.59%. The comprehensive ranking of soil multifunctionality and coffee yield and coffee quality across all treatments consistently followed the order: POF > POLY > MOP > SOP > CK. Additionally, correlation analysis revealed that SMF was significantly positively correlated with both coffee yield and FQI ($P < 0.01$). The random forest model further indicated that soil organic carbon, extractable calcium, microbial biomass carbon, microbial biomass nitrogen, available potassium, urease and sucrase were the key indicators influencing soil multifunctionality in coffee plantations. In conclusion, the combined application of mineral fertilizer and bio-organic fertilizer can enhance soil fertility and soil multifunctionality of coffee plantation and improve yield and quality of coffee green bean. This provides an effective fertilization strategy for synergistic improving coffee quality and yield and sustainable production in coffee plantations.

**ABSTRACT**

Peanut (*Arachis Hypogea* L.) is a multifaceted crop with global importance. As an essential nutrient for higher plants, calcium (Ca) is particularly critical in peanut production. Insufficient Ca supply leads to low yield, substandard seed quality, and higher incidence of pathogen infection. However, soils suitable for peanut production are often low in Ca availability. It is thus important to ensure adequate Ca supply during peanut production. Improvement of crop productivity including nutrient use efficiency can be achieved through two main strategies: optimizing agronomic practice and breeding nutrient efficient crop cultivars. The improvement of Ca use efficiency in peanut through breeding effort is lagging far behand, it is more feasible to maintain and improve peanut productivity by optimizing nutrient management practices. In this work, molecular mechanisms of Ca-mediated peanut pod development are summarized, which offers new insights into breeding Ca-efficient peanut cultivars. In addition, enhancement of Ca use efficiency through nutrient management practices including Ca source, rate, timing, placement, and irrigation are thoroughly discussed. Research gaps and future endeavors regarding Ca use efficiency in peanut are also identified.

# Organic Fertilizer Substitution Reshapes Carbon Component Distribution in Soil Aggregates Driving Niche Differentiation of Nitrogen Functional Microorganisms and Regulating Nitrogen Use Efficiency

**Bingqian Xu[1], Yanan Wang[1*], Xibai Zeng[1]**

[1] *Institute of Environment and Sustainable Development in Agriculture, Key Laboratory of Agro-Environment, Chinese Academy of Agricultural Sciences, Ministry of Agriculture and Rural Affairs of the P.R. China, 100081 Beijing, China*

**ABSTRACT**

Long-term use of chemical fertilizers leads to soil texture and structure degradation, carbon-nitrogen imbalance, and reduced nitrogen use efficiency (NUE). Partial substitution of chemical fertilizers with organic fertilizers is a key strategy for improving soil health and nutrient cycling, but the microscale mechanisms by which different organic fertilizers regulate the distribution of carbon components in soil aggregates, thereby affecting the spatial distribution of nitrogen functional microorganisms and NUE, remain unclear. In this study, an 8-year field experiment was conducted with seven fertilization treatments, including chemical fertilizer alone and organic fertilizer substitution using pig manure (30%, 60%, and 100% of substitution ratio) or rapeseed cake (30% and 60% of substitution ratio). Aggregate composition and carbon fractions (particulate organic carbon, POC; mineral-associated organic carbon, MAOC; microbial biomass carbon, MBC), together with nitrogen-cycling microbial communities (abundances of *amoA*-AOA, *amoA*-AOB, *nirK*, *nirS*, *nosZI*, and *nosZII*), were quantified. Organic substitution improved aggregate stability and altered carbon allocation. The 60% rapeseed cake substitution ($COF_{60}$) had the highest proportion of macroaggregates (51.92%) and increased POC and MAOC contents, whereas pig manure substitution enhanced MBC accumulation. NUE was highest in clay fractions, with partial organic substitution (30-60%) increasing NUE by 13.6-27.4%. Nitrogen-cycling functional genes showed distinct spatial distributions: the *amoA* of AOA and AOB gene abundances were enriched in MAOC-rich clay fractions, whereas *nirK* and *nirS* gene abundances were concentrated in POC-rich macroaggregates. The $OF_{60}$ treatment had the highest *nirK* and *nirS* gene abundances ($8.07\times10^5$ and $9.07\times10^5$ copies·$g^{-1}$). Structural equation modeling revealed significant positive relationships between POC contents and the (*nirS*+*nirK*)/(*nosZI*+*nosZII*) ratio (0.58, $P<0.01$), and between MAOC contents and the AOA/AOB ratio (0.65, $P<0.01$). In turn, the (*nirS*+*nirK*)/(*nosZI*+n*osZII*) ratio exerted a negative effect on NUE ($P<0.001$), whereas the AOA/AOB ratio positively affected NUE (0.49, $P<0.05$). Overall, organic fertilizer substitution reshaped the spatial distribution of carbon components in soil aggregates, driving the differentiation of nitrogen functional microorganisms: POC promoted denitrifier enrichment, while MAOC enhanced ammonia-oxidizing populations, jointly forming a coupled “carbon-microbe-NUE” regulatory mechanism that links aggregate-scale carbon stabilization with nitrogen transformation efficiency and supports the design of optimized organic substitution strategies.

## ABSTRACT

Sustainable agricultural systems increasingly rely on mineralization of large organic nitrogen (N) pools, with organic fertilizers such as compost, manures, and crop residues partially substituting for synthetic inorganic N inputs. However, plant organic N acquisition pathways remain poorly resolved. Although plants are now known to directly take up and assimilate organic N, most studies have focused on amino acids, overlooking the substantial diversity of organic N metabolites—including nucleobases, nucleosides, and amino sugars—that may serve as alternative N sources and modulate plant–microbe interactions governing N cycling and uptake.

Here, we first screened 26 low–molecular weight organic N-containing compounds commonly detected in soils as potential N sources for the model grass *Brachypodium distachyon* and identified the nucleobase uracil as a particularly promising compound that stimulated root growth. We then compared plant uptake from organic N (uracil) and inorganic N ($NH_4^+$, $NO_3^-$) using a short-term $^{15}N$-labeling experiment. Plants were cultivated for 5 weeks in unfertilized marginal soil amended with uracil, $KNO_3$, or $(NH_4)_2SO_4$. Subsequently, pots received solutions containing equal amounts of ammonium-N, nitrate-N, and uracil-N, with only one N form $^{15}N$-labeled ($NH_4$-$^{15}N$, $NO_3$-$^{15}N$, or uracil-$^{15}N$). Plants and soils were harvested 40 h after labeling to quantify $^{15}N$ in plant tissues and soils and to relate N uptake patterns to rhizosphere microbial communities characterized by 16S rRNA gene sequencing.

We observed enhanced plant N assimilation following shifts in N source, both from inorganic N to mixed inorganic–organic N and from organic N to mixed N. This may reflect transient decoupling between microbial demand and the newly supplied N form, leaving more available N for plant uptake. Uracil pretreatment increased soil microbial biomass C, indicative of stimulated microbial activity and potentially accelerated nutrient cycling. Uracil pretreatment also significantly altered rhizosphere bacterial community composition and diversity, notably increasing the relative abundance of *Nitrospirota*, which was positively correlated with shoot and root biomass and with soil $NH_4^+$ and $NO_3^-$ concentrations.

Collectively, our findings identify nucleobases as overlooked organic N sources capable of restructuring rhizosphere microbiomes and enhancing plant N acquisition, thereby advancing our understanding of how specific organic N compounds and their uptake pathways influence soil microbial processes and plant nutrition.

## ABSTRACT

Excessive nitrogen (N) losses from wet and warm sugarcane cropping systems pose severe environmental risks, yet mitigation strategies often carry uncertainties. While individual management practices have been widely studied, a comprehensive evaluation of their trade-offs remains limited. We compiled global sugarcane data and conducted meta-analysis to estimate the effects of management practices (inhibitors, straw retention, reduced N, carbon materials) on $NH_3$ volatilization, $N_2O$ emission, and yield. We also simulated N management scenarios predicting the magnitude of N losses and yield using Monte Carlo simulations. The meta-analysis revealed that nitrification inhibitors (NI) and urease inhibitors (UI) significantly reduced $NH_3$ volatilization and $N_2O$ emission. Monte Carlo simulations highlighted trade-offs between strategies. The application of dual inhibitors (UI and NI) emerged as the most robust strategy, reducing N losses without incurring a yield penalty. Conversely, scenarios simulating straw removal and reduced N rates illustrated substantial reduction in environmental N losses but also predicted yield decline. These findings suggest that dual inhibitors offer a viable pathway for sustainable intensification, decoupling N loss mitigation from yield penalties. However, relying solely on N rate reduction or residue management requires careful optimization to avoid compromising food security.

**ABSTRACT**

Intercropping enhances productivity through species complementarity. In legume-cereal systems, legumes fix nitrogen for cereals while cereals' roots improve soil structure, creating sustainable synergies.This synergistic relationship not only enhances yield stability and nutrient utilization efficiency but also improves soil health and strengthens climate resilience against extreme weather events.Water-nitrogen coupling serves as a fundamental mechanism for regulating intercropping systems. The coordinated interaction between water and nitrogen availability enhances photosynthetic performance, promotes deep root development, and improves both soil water-nitrogen cycling efficiency and rhizosphere microbial community structure. Through precise synchronization with critical crop growth stages, this approach effectively minimizes interspecific competition while reinforcing mutualistic relationships between component crops.The COMSOL Multiphysics simulation platform offers powerful analytical capabilities by integrating soil water transport equations, nutrient advection-diffusion models, and root uptake kinetics. This integrated methodology enables accurate quantification of water and nitrogen migration fluxes at the soil-root interface, reveals fundamental physiological principles governing crop growth responses, and overcomes limitations inherent in traditional experimental approaches for characterizing soil transport processes.This research advances modeling applications to elucidate regionally differentiated effects of water-nitrogen coupling across diverse climate zones and soil types. The findings support the development of precise, regionally adapted water-nitrogen management strategies, thereby providing robust theoretical foundations and effective technical solutions for sustainable optimization of intercropping systems. These advancements contribute significantly to agricultural sustainability and food security objectives across varying production environments.

**ABSTRACT**

Iron (Fe), though one of the most abundant elements in soils, its deficiency is a worldwide problem in many crops particularly in calcareous soils. The availability of Fe rather than quantity in the soil that affects the growth and development of plants, and has consequence on animals and humans. As effective, economical, and long-term solutions to Fe chlorosis remain limited, the use of Fe efficient genotypes capable of better utilizing native soil Fe offers a promising and sustainable approach.

To select Fe efficient groundnut genotypes for calcareous soil, a pot culture experiment with 20 groundnut genotypes was conducted under Fe-sufficient (+Fe) and Fe-deficient (–Fe) conditions. The soil was sandy clay loam, alkaline in nature with low salinity, high calcium carbonate (12%), low organic carbon (0.23%), and low available Fe (3.85 mg $kg^{-1}$). The genotypes behaviour in terms of morphological, biochemical and yield under +Fe and -Fe application was studied. Based on the data obtained and cluster analysis the genotypes were classified as Fe efficient and Fe inefficient.

Variation was observed in the genotypes under Fe sufficient and Fe stress condition. TAG 24 and VRI 13149 recorded minimum reduction in root length over control (+Fe). The reduction in root volume was minimum with ALR 2 (5.5 %) at vegetative stage and JL 24 (2.3%) at harvest stage. SPAD reading, a parameter closely associated with chlorophyll content of the leaf, varied significantly and minimum reduction in SPAD reading was observed in JL 24 followed by VRI 5.

Catalase, peroxidase activity and active Fe content were highly variable among the genotypes. The genotypes CO7, VRI 8 and VRI 16075 maintained same level of catalase activity both under +Fe and - Fe treatments. Genotypes, TAG 24, CO 7 and JL 24 recorded higher active Fe content under -Fe at vegetative and harvest stage. Release of organic acids, amino acids in the root exudates of groundnut plants especially under Fe stress was observed which could have increased native soil Fe utilization efficiency and ensuring adequate Fe nutrition for the growing groundnut plants. VRI 8 and CO 7 had high response to release of root exudates to the calcareousness condition compared to TMV 7 and VRI 5.

The genotypes TAG 24, CO7, JL 24 and TMV 1 recorded higher Fe content at harvest both under +Fe and -Fe condition. The percentage reduction in Fe content was less than 10 % under -Fe when compared to +Fe. TAG 24 maintained a relatively higher pod yield of 19.9 g $plant^{-1}$ under -Fe.

Based on cluster analysis, the groundnut genotypes, VRI 13149, TMV 2, JL24, TMV 1, TAG 24, CO7, ALR 2, VRI 13113, VRI 8 and VRI 16086 were identified as Fe efficient which can be exploited under calcareous condition to combat Fe deficiency and to increase the Fe Use Efficiency.

# Effects of gypsum application on rice growth and yield in paddy soils with varying heavy metal content

**Watanabe, A.[1], Hamamoto ,T.[1*], Makino, T.[1]**

[1] *Graduate School of Agricultural Science, Tohoku University Miyagi Japan*

*toru.hamamoto.d1@tohoku.ac.jp

**ABSTRACT**

Sulfur (S) deficiency in paddy rice, characterized by suppressed tillering and the yellowing of lower leaves, has been reported globally. In paddy soils, sulfate-S (available S) is reduced to sulfide-S, leading to the precipitation of insoluble sulfides such as copper sulfide (CuS) and zinc sulfide (ZnS). This suggests that S deficiency may be driven not only by low available S levels but also by an abundance of heavy metals which form insoluble sulfides. However, the effects of gypsum-derived S application on yield, particularly in relation to sulfide formation and heavy metal dynamics, remain insufficiently understood. This study aims to investigate the effects of gypsum application on rice growth and yield in soils with varying heavy metal contents, focusing on the dynamics of S and heavy metals.

A pot experiment was conducted using five paddy soils. The available S content of the tested soils ranged from 8.0 to 46.2 mg $kg^{-1}$. According to Dobermann and Fairhurst (2000), S deficiency is likely when available S is below 9 mg $kg^{-1}$; only one of the tested soils was below this threshold. In contrast, in four of the soils, the concentrations of 0.1 M HCl-extractable metals (sum of Cu, Zn, Pb, Cd, and Ni) exceeded the the available S content. Two S application treatments were applied to each soil, including a control without gypsum (−S) and a gypsum application of 1.5 g $kg^{-1}$ (+S), with four replications. The rice cultivar 'Hitomebore' was cultivated for 126 days. Soil solutions were analyzed for elemental concentrations at regular intervals during the cultivation.

Results showed that the S concentration in the soil solution significantly increased with gypsum application until 42 days after transplanting (DAT). Correspondingly, plant growth in the +S plots was significantly higher than in the −S plots after 42 DAT. The concentrations of Cu and Zn in the soil solution, the dominant 0.1M HCl-extractable metals, decreased as cultivation progressed. Solubility product calculations confirmed indicated that the soil solution became saturated with CuS and ZnS. Gypsum application improved rice yield in all soils; specifically, grain yields increased significantly (by 2- to 38-fold) in the four soils where heavy metal content exceeded available S. Furthermore, a negative correlation was observed between the net difference in (available S minus 0.1 M HCl-extractable metals) and the use efficiency of gypsum-derived S. These results suggest that S fertility in paddy rice depends not only on the S content itself but also on its interaction with heavy metal content.

# Spatial distribution of medium and trace elements in tea garden soil of Laoshan District, Qingdao

**Zhenghuan Kong[1]*, Jiani Ma[1], Xiangyun Song[1]**

*[1]College of Resources and Environment, Qingdao Agricultural University, Qingdao, China*

*E-mail: 17663984783@163.com

**ABSTRACT**

The yield and quality of tea are affected by the soil environment, especially the content of medium and trace elements. Therefore, the abundance and deficiency of medium and trace elements in the soil of the tea garden play a crucial role in the growth and quality of tea. The spatial variation characteristics and effect factors of 7 medium and trace elements (Fe, Mn, Cu, Zn, B, S, Mo) in 0-20 cm and 20-40 cm soil in Laoshan District of Qingdao City were studied by Pearson correlation analysis, single factor analysis of variance and geostatistics, and the current situation of micronutrient content in the soil in Laoshan District was analyzed too. In the study, the available sulfur in 0-20 cm and 20-40 cm soil layers showed strong variation, and other medium and trace elements showed moderate variation. The results of correlation analysis showed that the soil available copper in 0-20 cm and 20-40 cm soil layers were significantly positively correlated with available zinc and altitude. The results of variance analysis showed that altitude had significant differences in the contents of Fe, Cu, Zn, B, S and Mo in 0-20 cm soil layer ($P < 0.05$), while it had significant differences in the contents of Cu, B and S in 20-40 cm soil layer ($P < 0.05$). With the increase of altitude, the soil available copper in 0-20 cm and 20-40 cm soil layers increased with the altitude. The results of semi variance function showed that the soil available iron, available manganese, available copper and available boron were affected by structural factors (topography, parent material, etc.) and random factors (fertilization, tillage, etc.). The order of variation coefficients of seven medium and trace elements in 0-20 cm soil layer were as follows: S > Zn > Cu > B > Mo> Fe> Mn. Moreover, the order of variation coefficients of seven medium and trace elements in 20-40 cm soil layer were as follows: S > Zn > Cu > Mo >B >Mn >Fe. The distribution of available sulfur, available iron and available zinc in soil showed a trend of high level in the South and low in the north of tea garden. The seven medium and trace elements in teagarden of Laoshan were affected by altitude, topography, parent materials and so on.

*E-mail Address: phomku@gmail.com

## ABSTRACT

Sugarcane (*Saccharum officinarum* L.) is an important economic crop in Thailand, known for its high nutrient uptake. Growth and yield reduction may occur under soil conditions, especially in calcareous soils containing high levels of free calcium carbonate and other carbonate salts, affecting the availability of nutrients in the soil. Soil fertilization alone may partially solve this problem. This study investigated the effects of foliar manganese application with *Bacillus australimaris* KU32 on the growth and yield of the sugarcane cultivar Khon Kaen 3 grown in calcareous soils (Khao Phlong soil series: Kpg-hb, cal; coarse-loamy, siliceous, semiactive, isohyperthermic Typic (Kandic) Paleustults. A factorial design in a completely randomized block design with 3 replications was used (2 x 3 Factorial in RCBD, 18 subplots), consisting of two factors. The first factor was bacterial inoculation (non-inoculation and inoculation). The second factor consisted of three levels: a control group without spraying and manganese (manganese sulfate) foliar spray at concentrations of 1% and 2%, respectively. The inoculation was performed simultaneously with the planting process using a sugarcane transplanter, whereas manganese spraying was performed at 2 and 4 months after planting. The experimental plots were located in Nong Krathum Subdistrict, Dem Bang Nang Buat District, Suphan Buri Province (14°52'47.2"N 99°49'16.6"E). Growth data, such as height, stalk number per tiller, leaf greenness, and proline content, were collected every two months until elongation stage. Nutrient content in sugarcane leaves was analyzed at 2, 4, and 6 months after planting. Soil microbial diversity and classification data were collected at 4 and 5 months after planting. The experiment revealed that *Bacillus australimaris* KU32 inoculation exhibited the greatest growth parameters, nutrient accumulation, and microbial diversity of soil compared to non-inoculation. Foliar spray with manganese at 1% concentration is appropriate for plant height, stalk number, and leaf greenness. The findings indicated that sugarcane cultivated in calcareous soils, when treated with a combination of bacterial inoculation and manganese, exhibited the greatest growth and nutrient accumulation compared to all other treatments. Our results will lead to efficient and sustainable plant nutrient management guidelines for sugarcane production in calcareous soil areas.

## ABSTRACT

Soil potassium (K) reserves are abundant, yet the vast majority are structurally bound within minerals, hindering direct uptake by plants. Plants activate mineral K by secreting root exudates that disrupt mineral structures in response to K deficiency stress. However, the microscopic morphological evolution at the mineral-solution interface and the changes in chemical bond energy and potential energy during the release of minerals $K^+$ remain a “black box”. This research investigated the release behavior of minerals K at the microscopic scale and its thermodynamic mechanisms, which is crucial for unlocking soil K resources. The microcosm experiment examined the K release kinetics and biotite morphology changes during its reaction with low-molecular-weight organic acids and biotite under different pH conditions (pH=4, 6, and 8). The mechanism of mineral K release was elucidated by revealing changes in the chemical bond energy of biotite. Results showed that the K and iron (Fe) were preferentially released relative to framework ions silicon [Si], aluminum [Al] during biotite dissolution. The release rates of these metal ions increased significantly with decreasing pH. Atomic force microscopy (AFM) revealed that the initially smooth biotite surface developed pits in the presence of oxalic acid (OA) or citric acid (CA), accompanied by the formation of fibrous precipitates. Raman spectroscopy (RS) was employed to monitor changes in the vibrational modes of biotite bonds. Reaction with organic acids weakened the 105 $cm^{-1}$ peak (assigned to K-O vibrations), facilitating the release of $K^+$ from biotite. Moreover, organic acids attenuated the 675 $cm^{-1}$ peak (Si-O-Si vibrations), which destabilized the mineral framework and promoted biotite dissolution. RS spectra also revealed the presence of peaks characteristic of carboxyl (COOH) functional groups. To investigate how organic acid functional groups influence mineral dissolution and K release, dynamic force spectroscopy (DFS) was used to quantify changes in the binding energy between hydroxyl (–OH) and –COOH groups and the biotite surface. As the pH of the microcosm decreased from 6 to 4, the binding energies increased from 7.0 to 10.3 kJ $mol^{-1}$ for –OH, and from 4.2 to 8.5 kJ $mol^{-1}$ for –COOH. Low-molecular-weight organic acids weakened the framework stability of biotite and disrupted its morphological structure by lowering the pH of the microenvironment and promoting the adsorption of organic functional groups onto mineral surfaces. It caused disorder in the K coordination environment and promoted the release of $K^+$ by reducing their binding strength.

**Key word:** Mineral potassium release; Mineral dissolution; Functional group; Proton action; Chemical bond.

# Balanced NPK Nutrition via TNAU-Water Soluble Fertilizer for Higher Yield and Nutrient Efficiency in Cotton

**M.R.Backiyavathy [1], K.Ramah[2] and S.Somasundaram[3]**

[1]Professor, Department of Soil Science and Agricultural Chemistry Tamil Nadu Agricultural University (TNAU), Coimbatore, India

[2] Associate Professor, Agricultural Research Station (TNAU), Bhavanisagar, India

[3] Professor and Head, Cotton Research Station (TNA U), Veppanthattai, India Email : backiyavathy.mr@tnau.ac.in

**ABSTRACT**

Balanced nutrition is critical for achieving higher yield and better nutrient efficiency in cotton. Nitrogen, phosphorus and potassium play complementary roles in crop growth and their balanced supply ensures optimal vegetative growth, reproductive development and boll formation. Water soluble fertilizers are designed to dissolve completely in water, releasing nutrients that are immediately available for plant uptake. This facilitates rapid absorption by roots and/or foliage, helps synchronize nutrient availability with crop demand and reduces losses associated with leaching, volatilization, fixation, or immobilization in the soil. As a result, water soluble fertilizers generally exhibit higher nutrient efficiency and more precise delivery compared with conventional soil-broadcast granular fertilizers.

Field experiments were carried out to evaluate the influence ofTNAU -Water Soluble Fertilizer (WSF) on seed cotton yield and nutrient efficiency in cotton (Variety CO 17). The experiment comprised graded levels of NPK (0, 25, 50, 75, and 100%) as main plot treatments and different levels of TNAU-WSF (0, 20, 40, 60 kg $ha^{-1}$ and 1% foliar spray) as subplot treatments. The study was conducted in strip plot design with two replications. The experimental soils were analyzed for initial nutrient status, and graded levels of NPK were applied based on the Soil Test Crop Response (STCR) approach, targeting a yield of 30 quintals per hectare. Biometric parameters such as plant height, number of branches and leaf area index were recorded. Seed cotton yield, nutrient uptake and nutrient efficiency were also assessed. The results revealed that application of 100% STCR-NPK along with TNAU-WSF @ 40 kg $ha^{-1}$ through fertigation recorded the highest biometric values, including plant height (128 cm), number of primary branches (25), leaf area index (4.8), number of bolls per plant (25.1) and seed cotton yield (3189 kg $ha^{-1}$). These results were statistically comparable with 75% STCR-NPK + TNAU-WSF @ 40 kg $ha^{-1}$. However, the maximum net profit (3.18) and nutrient efficiency (N: 81.9%, P: 67.4%, and K: 80.7%) were observed with 75% STCR-NPK combined with TNAU-WSF @ 40 kg $ha^{-1}$. To conclude, application of 75% STCR-based NPK + TNAU -WSF @ 40 kg $ha^{-1}$ is recommended for achieving higher seed cotton yield, improved nutrient efficiency and enhanced economic returns.

# Modelling the effect of soil nutrient and carbon mitigation measures in European agriculture

**C.M.J. Hendriks[1*], K. Duan[1], K. Nikolaus[1], D. Xu[2], M. Wang[2], G.H. Ros[2,3], W. de Vries[2], and J.P. Lesschen[1]**

*[3]Nutrient Management Institute B. V. (Wageningen, The Netherlands)*

* Chantal. hendriks@ wur. nl

**ABSTRACT**

Soil nutrient imbalances can have negative impacts on the environment and crop yield. Across the globe, policies are made to improve agricultural sustainability. This study focusses on the policy goals set by the European Union. Trade-offs and synergies can occur when implementing nutrient and carbon measures to improve soil quality, water quality, crop productivity, and biodiversity, and to reduce GHG emissions. Unfortunately, there is little known about trade-offs and synergies when these measures are applied. This study evaluates the potential effect of nutrient and carbon measures along these five goals. Because of this integrated approach, policymakers can make substantiated decisions on the adoption or stimulation of mitigation measures to reconcile agronomic and environmental objectives. The deterministic emission and nutrient flow model MITERRA-Europe model was used to evaluate the measures at regional level for EU-27, the United Kingdom and Switzerland (Duan et al., 2025). This model evaluates a wide range of nutrients (N, P, K, S, Ca, Mg, Zn, Cu) that are important for plant growth and soil fertility, but when applied inappropriate, they can also harm the environment. The model also evaluates the turnover of soil organic carbon, based on the RothC model, and its interactions with soil organic nitrogen. First, the current and desired soil nutrient and carbon budgets, i.e. difference between inputs and outputs, were assessed to understand the gap that needs to be bridged. Secondly, the effect of a series of mitigation measures was evaluated, summarized in ten roadmaps. Depending on the prioritized goal and focus area, one or multiple objectives could be achieved, underpinning policies on site specific management to reach the desired objectives. These roadmaps will soon become available on the NutriPlatform, i.e., a platform that was built as part of the NutriBudget project (Grant agreement ID: 101060455). This platform serves as a decision support tool for multiple stakeholders, because it includes also an interactive farm-level tool (i.e., NutriFarm).

# Calibration and Validation of a Site-Specific Nutrient Expert Tool for Sorghum in the Sudano-Sahelian Region of Nigeria

**ABSTRACT**

Low soil fertility and inadequate nutrient management severely constrain sorghum productivity in the Sudano-Sahelian region of Nigeria, undermining food security. Blanket fertilizer recommendations fail to account for the high spatial variability of soil nutrient status, resulting in suboptimal yields and inefficient fertilizer use. To address this challenge, we developed and validated a site-specific Nutrient Expert (NE) tool for sorghum using the QUEFTS model framework.

The NE tool was calibrated using data from 60 on-farm nutrient omission trials (NOTs) conducted during the 2020 rainy season across 12 Local Government Areas in four states. Forty-six fields (76%) were randomly selected for calibration, while 14 fields (24%) were reserved for validation. Yield responses to nitrogen (N), phosphorus (P), potassium (K), and sulfur (S) were calculated from NPKS and nutrient omission treatments. Nutrient requirements were estimated using agronomic efficiency for N and recovery efficiency indices for P, K, and S. Spatial soil data at 5×5 km resolution from ISRIC and iSDA databases were used to generate location-specific recommendations based on soil nutrient supply indices.

The calibrated tool produced spatially variable nutrient recommendations: N requirements ranged from 24 to 75 kg/ha (mean 55–75 kg/ha in most areas), P from 17 to 41 kg $P_2O_5$/ha (mean 26–41 kg/ha), K from 12.6 to 25.7 kg $K_2O$/ha, and S from 0 to 31 kg/ha (mean 0–6 kg/ha in most areas). Attainable yields ranged from 2,879 kg/ha in Bauchi State to 3,127 kg/ha in Katsina State. Model validation using the reversed QUEFTS approach on the independent validation dataset yielded an $R^2$ of 0.53 for the relationship between observed and predicted yields, indicating fair predictive performance. The model's precision is expected to improve significantly with ground-based field soil test data.

To facilitate widespread adoption, a user-friendly web-based platform was developed that enables farmers and extension agents to generate customized fertilizer recommendations by selecting their location and inputting farm management data. The platform translates model outputs into practical fertilizer product equivalents and application guidelines consistent with 4R Nutrient Stewardship principles.

The Sorghum NE Tool represents a significant advancement in decision support for smallholder farmers in the Sudano-Sahelian region. By providing accessible, science-based, and site-specific fertilizer recommendations, it offers a scalable pathway to enhance fertilizer use efficiency, improve sorghum yields, and strengthen regional food security. Future work will focus on transitioning to a scalable API-driven architecture, and integrating real-time climate data.

# Paddy-Upland Rotation in Southern China's Red-Yellow Soils: A Meta-Analysis Reveals Short-Term Benefits and Long-Term Risks

**Chongwei Zhong[1,3], Jiu Huang[2], Lu Zheng[1,3], Renfang Shen[1,3] and Xiaofang Zhu[1,3]***

## ABSTRACT

Paddy-upland rotation is widely regarded as an effective strategy to overcome obstacles associated with continuous rice monoculture. Compared with the conventional long-term flooded rice cropping system, this approach not only significantly enhances grain yield and quality but also improves overall soil health and enhances microbial diversity and activity. Along with socioeconomic development, cropping systems in the red-yellow soil regions of southern China have undergone substantial transformation. While traditional double-rice cultivation has declined, paddy-upland rotation has expanded rapidly; however, its system-level impacts on soil quality and crop productivity remain insufficiently understood.

This study employed a meta-analysis to systematically examine the effects of paddy-upland rotation systems—focusing on rotation duration and regional factors—on soil quality and crop yield in this region. Results indicate that during the initial five-year period, compared to continuous flooded cultivation, rotation significantly enhanced soil fertility and rice yield: soil pH significantly increased, bulk density decreased by 5.3%, and total nitrogen, total phosphorus, available nitrogen, available phosphorus, and available potassium showed significant increases ranging from 5.3% to 21.1%. These changes help mitigate the typical nitrogen, phosphorus, and potassium deficiencies in red-yellow soils. However, when extended beyond five years—particularly over fifteen years-rotation leads to soil acidification and depletion of available nitrogen and available potassium reserves, which may ultimately constrain crop growth and yield. These adverse effects were most pronounced under the double rice-rapeseed rotation system. Regional analysis revealed that in Hunan Province, where double rice-rapeseed rotation predominates, soil organic matter, available nitrogen, and available potassium decreased significantly, with reductions ranging from 10.5% to 22.1%. Fertilization management played a critical role in modulating system outcomes: moderate nitrogen application significantly improved nutrient availability and grain yield, whereas excessive nitrogen (>360 kg/ha) exacerbated acidification and reduced the availability of nitrogen, phosphorus, and potassium.

In summary, while short-term paddy-upland rotation can improve soil quality, particularly by enhancing nitrogen-phosphorus availability in red-yellow soil regions, long-term practice without amendments accelerates acidification. Sustaining soil productivity and rice yields requires site-specific optimization of rotation sequence, duration, and nutrient management.

# Vegetation types and management practices reshape mineral element cycling in tropical soil–plant systems

**ABSTRACT**

Land-use change and intensive agricultural management in tropics are altering biogeochemical cycling within soil–plant systems. Understanding mineral element cycling under different vegetation types and management practices is essential for sustaining soil fertility and preventing nutrient depletion. To explore the relative roles of vegetation types and agricultural management in element cycling, we investigated four vegetation types on Hainan Island, China, including natural forest, rubber, banana, and paddy field. Through two-year monitoring of throughfall, irrigation, runoff, and plant organs, we quantified the budgets of Si, K, Ca, Na, and Mg. Canopy leaching influenced throughfall inputs. K showed stronger canopy leaching, and Si leaching correlated positively with leaf Si content. Management altered element budgets by regulating inputs and outputs. Banana showed net accumulation, while plant uptake accounted for only 39% of external K inputs. In paddy fields, harvest resulted in a Si deficit of 365 kg $ha^{-1}$ $yr^{-1}$. Rubber showed net Mg losses due to NPK-dominated fertilization and latex tapping. Element cycling efficiency (ECE) revealed mechanisms of element imbalance. Low ECE in rubber (44%) resulted in insufficient litterfall inputs to offset runoff losses. Banana exhibited high ECE (85%), but excessive inputs from fertilizer caused element accumulation. In paddy fields, K and Ca cycled efficiently, while Si was depleted due to harvest. Natural forest maintained balance for most elements through moderate ECE (61%). This study reveals that agricultural management overrides vegetation types as the dominant driver of element cycling. Future management should prioritize integrated strategies centered on element balance to achieve soil productivity.

# Trends and geographic variation in adverse impacts of nitrogen use in Europe on human health, climate, and ecosystems: A review

**Gerard H. Ros[1] and Wim de Vries[1]**

[1] *Wageningen University and Research, Earth Systems and Global Change Group, PO Box 47, 6700AA Wageningen, the Netherlands*

*gerard.ros@wur.nl

**ABSTRACT**

Human activities have greatly increased the loss of reactive nitrogen compounds, especially of nitrogen oxides ($NO_x$), ammonia ($NH_3$), nitrous oxide ($N_2O$) and nitrate ($NO_3$), to air and water. This review assesses the impacts of trends in reactive nitrogen use on air, soil, and water quality across Europe from 1990 to 2019, focusing on temporal trends and spatial patterns. The analysis is based on long-term monitoring data and air quality modelling using the EMEP model, and evaluates consequences for human health, terrestrial and aquatic ecosystems, and climate change. Ecological and health risks are quantified by examining exceedances of critical nitrogen levels and loads.

Over the studied period, emissions of nitrogen oxides ($NO_x$) and ammonia ($NH_3$) declined substantially, by 57% and 27% respectively. Despite this, atmospheric $NH_3$ concentrations slightly increased, largely due to reduced sulfur emissions. Improvements in ozone-related indicators and ecosystem exposure were limited. Nitrogen deposition and exceedances of critical loads in terrestrial ecosystems decreased by about 60%, yet the total area affected declined by only 10%, indicating persistent pressure on sensitive ecosystems. Groundwater nitrate concentrations remained largely stable across Europe, while nitrogen levels in rivers, lakes, and coastal waters generally declined. However, eutrophication continues in many coastal areas, partly driven by high phosphorus inputs. Overall, nitrogen pollution hotspots remain, especially in regions with intensive agriculture and high population density.

The review also evaluates the economic dimensions of reactive nitrogen use, concluding that environmental and health costs exceed the economic benefits of agriculture. While nitrogen is essential for food production, more efficient and integrated nutrient management is needed to reduce losses. The study highlights the importance of reducing nitrogen emissions throughout the entire food supply chain, in line with the EU Farm to Fork Strategy, which aims to cut nutrient losses by 50% by 2030.

# Potassium Management Strategies for Soybean–Corn Rotation Under No-Tillage in a Brazilian Oxisol

**Paulo C. Teixeira[1*], José C. Polidoro[1], Vinicius M. Benites[1], and Jorge M. Alonso[1]**

[1] *Brazilian Agricultural Research Corporation - Embrapa (Embrapa Soils, Rio de Janeiro-RJ, Brazil)*

*paulo.c.teixeira@embrapa.br

**ABSTRACT**

Efficient fertilizer management involves selecting the appropriate source, rate, timing, and placement to ensure nutrient availability for plant uptake while minimizing environmental losses. This study evaluated the effects of different rates, timings, and placements of potassium (K) fertilizer on a soybean–corn (*Glycine max* L. – *Zea mays* L.) rotation, starting with soybean, under a no-tillage system in a sandy soil (Cerrado) in Brazil. The experiment was conducted over eight consecutive growing seasons in a well-established area with a history of consecutive soybean and corn cultivation and previously built soil fertility**.** The following annual treatments were applied to both crops:0P0K (control without P and K); 0K (fertilization without K); 100F (100% K in the planting furrow); 100T (100% K as topdressing post-emergence); 50S/50T (50% K at planting + 50% as topdressing, both surface-applied); 50S (50% K at planting, surface-applied); 100S (100% K at planting, surface-applied); and 100F/50T (100% K in the furrow + 50% as topdressing). Grain yield, agronomic efficiency, and the partial K balance were determined. Data were subjected to Bartlett's and Shapiro-Wilk tests ($p < 0.05$) to verify variance homogeneity and residual normality, respectively. ANOVA was performed, and means were compared using the Scott-Knott test ($p < 0.05$). No significant differences were observed among treatments during the first soybean crop. However, the 0P0K treatment resulted in lower yields in the first corn crop, indicating P deficiency preceded K deficiency. Starting from the second soybean crop (the third harvest analyzed), surface K applications led to higher yields than furrow applications, with no significant effect of application timing. Applying half of the recommended K rate on the surface was effective in the short term but resulted in a negative K balance, potentially compromising soil fertility over time. Surface application of the full recommended K rate at planting is the most effective strategy for soybean-corn rotations in sandy soils of Western Bahia, Brazilian Cerrado, promoting higher productivity and long-term maintenance of soil fertility.

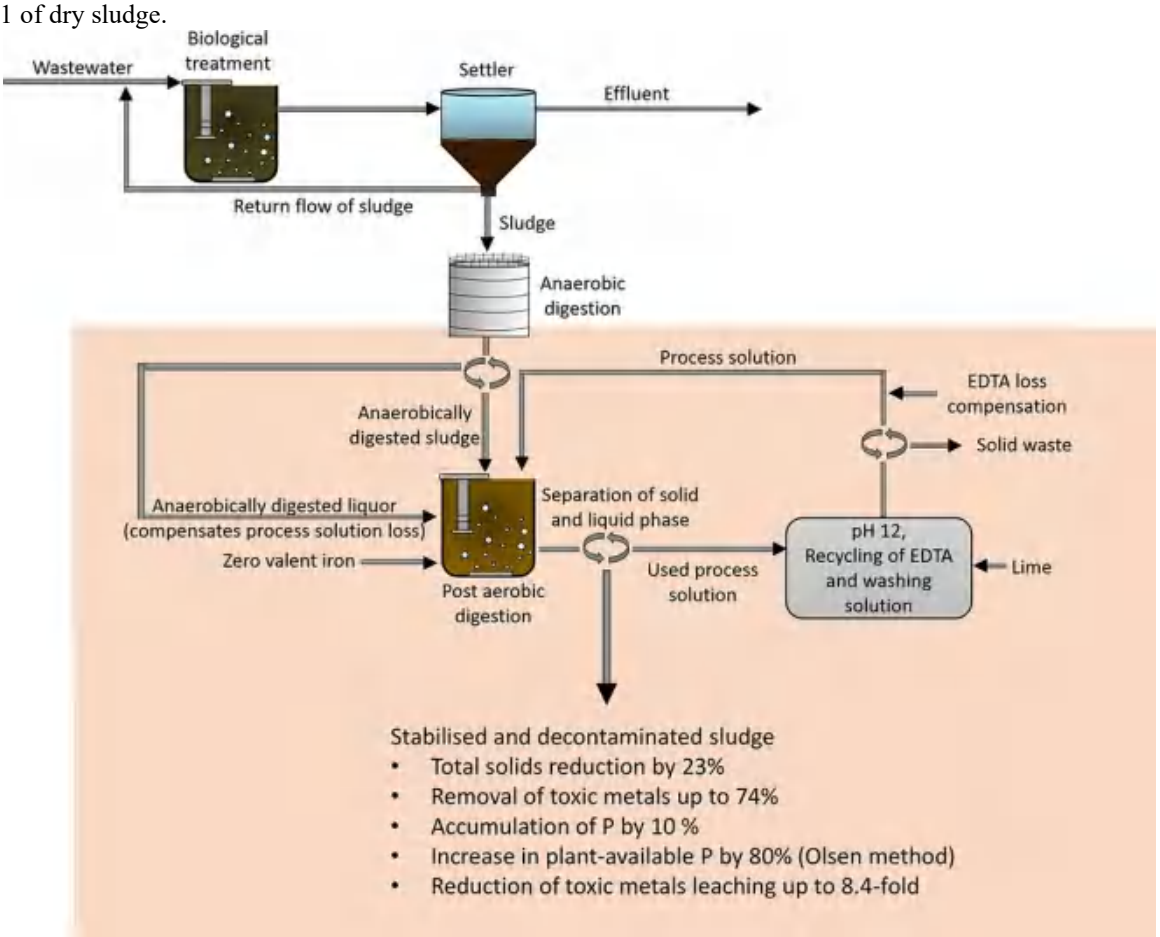
# Simultaneous aerobic stabilisation of sewage sludge and chelator-assisted removal of toxic metals in a closed-loop process



**Barbara Fojkar*** **and Domen Lestan**[1]

[1] *Biotechnical faculty, University of Ljubljana, Jamnikarjeva 101, Ljubljana 1000, Slovenia*

*barbara.fojkar@bf.uni-lj.si

## ABSTRACT

Sewage sludge is a valuable source of phosphorus but contains toxic metals that hinder its use as fertilizer. We present a novel process that simultaneously stabilises sludge through post-aerobic digestion (12 days, pH 5.8–7.6, solid-to-liquid ratio 1:25 (dry w/v)) and removes toxic metals using ethylenediaminetetraacetate (EDTA, 10 mM). On average, 74.4% of EDTA was successfully recycled by alkalinization of process solution with quicklime (CaO) to pH 12.5 and reused in subsequent batches. Chelator losses were compensated by the addition of Na-EDTA. Toxic metals, along with excess Ca and Na, were effectively removed from the recycled process solution, enabling closed-loop operation without wastewater generation. During five consecutive batches, total solids in the sludge were reduced by an average of 23.2%, and 74, 61, 26, and 43% of Zn, Cu, Cr, and Pb, respectively, were removed. The leaching of residual toxic metals from the stabilised and decontaminated sludge was further reduced by 55–88% through the addition of zero-valent iron (3% dry w/w). The process also increased the phosphorus concentration in the sludge by 15% and improved its phytoavailability up to 1.8-fold (as determined by ammonium-lactate extraction). This process is sustainable: it preserves valuable nutrients, can be integrated into existing wastewater treatment plant operations, generates only 17% solid waste (relative to the dry weight of the sludge), and produces no wastewater. Due to the recycling of costly EDTA, reagent costs were halved, reaching €73 t-1 of dry sludge.

# Blended Amendments to Reduce Soil Phosphorus Solubility and Mitigate Phosphorus Loss with Snowmelt Flooding

**D.Kumaragamage[1*], A.I. Dissanayake[1], I. Hetti Arachchige[1], D. Goltz[1], I. Amarakoon[3], S.P. Indraratne[1] and N. Casson[1]**

*[1] The University of Winnipeg, Winnipeg, Canada*

*[2] University of Manitoba, Winnipeg, Canada*

*d.kumaragamage@uwinnipeg.ca

## ABSTRACT

Spring snowmelt flooding is a major pathway of phosphorus (P) loss from croplands in cold regions such as the Canadian prairies, posing a threat of eutrophication to freshwater bodies. The beneficial management practices commonly adopted to minimize P losses due to soil erosion and rainfall runoff (e.g., conservation tillage) have often led to an increase in dissolved P losses with snowmelt, particularly in non-erodible flat landscapes. Thus, alternative P loss mitigation strategies are needed for cold, flat regions where P loss is dominated by snowmelt runoff. The application of soil amendments is a strategy to decrease soluble P in surface soils, thereby reducing losses. Since a range of soil- and amendment-specific mechanisms are responsible for reducing P loss, blended amendments are a more effective approach than applying a single amendment. We evaluated gypsum ($CaSO_4.2H_2O$) and ferric chloride ($FeCl_3$) applied singly (2.5 Mg $ha^{-1}$), or as a 1:1 blend (2.5 Mg $ha^{-1}$ of each) on soil P solubility and P release from flooded soil under cold conditions in packed and intact soil columns. To investigate the amendment effects on P solubility, six soils collected from agricultural fields in Manitoba, Canada, were treated with gypsum, ferric chloride, or their blends, and incubated at room temperature with an unamended control and analyzed for water extractable P (WEP) at 0, 28, and 84 days. To investigate the amendment effects on P release under simulated snowmelt conditions, packed (same six soils) or intact soil columns (four selected soils) were amended with gypsum, ferric chloride, or their blends, flooded with ultrapure water, and incubated at cold temperatures (+4 °C) for 56 days. Floodwater samples collected bi-weekly were analyzed for dissolved reactive P (DRP) concentrations. Both single and blended amendment treatments significantly reduced WEP in soils compared to the unamended control, with blended amendment treatment showing a superior impact than single amendments. In the packed soil column study, blended amendment resulted in greater DRP reductions in floodwater, with an 87% decrease in DRP concentration at 56 days, compared to 64% and 46% reduction with ferric chloride and gypsum, respectively, applied alone. In the intact soil column study, the decrease in DRP concentration in floodwater of intact soil columns ranged from 31 to 56% for gypsum, 93 to 99% for ferric chloride, and 95 to 98% for blended amendment, with no significant difference between single amendment of ferric chloride and blended gypsum-ferric chloride treatments. Our results suggest that amendment blends can be more effective in reducing P loss from soils with snowmelt flooding; however, the long-term impacts of amendment applications need to be investigated in the field under varying environmental conditions.

*E-mail sushila.joshi@uq.edu.au

**ABSTRACT**

Improving soil phosphorus (P) availability is critical for crop productivity, as only 0.1-0.5% of total soil P is readily available to plants. In the grain production regions of northeast Australia, this is particularly important on the alkaline Vertosols in which high calcium availability restricts P solubility. The study aimed to understand the fate and dynamics of fertiliser-derived P in a Vertosol under cultivation for 36 years in the Colonsay long-term field experiment, focusing on the accumulation, transformation, and mobility of P across depths and soil P pools. The study used soil from four long-term treatments: 0N 0P, 0N 20P, 80N 0P, and 80N 20P, with soil P availability assessed using intensity, quantity, and buffer capacity factors. Samples from the topsoil (0–10 cm) and subsoil (10–30 cm) were analysed using BSES, NaOH-EDTA, and ignition-$H_2SO_4$ extraction to quantify P pools. Sorption-desorption kinetics and isotope exchange kinetics (IEK, $^{32}PO_4$–$^{31}PO_4$ exchange under steady-state conditions) were employed to evaluate P binding and release dynamics. Results showed that approximately 30% of applied P accumulated in the topsoil, primarily within moderately to sparingly labile pools, with NaOH-EDTA and BSES extractions accounting for 56% and 53% of total P, respectively, under fertilised conditions. Subsoil P concentrations also increased with fertilisation but remained lower than in the topsoil, indicating P uptake from deeper layers where soil moisture persists for longer. Long-term fertilisation reduced P sorption capacity, lowered hysteresis ratios, and enhanced desorption, thereby improving P mobility and availability. Conversely, unfertilised soils exhibited higher buffering capacity and limited P release potential. These findings demonstrate that fertiliser history modifies soil reactive surfaces and the behaviour of legacy P. Overall, surface-applied P fertilisers appear ineffective in improving crop P availability in Vertosols used for rainfed cropping, whereas deep banding in the subsoil may enhance P use efficiency and long-term sustainability.

# Fungal-mediated synergy between nitrogen fixation and phosphorus acquisition in a maize-lablab mixture

**ABSTRACT**

The productivity of legume-cereal intercropping systems is largely governed by symbiotic nitrogen fixation (SNF) and phosphorus (P) mobilization. Yet, how these processes interact synergistically to drive N and P facilitation remains poorly understood. Through a factorial experiment manipulating N level, P form, and root separation in a lablab-maize mixture system, we assessed plant nutrient, root traits, and microbial communities. We found that SNF in lablab was strongly correlated with tissue P concentration. Strikingly, structural equation modeling identified a direct, bidirectional reinforcement: shoot Ndfa was the strongest predictor of shoot P accumulation ($\beta$=0.52, $p<0.01$), and vice versa, shoot P was the strongest predictor of shoot Ndfa ($\beta$=0.55, $p<0.001$). Mixture (under mesh and no barrier) reduced the optimal N application rate for maize by around 50%, underscoring a significant N-saving effect. Compartment-specific fungal community mediated this synergy: under N amendment, lablab rhizosphere fungi correlated with maize soil nitrate ($NO_3^-$) (mesh) or specific root length (no barrier), while under P amendment, maize rhizosphere fungi were associated with lablab shoot Ndfa (mesh) or soil $NO_3^-$ (no barrier). These findings establish a novel paradigm of direct legume-mediated N–P coordination, positioning fungal communities as central hubs orchestrating nutrient synergies in cereal-legume systems.

*vonty@issas.ac.cn

**ABSTRACT**

Phosphorus (P) is a major limiting nutrient for crop production in many agroecosystems. Phosphorus-solubilizing microorganisms (PSMs) play crucial roles in mobilizing fixed soil P by secreting P-mineralizing enzymes such as acid phosphatase (ACP) and alkaline phosphatase (ALP). Fertilization, as a key anthropogenic disturbance, significantly shapes the diversity and composition of PSM communities, thereby influencing soil P mineralization. However, the responses of *phoC*- and *phoD*-harboring bacterial communities to different fertilization strategies, as well as the relative contributions of rare versus abundant taxa to P cycling, remain poorly understood. This knowledge gap hampers the development of microbiome-based solutions for sustainable agriculture.

In this study, we conducted a long-term fertilization experiment in the North China Plain, comparing organic manure and mineral fertilizer treatments with equal nutrient inputs. We assessed soil properties, phosphatase activities, and the diversity and assembly processes of *phoC*- and *phoD*-harboring bacterial communities. Organic fertilizer significantly enhanced ACP and ALP activities and altered the microbial community structure. Although rare taxa exhibited low relative abundance, they contributed disproportionately to community diversity and functional regulation, particularly under organic fertilization. Our results revealed distinct mechanisms underlying the contributions of *phoC*- and *phoD*-harboring communities. The diversity and network structure of rare *phoC* taxa were strongly associated with ACP activity and were primarily driven by species substitution processes. In contrast, the composition and function of *phoD* communities, particularly among abundant taxa, were mainly regulated by indigenous microorganisms. These contrasting mechanisms highlight the ecological significance of rare taxa and demonstrate that *phoC* and *phoD* communities contribute to soil P mineralization through different regulatory modes.

Collectively, this study provides novel insights into the functional roles of rare and abundant microbial subcommunities in soil P cycling. By uncovering the divergent regulatory mechanisms of *phoC* and *phoD* communities under fertilization, our findings offer a scientific basis for developing sustainable fertilization strategies and improving soil–plant health.

## ABSTRACT

The Mehlich 3 extraction (M3) is a high-throughput evaluation method for macronutrient availability in soils. Although M3-extractable amounts of exchangeable bases are generally comparable to those obtained by conventional extractions, notable discrepancies between the two approaches—particularly for phosphorus—have also been documented. These discrepancies tend to increase when mineralogical composition varies substantially among samples. In Japan, the dominant factor driving such variability is the influence of volcanic ash deposition on soil development. Therefore, we hypothesized that discrepancies between M3 and conventional extractions would be amplified in large-scale datasets encompassing paddy soils with contrasting degrees of volcanic ash influence. To test this hypothesis, we compared the Mehlich 3 method with conventional extractions using a multi-scale dataset of Japanese paddy soils to assess the reliability of converting M3-derived phosphorus and exchangeable bases. A total of 300 soil samples were collected across Japan, and classified into Local (n = 60), Regional (n = 145), and National (n = 95) scale datasets. The variability of physicochemical properties decreased with decreasing spatial scale, especially acid-oxalate extractable elements. Phosphorus and three base cations (Ca, Mg, K) were extracted either with the Mehlich 3 method or conventional methods; Bray 2 and Truog for P and ammonium acetate for base cations. Although the M3 method provided consistent extractability for exchangeable bases ($R^2 > 0.87$), its correspondence with conventional P extractions was weak when all soil samples were analyzed regardless of their spatial origin (Bray 2: $R^2 = 0.62$, Truog: $R^2 = 0.35$). Stratifying the dataset by spatial scale markedly strengthened their relationships as spatial scale narrowed, yielding strong linear correspondence at the Local scale (e.g., Bray 2: Fig.1). To identify the factors responsible for low correspondence at broader scales, we quantified the divergence as the ratio of P extracted by each conventional extraction to the M3 (Bray 2/M3 and Truog/M3) and performed multiple regression analysis using soil physicochemical properties as explanatory variables. The analysis identified amorphous Fe and Al (hydr)oxide contents ($Fe_o$ and $Al_o$) as the primary predictors controlling the divergence between M3-P and both conventional extractions ($p < 0.001$), indicating that their variability largely governed the divergence in P extractability between the methods. Overall, these findings indicate that the M3 method enables high-throughput evaluation of macronutrient availability in settings where the variability of amorphous Fe/Al (hydr)oxides is limited, such as local-scale domains. This study highlights the importance of recognizing mineralogical variability in the target dataset for achieving accurate nutrient evaluation and developing precision nutrient-management strategies in paddy soils with heterogeneous pedogenic settings.

**ABSTRACT**

Phosphorus (P) is one of the limiting nutrients for agricultural production in the tropics due to its high rates of adsorption and precipitation in the soil. The cultivation of cover crops associated with conservation management systems can enhance the efficiency of P use. Therefore, this study aimed to evaluate the accumulated yield of soybean and cotton in rotation and the changes in soil P dynamics promoted using cover crops and different soil management systems in three long-term experiments established in the Brazilian Cerrado. The treatments consisted of: two management systems (conventional tillage - CT and no-tillage - NT), three cover crops (pearl millet, ruzigrass and crotalaria) and a fallow. The cumulative yield of soybeans and cotton (Mg $ha^{-1}$) and changes in soil P fractions (0-5, 5-10, 10-20 and 20-30 cm) were determined after more than 15 years of cash crop/cover crop rotation. Cover crops, especially ruzigrass, increased soybean and cotton yields in the long term by up to 13.37 and 19.65%, respectively. In general, fallow and CT contributed to increasing the levels of labile P in the soil, while grasses (ruzigrass and pearl millet) reduced the less labile fractions of P. Our results indicate that the long-term use of cover crops increases the yield of cash crops. In addition, these plants can temporarily immobilize P in their biomass and access the less available forms of P in the soil, thus promoting legacy P cycling.

## ABSTRACT

In highly weathered acidic soils (pH<5.5), the phosphate ions ($HPO_4^{2-}$ and $H_2PO_4^-$) released from the phosphorus (P) source fertilizers tend to adsorb with the hydrolyzed aluminium ($Al^{3+}$) and iron ($Fe^{2+}$) in the soil solution, thus reducing P uptake and use efficiency by the plants. The use of Calciprill and sodium silicate can release of calcium ($Ca^{2+}$) and silicon (Si) ions to increase the pH of acidic soils and transform the active $Al^{3+}$ and $Fe^{2+}$ into insoluble hydroxides, thus changing the P adsorption behaviour in soils. A phosphate sorption study was conducted to elucidate the effects of Calciprill and sodium silicate on P sorption behaviour in an acidic soil (Bekenu series, *Typic Paleudults*). Four treatments were evaluated: (i) soil only without any amendment (S0); (ii) soil + Calciprill at 100% calcium saturation (C100); (iii) soil + sodium silicate at 150 kg $ha^{-1}$ (S150); and (iv) soil + Calciprill + sodium silicate (C100+S150). The P adsorption capacity was determined through the addition of P isonormal solutions at 250, 500, 750, and 1000 mg $L^{-1}$ P by establishing a linear relationship between the amounts of P adsorbed and left in the equilibrium solution. The collected data were fitted to Langmuir and Freundlich isotherms to reveal the P adsorption behaviour in the treated soils. The same soil samples were added with 0.01 mol $dm^{-3}$ calcium chloride to desorb the phosphate ions. Results revealed that C100+S150 significantly improved P adsorption compared with C100, whereas the insignificant difference in the amount of P adsorbed for S150 and S0 suggests that Calciprill dominantly increased P adsorption. It was observed that the P adsorption in S0, C100, and C100+S150 followed the Langmuir isotherm, whereas S150 followed the assumptions of Freundlich isotherm, indicating that the use of different amendments can influence P adsorption behaviour. For P desorption, the significantly higher P desorption in S150 was due to the higher affinity of water-soluble Si to mobilize P from the soil minerals, whereas lower P desorption in C100 was due to P fixation by the Calciprill temporarily as Ca-phosphate. These findings indicate that Calciprill can reduce P losses, whereas sodium silicate can release available P for crop uptake.

**ABSTRACT**

Excess phosphorus (P) loading has led to eutrophication and deteriorated the water quality globally. The existing limitation of analytical methods for tracing residual and recalcitrant P pools has posed a challenge to discern specific sources, specifically legacy sources, which are considered the missing piece of the global P puzzle. In this study, residual P pools of soils and sediments from the East Creek micro-watershed in the Chesapeake Bay watershed were sequentially extracted using 10 M $HNO_3$, 10 M NaOH, and aqua regia, and phosphate oxygen isotopes ($\delta^{18}O_P$) of these soil P pools were then measured. Additionally, the isotope integrity of each reagent was
assessed and found that 10 M $HNO_3$ and 10 M NaOH do not significantly compromise the original isotope values over the extraction time. The isotopes of inorganic residual soil Pi pools revealed a distinct range of isotope values among different land uses as well as specific landforms within each land use, suggesting the usefulness of isotopes of residual Pi pools to discriminate different P sources in sub-land uses. Furthermore, isotopes of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) of residual soil pools showed distinct signatures among sources and pointed to potential signals imprinted from the past cropping systems. Contributions of soils from wetland, streambank, agricultural
land, and forest sources varied systematically along East Creek. The Bayesian elemental fingerprinting model provided the effect of the dynamic nature of sources, as well as potential creek meanders. In conclusion, the integration of multi-isotope and elemental fingerprinting methods of residual soil P pools presents a promising and complementary tool for tracking sources in watersheds.

**ABSTRACT**

Phosphorus (P) deficiency is a major constraint to crop productivity and grain nutritional quality in cereal-based cropping systems worldwide. Moreover, unsustainable P management increase the risk of P accumulation in soils and subsequent transfer to surface waters. Enhancing phosphorus use efficiency (PUE) is therefore critical to simultaneously address agronomic, environmental, and resource-security challenges associated with P management. Effective and responsible P stewardship requires a comprehensive understanding of P dynamics within the soil–plant system and must be adapted to soil properties, climatic conditions, cropping system characteristics, and management intensity. Best management practices (BMPs) encompass not only fertilizer strategies but also crop and rotation management, soil acidity management, nutrient interactions, conservation tillage, assessment of off-site P loss risk, and farm-level economic and logistical factors. The 4R nutrient stewardship framework (right source, rate, time, and placement) provides a scientifically grounded approach for optimizing fertilizer use (IPNI, 2016). A wide range of P sources is currently available, including conventional mineral fertilizers, novel P formulations, organic amendments, and recycled products such as manure, sewage sludge, and food-processing wastes. These alternative sources require rigorous evaluation under laboratory, greenhouse, and field conditions to support science-based recommendations.

Selection of appropriate P rates is fundamental not only for maximizing crop response but also for managing P residual effects and minimizing environmental losses. Soil testing remains the principal tool guiding P fertilization decisions across most agricultural regions. A variety of fertilizer placement methods—seed-banding, side-banding, deep banding, and broadcasting—are used in cereal systems, and their effectiveness can be further enhanced through site-specific management and precision-agriculture technologies.

Timing of P application depends on soil P dynamics, crop requirements, and P source/placement. Given the low mobility of P in soils, applications are often made before planting to ensure adequate early-season P supply, a key determinant of yield potential and PUE.

Collectively, fertilizer BMPs constitute the foundation for sustainable P management in cereal-based cropping systems, contributing to improved P recovery and recycling in the soil, mitigation of environmental impacts, and long-term P resource sustainability.

# Managing Legacy Phosphorus for Sustainable Soil Fertility

**Mohamed El Mazlouzi[1*] and Fernando O. Garcia[2]**

[1] *The Global Phosphorus Institute, Benguerir, Morocco*

[2] *National University of Mar del Plata, Balcarce, Argentina*

[*] Mohamed.ELMAZLOUZI@tgpi.org

**ABSTRACT**

Legacy phosphorus (P) in agricultural soils presents a dual challenge: in some systems, accumulation offers a substantial nutrient reserve, while in others, depletion limits crop productivity. Harnessing these contrasting realities requires context-specific management strategies that optimize P use efficiency and sustain soil fertility. In P-rich soils, legacy stocks represent a potential nutrient capital, yet their mobilization is constrained by complex soil chemical dynamics, including adsorption-desorption equilibria, mineral precipitation, and sorption mechanisms. Advances in soil chemistry reveal that not all accumulated P is equally available, necessitating innovative approaches such as pH modulation, competitive anion management, or targeted biological interventions to improve accessibility. Conversely, P-depleted soils pose critical limitations to agricultural productivity, demanding interventions to rebuild soil P capital and ensure long-term food security. Across all systems, considerable gaps remain in understanding which legacy P forms can be effectively mobilized, optimal threshold values for use, and practical strategies to integrate these insights into field management. Long-term, multi-environment research is essential to develop strategies tailored to diverse soils, climates, and cropping systems. By integrating chemical, biological, and agronomic knowledge, it is possible to leverage legacy phosphorus as a strategic resource, enhancing soil fertility sustainably while supporting resilient and productive agroecosystems worldwide.

# Domestication of intercropping soil microorganisms: Legacies from a Long-Term Field Experiment

**Yuhong Lin[1*], Li Tang[2], Yi Zheng [3], Jingxiu Xiao[4]**

**ABSTRACT**

There have been numerous studies on crop phosphorus (P) uptake and utilization as well as soil P transformation in intercropping systems, yet few reports have addressed the legacy effects of soil microorganisms on P acquisition in such systems. The present study investigated the legacy effects of intercropping soil microorganisms adapted to long-term intercropping of corn and soybeans under different P application levels. A soil pot experiment was conducted using soil inoculated with training intercropping corn rhizosphere microorganisms from a continue seven-year intercropped corn field trial, and a sterilized soil treatment was included as a control. The field intercropping training trial involved three P application levels: 0, 60, and 90 kg $P_2O_5$ $ha^{-1}$ (labeled P0, P60, and P90). Corn growth, P absorption, mycorrhizal characteristics, soil bacterial, and arbuscular mycorrhizal fungi (AMF) diversity and composition under two P application rates: no P application (-P) and 40 mg P $kg^{-1}$ soil (+P) were measured. The results showed that inoculation with intercropping soil microorganisms significantly increased corn aboveground biomass and P acquisition. Under no P conditions, compared with the sterilization treatment, inoculation with intercropping soil microorganisms increased the corn aboveground biomass and P acquisition by 322-521% and 70-308%, respectively, which was significantly higher than the increase of 61-99% and 27-34% under +P conditions. Inoculation with soil microorganisms and P application levels jointly affected mycorrhizal characteristics. Compared with no P conditions, inoculation with soil microorganisms under +P conditions significantly increased the AMF colonization rate in the roots of corn by 171.06%, the hyphal length density in the rhizosphere soil by 63.44%, and the spore density by 43.28%. The colonization rate, hyphal length density, and spore density of AMF in corn inoculated with P0 treatment were significantly lower than those in P60 and P90 treatments. Phosphorus application reduced the diversity of AMF communities in the soil and enriched *Glomus*, *Claroideoglomus*, and *Acaulospora*. However, neither the P application levels nor microbial inoculation had a significant effect on soil bacterial diversity. In contrast, both treatments resulted in the enrichment of specific phyla, including *Proteobacteria*, *Actinobacteriota*, and *Chloroflexi*. In conclusion, the P application levels affected the intercropping legacy effects of P-acclimated soil microorganisms. Under the condition of P deficiency stress, intercropping soil microorganisms had a higher promoting effect on the corn growth and P absorption. Hence, appropriate reduction of P fertilizer application rate combined with intercropping could facilitate the role of soil microorganisms and promote the green and sustainable development of agriculture.

# Characterization and Dynamics of NaOH-Extractable Organic Phosphorus Species in Soils

**Yaqin Wang[1,2], Zheng Chen[1,2]***

*[1] Department of Health and Environmental Sciences, Xi'an Jiaotong-Liverpool University, Jiangsu 215123, China*

*[2] Department of Environmental Science, University of Liverpool, Liverpool L69 7ZX, UK*

* Zheng.Chen@xjtlu.edu.cn

**ABSTRACT**

Organic phosphorus (Po) plays a critical role in soil phosphorus (P) cycling, yet the behavior and fate of specific Po species remain elusive. This study utilizes ion chromatography coupled with inductively coupled plasma mass spectrometry (IC-ICP-MS) to characterize NaOH-extractable Po species in two soil types, tracking their temporal dynamics and response to degradation. Nine distinct P peaks were identified in soil extracts, four of which remain unidentified. These species were classified into three groups: unstable species, detected only in fresh plant or algal samples; stable species, consistently present across all samples with minimal variation; and indicator species, moderately sensitive to environmental changes. Notably, the indicator species α-glycerophosphate (α-gly) and an unidentified compound (P150) exhibited significant declines over time. Along a degradation gradient, P150 concentrations decreased by 66% in highly degraded grassland soils compared to non-degraded soils, while α-gly decreased by 27%. Furthermore, IC-ICP-MS revealed a tenfold discrepancy between colorimetric and direct Po measurements, underscoring the prevalence of recalcitrant macromolecular Po in soils. These findings enhance our understanding of soil P cycling and highlight the pivotal role of small-molecular Po in maintaining soil fertility and ecosystem resilience.

# Acidic Phosphorus-Rich Biochars Promote the Gorwth of Okra in Coastal Salt-Affected Soil: The Critical Role of Phosphorus-Transforming Bacteria

**Qiang Liu[1, *], Xianxiang Luo[1, 2], Fengmin Li[1, 2], Hao Zheng[1, 2]**

[1] *Institute of Coastal Environmental Pollution Control, Ministry of Education Key Laboratory of Marine Environment and Ecology, Frontiers Science Center for Deep Ocean Multispheres and Earth System, Ocean University of China, Qingdao 266100, China*

[2] *Laboratory for Marine Ecology and Environmental Science, Qingdao Marine Science and Technology Center, Qingdao 266237, China*

* E-mail Address of Presenting Author: liuqiang906@163.com

**ABSTRACT**

Coastal salt-affected soils, as typical marginal soils, are characterized by high salinity and strong alkalinity, which easily immobilize phosphorus (P) and result in extremely low P bioavailability. Meanwhile, the global depletion of P resources has exacerbated the bottleneck in the sustainable agricultural development of these areas. Acidic phosphorus-rich biochars (PBCs), with low pH, high P-loading capacity and slow-release potential, have emerged as a potential solution. However, the mechanisms by which PBCs enhance P bioavailability and soil primary productivity through regulating rhizosphere microbial communities remain unclear. Therefore, this study used original wood chip biochar (BC1) as the control, and three types of PBCs were additionally prepared through pre-modification with $H_3PO_4$ (BC2), post-activation with $H_3PO_4$ (BC3), and co-pyrolysis of $Ca(H_2PO_4)_2$ with wood chip (BC4). A 52-day pot experiment was conducted using okra (*Abelmoschus esculentus* L.) as the test crop in coastal salt-affected soils of the Yellow River Delta, aiming to systematically evaluate the performance of PBCs in enhancing P availability and primary productivity, and to reveal the key mechanisms by which PBCs drive microbial remodeling of soil microecology and P cycling. The results showed that compared with BC1, BC2 and BC4 achieved slow and long-term P release through the combination of stable Ca-P structures, P-containing group loading, and polyphosphate precipitation. BC2 and BC4 significantly reduced the pH of coastal salt-affected soils, and increased soil available P content by 78.8%-316% 211%-431%, respectively, thereby significantly promoting okra growth and fruit yield compared with BC1. Mechanistically, PBCs restructured the rhizosphere microbial community and enriched P-transforming bacteria (e.g., *Xanthomonas*, *Pseudomonas*) with functions of organic P mineralization (*phoD*), phosphate solubilization (*gdh*), polyphosphate hydrolysis (*ppx*), and phosphate transport (*pitA*). These bacteria drove the continuous mineralization and dissolution of P in coastal salt-affected soils, thereby significantly promoting okra growth and fruit yield. This study demonstrates that PBCs significantly enhance soil P bioavailability and plant productivity in coastal salt-affected soils by reshaping the rhizosphere microbial community, which provides a new perspective for understanding the microbial regulatory mechanisms of P cycling in coastal salt-affected soils, and further offers a feasible solution with both ecological and agricultural benefits to alleviate global P resource pressure, ensure sustainable agricultural development, and promote ecological restoration in coastal regions.

**Key words:** coastal salt-affected soil remediation; acidic phosphorus-rich biochars; P availability; rhizosphere bacterial community; P-transforming functions.

## ABSTRACT

Traditional P fertilizer recommendation is to apply all fertilizers as basal and incorporates into soils. These ways of application result in ferric phosphate and aluminum phosphate precipitations in acid soils, and calcium phosphate precipitations in calcareous soils. These precipitations are extremely difficult to turn into available form again due to their very low solubility constants. On the other hand, acidic root exudates may not help to increase the availability of P when the roots are not fully developed in early growth stage. Incubation studies in red soil and calcareous soil indicated that P availability decreased to 38%, 44% of the amounts applied at 10 days after application (DAA) and further decreased to 30%, 26% at 180 DAA. All evidences have shown that large amounts of P fertilizer as basal lead to form the precipitates, which are subject to erosion and consequently increase risks of eutrophication in the nearby river. Plants' growth is actually related to nutrient concentration in soil solution near rhizosphere soils. Research results showed that P concentration was extremely low in real soil solution near roots, e.g., 0.5–1 mg/L. However, in hydroponic system, most plants' roots could endure N, P, K concentration as high as 210, 31, and 235 mg/L (Hogland's formula). Therefore, nutrient management that focuses on increasing nutrient concentration in soil solution near rhizosphere would be an innovative way to increase nutrient use efficiency and also improve crop yield while reduce total fertilizer applications. A series of fertilizer trials were designed and tested for major vegetables grown in the area. Type of fertilizers used, concentration of nutrients in starter solution, application method, and timing of application were step-wise evaluated and final recommendation as "Starter Solution Technology" is presented.

Application with a P starter solution (180 mg/50 mL/plant) alone after transplanting increased initial growth of tomato transplants by 36%, and application with a N starter solution (240 mg/50 mL/plant) alone boosted initial growth of tomato transplants by 105%. However, combinations of N, P and K in starter solution (4800-4200-4000 mg/L of N–P–K), could boost early growth of tomato plants by 205% at 3 weeks after transplanting (WAT) and increased 155% of early growth in chili pepper plants at 2 WAT.

To obtain higher productivity and maintain soil sustainability, same starter solution was applied at 1st and 3rd timing of topdressing, and applied of solid side-dress fertilizer at 2nd and 4th timing of application. Regardless of season or crop tested, band application of 10 ton/ha organic fertilizers as basal, plus starter solution and both liquid, solid side-dresses was always identified as the best fertilization practices in all trials. This technology increased tomato fruit yields by 27-35%, and chili pepper yields by 19-20% as compared with chemical fertilizer check. Although concentrations of N–P–K in starter solution were extremely high, however, no injures of roots were found. Same fertilization technology can be also applied in organic agriculture by replacing the starter solution to organic liquid solution.

By using this starter solution technology, total amounts of fertilizers can be reduced to 67% of N–K, 50% of P in the chemical fertilizer check treatment. Reduction of total fertilizer application results in less nutrient accumulation in soils and improves soil health. Decreases the risks of soil erosion and eutrophication, reduces of fertilizer production are all contribute to less carbon emission of soil environment.

**Keyword:** rhizosphere fertility management, starter solution, starter solution technology.

# Sustainable Phosphorus Recovery Using Modified Olive Pomace Biochar

## ABSTRACT

In line with circular economy principles, transforming waste biomaterials into adsorbents for phosphorus recovery from wastewater offers a cost-effective approach by reducing both biowaste disposal and adsorbent production expenses. Numerous studies have shown that phosphate adsorption using waste-derived biomaterials is a more attractive and environmentally sustainable option, as it converts wastes into valuable resources. Furthermore, the use of biowaste-based adsorbents represents an innovative alternative to conventional chemical precipitation methods, which are less environmentally friendly due to their reliance on metal-based coagulants and high operational costs.

In this study, a novel biowaste that has been poorly investigated for phosphate valorisation and recovery from both synthetic and real wastewater was explored. Specifically, the potential of olive pomace–based biochar was evaluated. The olive pomace was collected from a local olive oil extraction facility, dried, and subjected to pyrolysis at 500 °C for 2 h under limited-oxygen conditions. The pyrolysis yield of the raw olive pomace biomass was 38%, which falls within the expected range for this feedstock at 500 °C. The resulting biochar was subsequently modified to enhance its surface reactivity and introduce metal sites capable of strongly binding or precipitating phosphate. The modification strategies investigated included acid treatment and magnesium impregnation applied before and after pyrolysis, and their performance was compared with that of unmodified biochar.

To evaluate the influence of pH and biochar type on phosphorus adsorption capacity, batch experiments were conducted using a synthetic phosphorus solution with a concentration of 10 mg P/L. A 0.01 M NaCl solution was added as a background electrolyte to simulate ionic strength conditions similar to wastewater. In addition, the biochars were characterized by Fourier-transform infrared spectroscopy (FTIR) to identify surface functional groups, and zeta potential measurements were performed to assess surface charge behavior across different pH values. The biochar exhibiting the highest adsorption performance was subsequently selected for further investigation. Additional adsorption experiments were conducted to examine the effects of biochar dosage, phosphorus recovery at different initial P concentrations, adsorption kinetics over time, and the influence of shaking versus non-shaking conditions.

Our next step is to test the selected biochar under real wastewater conditions and evaluate its potential use in agriculture as a fertilizer and soil amendment.

# Higher leaf phosphorus and nitrogen concentrations and greater allocation of phosphorus to lipids in Helicia and Heliciopsis than in other genera within the Proteaceae

**ABSTRACT**

The Proteaceae is a predominantly southern hemisphere plant family that contains about 83 genera encompassing about 1600 species. Proteaceae are generally well adapted to soils poor in plant-available phosphorus (P), causing them to have generally low leaf P and nitrogen (N) concentrations, and relatively high leaf N/P ratios. One of the most recognisable adaptations to low P soils in most Proteaceae is the ability to form cluster roots, short-lived clusters of 10's to 100's of determinant rootlets per centimetre of secondary lateral root. When mature, cluster roots exude a burst of carboxylates and often phosphatases that release inorganic and organic P sorbed to soil particles and hydrolyse organic P to inorganic P, respectively. The mobilised inorganic P can then be taken up by plants. *Helicia* and *Heliciopsis* are the only genera of Proteaceae found in Asia. There are about 115 species of *Helicia*, ranging from the east coast of Australia to southern Japan and extending westward to Sri Lanka. There are about 20 species of *Helicia* in China. *Heliciopsis* contains about 14 species and is only found in south Asia, with three species found in China. We examined three species from each genus found on acid soils with low plant-available P in Yunnan and Guangxi provinces. We found cluster roots on four species, indicating that cluster roots are likely produced by most species in these genera. We found that both genera have high leaf P and N concentrations compared with most other genera of Proteaceae but have N/P ratios that are similar to genera from extremely P-poor habitats. These observations indicate that the higher leaf P concentration is likely used to increase leaf protein concentration. Upon examining one species from each genus, we found that each allocated a higher proportion of leaf P to phospholipids than to other P fractions when compared to species from severely P-impoverished environments. This difference in investment strategy presumably improves membrane function. Our results add knowledge to an understudied genus of low-P specialist plants that may be useful for forest restoration.

**ABSTRACT**

During their life cycle, plants encounter simultaneous biotic and abiotic stresses. A low availability of inorganic phosphorus (P) commonly limits plant growth in natural and agricultural ecosystems. Pathogen attacks pose risks to plant productivity and biodiversity, causing yield loss and ecosystem degradation. Plants evolved various strategies to cope with P limitation, which, in turn, affect their resistance to pathogens. However, a comprehensive understanding of how efficient plant P-acquisition strategies influence their pathogen resistance under P-limited conditions remains elusive. We highlight how these P-acquisition strategies can enhance or decrease pathogen resistance through multiple mechanisms. We advocate using this information to design more sustainable agricultural systems and explain species turnover in natural ecosystems, especially in the context of global change.

*Email: aahussain@abu.edu.ng, abbatygeotech@gmail.com

**ABSTARCT**

Phosphorus (P) is a critical yet limiting nutrient for crop production in many tropical soils due to fixation, low native availability, and inefficient fertilizer use. This study assessed the phosphorus fertility status of soils at the Institute for Agricultural Research (IAR) farm, Ahmadu Bello University, Zaria, Northern Nigeria, to generate evidence to support sustainable phosphorus stewardship and improved nutrient management. A total of forty-seven (47) disturbed soil samples were collected across the fields at 300m grid intervals at the top soil (0-30 cm) using Edelman auger and analyzed for available phosphorus alongside selected physicochemical properties. Results revealed spatial variability in soil available P, with values ranging from low (4.41 mg/kg) to an exceptional high level (73.5 mg/kg) across the farm, indicating significant heterogeneity in P availability. Observed P availability was strongly influenced by recent fertilization, soil pH, organic carbon content, and textural characteristics, highlighting the role of inherent soil properties in phosphorus dynamics. The findings suggest that blanket fertilizer recommendations may lead to inefficient P use and underscore the need for site-specific phosphorus management strategies. Adoption of soil test-based fertilizer application, integration of organic amendments, and improved placement techniques are recommended to enhance phosphorus use efficiency, reduce losses, and sustain soil fertility. This study provides locally relevant data that bridge soil science and practical nutrient management, contributing to regional efforts toward sustainable phosphorus use and resilient agricultural systems.

We sincerely appreciate Prof. Ado A. Yusuf, the Executive Director of the Institute for Agricultural Research (IAR), for his visionary leadership in initiating and sponsoring the Land Evaluation of the IAR Research Farm. This project would not have been possible without his unwavering support and commitment to advancing agricultural research and development.

We extend our heartfelt gratitude to the Institute for Agricultural Research (IAR) for providing the resources and enabling environment that ensured the successful execution of this project.

We are deeply indebted to the Head of the Department of Soil Science, Prof. Aisha Abdulkadir, whose guidance, mentorship, and encouragement were invaluable throughout the course of this work. Our appreciation also goes to the participating scientists for their expertise and dedication, which greatly contributed to the success of the study.

We also wish to specially acknowledge Prof. Ya'u S. L., whose mentorship profoundly shaped our perspective on spatial analysis and its integration with conventional soil survey approaches. His insights demonstrated how geospatial techniques and classical pedological methods are complementary, together providing a more robust and holistic framework for land evaluation and decision-making.

We are equally grateful to the technical staff for their diligence and tireless efforts in both the field and laboratory. Special recognition is given to the soil analysis laboratory team, whose meticulous analysis of soil samples played a critical role in achieving the objectives of this project.

Finally, we thank everyone who, in one way or another, contributed to the successful completion of this important work. Your collective efforts have not only enriched our understanding of the research farm but also laid a solid foundation for future advancements in agricultural research.

**ABSTRACT**

The limited global availability of phosphorus resources has increased the need for strategies that improve phosphorus use efficiency and reduce reliance on external inputs in agricultural systems. One of the major challenges in this context is the low availability of phosphorus in calcareous soils, where long-term pedogenic processes have resulted in high total phosphorus contents that remain largely inaccessible due to strong fixation by calcium carbonate. This constraint significantly reduces fertilizer efficiency and limits crop productivity in many arid and semi-arid regions.

In this study, the potential of a biosurfactant produced by *Pseudomonas putida KT2440* was evaluated as a biological approach to enhance phosphorus availability in calcareous soil. Both incubation and greenhouse experiments were conducted using a soil with low available phosphorus. The effects of biosurfactant application were compared with commonly used chelating agents and soil amendments, including EDTA, citric acid, and humic acid, in terms of soil nutrient availability, soil chemical properties, and maize growth.

The results demonstrated that biosurfactant application significantly improved soil phosphorus availability under calcareous conditions. Soil available phosphorus increased by up to fivefold compared to control, while maize phosphorus uptake increased by approximately 40%. In greenhouse experiments, biosurfactant-treated soils consistently produced higher maize biomass and phosphorus uptake than both the control and other treatments. Although EDTA showed strong chelation capacity, its application led to marked increases in soil electrical conductivity and altered nutrient balance, raising concerns about its environmental suitability.

The observed enhancement of phosphorus availability can be explained by several interacting mechanisms associated with biosurfactant activity. These include the formation of soluble complexes with calcium ions, which reduce calcium–phosphate precipitation, and surface-active interactions at the soil–solution interface that improve soil particle wettability and facilitate the release of phosphorus from soil minerals. Importantly, these processes occurred without substantial changes in bulk soil pH or electrical conductivity, allowing efficient phosphorus mobilization while maintaining overall soil chemical stability.

Overall, the findings of this study highlight the potential of microbial biosurfactants as a practical tool for phosphorus stewardship. By mobilizing existing, non-available soil phosphorus pools, biosurfactants can enhance nutrient use efficiency, reduce dependence on synthetic amendments, and support more sustainable soil fertility management and crop production systems, particularly in calcareous soils.

**ABSTRACT**

Phosphorus (P) is essential for plant growth but is frequently immobilized in insoluble forms. This is particularly relevant in arid and semi-arid, carbonate-rich soils, where alkaline pH promotes Ca–P precipitation. Despite P surpluses in many agricultural soils (about 70%), more than 55% of global cropland still shows low to medium-low P use efficiency. Microbial biostimulants, including non-pathogenic endophytic fungi, may enhance P mobilization via organic acid production and P-solubilizing enzymes.

Here, six *Trichoderma* spp. strains were isolated and screened for their ability to solubilize hydroxyapatite [$Ca_5(PO_4)_3(OH)$; Hap] in vitro. Screening was performed using a modified National Botanical Research Institute's phosphate medium in which tricalcium phosphate was replaced by Hap (NBRIP-Hap). Isolates were pre-cultured on potato dextrose agar (6 d, 22 °C) and inoculated into NBRIP-Hap under shaking conditions. Culture filtrates were collected after 1, 3, and 6 days to quantify soluble P and to determine pH and electrical conductivity. Fungal biomass dry weight and mycelial P content were determined at day 6.

Based on in vitro performance, the three best strains were selected for a pot experiment under controlled growth-chamber conditions using tomato (*Solanum lycopersicum* L.) as a model plant. Pots were filled with soils contrasting in key physical and chemical properties (texture, pH, carbonate content) and spanning different P backgrounds (total and plant-available P). The experiment aimed to quantify strain-dependent effects on soil P mobilization and plant P acquisition under standardized conditions. Results will be presented as an oral communication or poster.

# Innovative Approaches to Sustainable Nutrient Management

**Ping He**

[1] *Institute of Agricultural Resources and Regional Panning, Chinese Academy of Agricultural Sciences, Beijing, China*

heping02@caas.cn

**ABSTRACT**

Fertilizer has revolutionized crop production, but a lack of evidence-based fertilizer usage has resulted in negative economic and environmental ramifications, particularly for smallholder farmers. This study aimed at developing an innovative nutrient recommendation approach, Nutrient Expert (NE), for improving yields of grain crops, cash crops and vegetables, while optimizing fertilizer input through adoption of 4R (applying the right source of nutrients at the right rate, time and place) nutrient stewardship technologies. We also evaluated its large-scale performance in enhancing crop productivity and reducing environmental impacts across cropping systems. To validate the benefits of NE on both yield and environmental protection, we compared NE with current farmers' practices (FP) in over 3,000 field experiments conducted in major crop production areas of China.

Overall, the NE treatment increased grain yield by 4.6%–13.5% and profit by 6.2%–18.8% compared to FP. In addition, NE reduced fertilizer nitrogen (N) inputs by 29.0% and 14.7% relative to FP and the standard practice (ST), respectively. Across the 3,281 sites, NE improved nitrogen recovery efficiency by 4.6–13.4 percentage points over FP. On average, NE reduced reactive nitrogen losses by 36.2% and greenhouse gas (GHG) emissions by 21.5% compared to FP. Field experiments also showed that NE treatment alleviated early blight in potatoes and slowed yield reduction by 33.9%. When NE was combined with corn straw or sheep manure, particulate organic matter (POM) increased and the disease index declined. Based on NE-guided nutrient application rates, crop-specific controlled-release fertilizers were developed. Field trials demonstrated that these fertilizers increased yields by 9.2%–12.3% and improved crop quality in rice, potato, tea, citrus, and rapeseed, despite lower fertilizer inputs.

In summary, NE is a user-friendly tool with broad applicability across diverse farm types and climatic regions. It holds significant potential for improving fertilizer use efficiency and supporting food security in smallholder farming regions of China, where N fertilizer is often over-applied or used inappropriately. NE also contributes to soil health by reducing soil-borne diseases through its effects on soil POM dynamics. Moreover, NE-guided, crop-specific fertilizers enhance both yield and quality with reduced fertilizer use. This approach may be extended to help mitigate N losses and GHG emissions in other regions globally.

## ABSTRACT

Controlled-release fertilizer (CRF) has proven to be a highly effective strategy for driving substantial improvements in nutrient-use efficiency while minimizing environmental cost in intensive agriculture. However, CRF application alone has a limited effect on increasing crop yield and is therefore insufficient to meet the growing demand for food. Here, we used artificial intelligence (AI) to design high-yield maize production systems and develop region-specific CRF products, which were further integrated into an AI-based CRF application strategy for high-yield maize production system (ACHYS). Firstly, we developed an AI-based high-yield maize production system based on regional climatic resources, soil conditions, we optimized hybrid selection, planting density, and sowing date to improve yield potential, and close yield gaps. Second, based on the high-yield maize nitrogen requirement dynamic, we designed the controlled-release nitrogen application strategy by considering crop growth duration, pre- and post-silking nitrogen allocation, seasonal precipitation and soil fertility. The principle was that optimized controlled-release nitrogen proportion and its release duration to match the high-yield maize nitrogen demand, allowed common nitrogen to support early growth and controlled-release nitrogen to sustain post-silking nitrogen supply and grain formation. Third, we integrated controlled-release nitrogen fertilizer design with phosphorus and potassium management to develop regional specific controlled-release nitrogen formulated blended fertilizers. ACHYS built an enhanced AI- and product- driven integrated soil-crop system management approach. Over the past decade, 27 on-farm network experiments across China's major maize production regions have demonstrated that, ACHYS increased maize yield by 19.7%, improved nitrogen use efficiency by 54.4%, and significantly reduced greenhouse gas emission. Collectively, these findings prove that integrated AI-based high-yield crop system design with innovative fertilizer products can accelerate the transformation of intensive agriculture toward higher productivity and lower environmental cost.

## ABSTRACT

Pig manure and biogas slurry after anaerobic digestion are the reservoir of antibiotics and antibiotic resistance genes (ARGs), the application of unpretreated pig manure and biogas slurry to soil may be harmful to human health via food chain. This study explored the effects of adding biochar (Large particle sizes biochar, LPB, 5-10 mm; Small particle sizes biochar, SPB, < 0.074 mm) to pig manure aerobic composting and the cow manure biogas slurry bio-drying process as well as hydrochar addition and molecular membrane covering (MMC) on the variation patterns of antibiotics and ARGs; subsequently, the effect of low-dose (4.68 t/ha) and high-dose (18.73 t/ha) biochar-based compost products on ARGs migration within the soil-cucumber systems were investigated. **The results show that:** (1) Compared to LPB, SPB more effectively accelerated the rise in pile temperature and prolonged the high-temperature period (>50℃). SPB and LPB additions increased the antibiotic removal rate during composting from 40% to 50% and 76%, while SPB decreased the absolute abundance of ARGs and mobile genetic elements (MGEs) by 28% and 19%; (2) during cow manure biogas slurry bio-drying, the peak temperature of the pile reached 76.1–77.4°C, approaching ultra-high temperatures (>80°C) without the addition of ultra-high-temperature bacterial agents. The final moisture content decreased to 25.2%–31.5%, whilst achieving 95.4%, 98.6%, and 86.7% removal of antibiotics, ARGs, and MGEs from the biogas slurry during bio-drying, with the MMC showing enhanced efficacy over hydrochar addition. *Methanosarcina*, an anaerobic methanogenic archaea, was identified as a potential host for ARGs and MGEs exhibited the most significant direct effect on ARGs; (3) subsequently, the application of both traditional and biochar-based compost products at low-dose (4.68 t/ha) (2022) and high-dose (18.73 t/ha) (2023) levels to the same soils in different years increased soil organic matter and N, P, K content. However, the application of low-dose compost products increased the abundance of ARGs and MGEs in both soil and cucumbers. For high-dose (18.73 t/ha) compost products application, compared to pre-experimental values in soil, compost products application further suppressed the proliferation of ARGs and MGEs, with SPB-based compost products showing the most effective results, followed by LPB-based and conventional compost products. Moreover, compared to the control group without fertilizer application, high-dose compost products application decreased the abundance of ARGs and MGEs in cucumbers. Soil nutrient level is a significant factor influencing the migration of ARGs from soil to cucumbers. In summary, biochar addition and MMC were effective strategies for the high-efficiency removal of antibiotics and ARGs during pig manure composting and biogas slurry bio-drying, with subsequent application of high-dose (18.73 t/ha) compost products effectively suppressing ARGs spread from soils to cucumbers.

## ABSTRACT

According to the Food and Agriculture Organization of the United Nations (FAO), approximately 33% of the world's agricultural soils suffer from moderate to severe degradation. Notably, soil degradation in protected agriculture occurs at a rate 5 to 10 times faster than in open-field farming, posing a significant challenge to the sustainable development of global intensive agriculture. Greenhouse tomato production, representing one of the most widely cultivated vegetable crops worldwide, is severely constrained by soil degradation induced by continuous cropping, which hinders the high-quality advancement of the industry. While microbial regulation represents a core green technology for soil health maintenance, current commercial microbial inoculants generally suffer from limitations such as low targeted efficacy and inconsistent field performance. Therefore, this study aims to develop a multifunctional microbial inoculant specifically tailored for the continuous cropping systems of greenhouse tomatoes. Utilizing native microbial resources from forest ecosystems in Northeast China as the core germplasm, we screened and rationally constructed a composite microbial consortium comprising 5 *Bacillus* strains/species and 10 *Trichoderma* strains/species. This consortium integrates three core functions: disease suppression, growth promotion, and soil amelioration. Through a two-year consecutive field experiment, we systematically evaluated the restorative effects and underlying mechanisms of this inoculant on degraded soils. The results demonstrated that the functional microorganisms, applied via drip irrigation, efficiently colonized the rhizosphere and exerted multiple synergistic regulatory effects. First, the inoculant reshaped the rhizosphere microecology, suppressed soil-borne pathogens, and drove the succession of rhizosphere microbial communities toward a healthier state. Second, it significantly enhanced soil enzyme activities and expanded nutrient pools. Compared to the control, the activities of rhizosphere acid phosphatase, urease, and sucrase increased by 3.3, 2.1, and 2.1 times, respectively. Furthermore, soil organic carbon, total nitrogen, and available phosphorus contents increased by 4.63 g/kg, 0.545 g/kg, and 128.03 mg/kg, respectively. Third, it optimized tomato root architecture, increasing root volume by 2.17 times relative to the control. Field applications confirmed that the inoculant achieved the synergistic benefits of "soil restoration, yield improvement, quality optimization, and enhanced postharvest shelf life." In addition to ameliorating degraded soils, the treatment increased the maximum single fruit weight by 150 g, elevated sugar content by 3.1%, and extended shelf life by 5 to 12 days. This green regulatory system, developed using indigenous microbial resources from China, provides an effective "Chinese solution" for maintaining soil health in protected agriculture. Furthermore, it aligns closely with the "Zero Hunger" and "Life on Land" objectives of the United Nations Sustainable Development Goals (SDGs). Moving forward, we anticipate profound cooperation with global partners to jointly promote the development and field validation of specialized inoculants for diverse climatic regions, addressing global soil degradation challenges and safeguarding sustainable agricultural development.

# Research Progress and application of Slow/Controlled-Release Fertilizers

**Yuechao Yang**

*Shandong Agricultural University, Taian 271018, Shandong, China*

yangyuechao2010@163.com

**ABSTRACT**

Fertilizers play a critical role in ensuring grain yield improvement in China while the low nutrient use efficiency of conventional chemical fertilizers has resulted in considerable resource waste and environmental pressure. As an effective and sustainable solution, controlled-release fertilizers (CRFs) can significantly improve nutrient utilization efficiency and show great potential in labor saving, fertilizer reduction, and yield enhancement. However, traditional coating materials for CRFs are mainly dependent on non-renewable petrochemical resources, featuring high cost and poor biodegradability. The utilization of agricultural wastes such as straw for bio-based coating materials remains a global challenge due to their complex chemical composition, ambiguous film-forming mechanisms, and high hydrophilicity.

To address these issues, we identified the cellulose bond-breaking sites during straw liquefaction and confirmed that bio-based polyols are the dominant liquefaction products. A chain extension film-forming technology was developed to overcome the explosive polymerization reaction, laying a solid foundation for converting straw and other bio-based resources into qualified coating materials. Furthermore, a superhydrophobic modification strategy based on magnetic nanoparticle self-assembly was proposed. A thin air layer formed at the water-coating interface prevents direct water wetting, allowing moisture to diffuse inward only in vapor form, thereby delaying nutrient release. The hydrophobicity was improved by 90.5% compared with conventional petrochemical-based coatings.

An interpenetrating network densification technology densifies the coating structure and immobilizes internal impurities, inhibiting pore formation and extending the controlled-release period. The controlled-release longevity was increased by 333% relative to unmodified bio-based coatings and by 25.3% relative to petrochemical-based coatings. To improve the low toughness and high fracture rate of bio-based coatings, a self-healing modification technology using dynamic covalent bonds was constructed. The coating fracture rate was reduced from 8.1% and 5% for unmodified bio-based and petrochemical-based coatings to only 1%, achieving stable and reliable controlled-release behavior. Notably, the degradation rate of the developed bio-based coatings is 10-12 times that of petrochemical-based coatings, with complete degradation achievable within three years.

With these results and progresses, we have realized the strategic transformation from petrochemical-based coatings to green bio-based coatings for controlled-release fertilizers and provided a Chinese model for the intelligent and green production of controlled-release fertilizers. This offers important technical support for the green development of national agriculture and food security.

## ABSTRACT

Malnutrition, poverty and hunger are the devil of hidden hunger which has already gained its ultimate importance after setting of Millennium Development Goals (MDGs) followed by Sustainable Development Goals (SDGs). Worldwide, over 2 billion people suffer from micronutrient deficiencies such as vitamin A. Orange-fleshed Sweet potato (*Ipomoea batatas* (L) Lam) is one of the foremost vital crops since all parts are valuable for human utilization, animal feed, and industrial applications. The high nutritive value of Orange-Fleshed Sweet Potato makes it a helpful option for consumption especially among children and pregnant women in underdeveloped nations where Vitamin A deficiency is a major concern. This study was carried out on an Ultisol at Teaching and Research Farm of Faculty of Agriculture, Alex Ekwueme Federal University, Ndufu-Alike (AEFUNAI) Ikwo, Ebonyi State during the 2022 and 2023 planting seasons, to assess the growth and yield performance of Orange-fleshed Sweet potato (*Ipomoea batatas* (L) Lam) in order to determine the optimal rates of N, P and K fertilizer application and its impact on soil chemical properties at Ikwo. The treatments were Urea (N) applied at four levels namely 0, 45, 90, and 135 kg/ha; Triple Super Phosphate (TSP) applied at four levels namely 0, 15, 30, and 45kg/ha and Muriate of Potash (MOP) applied at four levels namely 0, 20, 40, and 60 kg/ha. The experiment was factorial arranged in a Randomized Complete Block Design (RCBD) with three (3) replications. Orange-fleshed Sweet potato (OFSP) data collected were vine length (cm), number of leaves, number of branches, weight of storage root/plot (kg/plot), and total storage root yield (t/ha). Soil samples were collected with a soil auger at a depth of 0 to 20cm at the end of the experiment for chemical analysis such as soil pH, organic carbon, available phosphorus, total nitrogen, exchangeable acidity, and total exchangeable bases such as $K^+$, $Ca^{2+}$, $Mg^{2+}$, and $Na^+$. All data collected were subjected to Analysis of variance (ANOVA) for factorial experiment in Randomized Complete Block Design (RCBD) using GenStat statistical package 17$^{th}$ Edition with the treatment means separated using the Fisher's Least Significant Different (FLSD) at 5% probability level and Pearson's correlation analysis was carried out between soil chemical properties values with that of growth and yield parameters of orange-fleshed sweet potato using IBM SPSS Statistics 20 package, while the optimum rates of N, P and K applications were determined following a graphical method using Microsoft Excel 2019 to obtain regression equations, which when differentiated produced x-values representing the optimum rates of applied fertilizers for orange-fleshed sweet potato production. The results obtained indicates that the application of fertilizer rate of 135 kg Urea, 45 kg TSP and 60 kg MOP produced greater improvement in soil chemical properties in both 2022 and 2023 planting seasons. Also, the growth and yield parameters of orange-fleshed sweet potato were improved significantly ($P < 0.05$) with the application of 90 kg Urea, 30 kg TSP and 40 kg MOP compared to the control in the two years of the experiment. Moreover, the application of 88.58kg and 89.92 kg N/ha produced maximum yield of 6.2t and 6.98t/ha; 32.51kg and 33.32kg P/ha produced maximum yield of 55.99t and 7.03t/ha; and 36.03kg and 42.25kg K/ha produced maximum yield of 6.07t and 7.06t/ha in 2022 and 2023 planting seasons respectively at Ikwo. Consequently, there is a positive and highly significant ($P = 0.01$) correlations between soil chemical properties and yield components of orange-fleshed sweet potato. The application rate of Urea fertilizer of 89kg/ha, TSP fertilizer of 32.5kg /ha and MOP fertilizer of 42kg/ha is highly recommended for the production of OFSP in Ikwo.

## ABSTRACT

This study aimed to evaluate the short-term effects of molasses-derived digestates from one- and two-stage anaerobic digestion processes on a winter wheat crop and selected soil characteristics. A microcosm experiment was conducted in Central Poland under a temperate climate. Twenty plots, each measuring 1 m x 0.5 m, were established in 2023, and winter wheat was planted during the subsequent two seasons at a sowing density of 400 grains per m². The experimental design included not fertilized (NF) plots and plots fertilized with an optimized mineral fertilizer (MF), as well as plots that received one-stage (1-SD) or two-stage (2-SD) digestate. The fertilizer doses were calculated based on nitrogen (140 kg $ha^{-1}$ per year), and applied at two doses. Soils were sampled from the humus horizon using a corer just before the first fertilizer application (early spring) and immediately after harvest. The soil pH, as well as the contents of total organic carbon (TOC), total N, and the bioavailable forms of N ($NO_3^-$N and $NH_4^+$N), P, Na, K, Ca, Mg, Mn, Cu, and Zn were determined. The wheat crop characteristics included plant density and height, grain and straw mass, number of grains per ear, and mass of 1000 grains. The results revealed significant variations in wheat crop characteristics depending on the fertilization variant. The greatest differences were noted between the NF and MF, which usually represented the minimum and maximum values, respectively. Wheat at NF plots was characterized by the lowest values of all studied parameters. In contrast, MF plots represented the highest values. Plots fertilized with digestates exhibited wheat crop characteristics intermediate between NF and MF, and differences between 1-SD and 2-SD were usually low. The effects of various fertilization practices on the studied soil properties were not fully clear. An increasing tendency in pH and relatively stable levels of TOC and N were recorded in every plot. Most of the bioavailable nutrients showed increasing trends during the experimental period; however, this occurred in all plots, including NF, which is difficult to explain. Such trends were typical for P, Ca, Mg, Mn, Cu, and Zn. Conversely, the contents of $NO_3$-N and $NH_4^+$-N decreased steadily without variation depending on the fertilization variant. The application of digestates significantly increased the content of bioavailable Na and K compared to the NF and MF variants. However, there were no significant differences between the 1-SD and 2-SD plots. In summary, we confirmed the fertilization value of one- and two-stage digestates. However, the effects of their application are much lower compared to optimized mineral fertilization. Additionally, the differences between the tested types of digestate are low in terms of their effects on the wheat crop and soil properties.

**ABSTRACT**

The development of controlled-release urea (CRU) using ethyl cellulose (EC) represents a significant strategy for advancing the green and sustainable development of agriculture. However, limited research on EC-coated urea preparation was reported before. This study employed EC/ethanol to develop CRU through fluidized bed technology and investigated the effects of the coating processes, material plasticization modification and surface treatment on the film structure and nitrogen release properties of CRU. The results demonstrated that the fluidizing gas temperature significantly influenced both the film structure and release performance. When the coating temperature was 50 ℃, a continuous and uniform dense film was formed, resulting in optimal controlled-release performance lasting up to 7 days. Additionally, the effects of the peristaltic pump rate and coating liquid concentration were minimal. The plasticization effect of DBS was validated through XRD analysis, which demonstrated a reduction in the crystallinity of the EC, an enhanced fracture elongation of the film, and an extended controlled-release performance to 10 days. Furthermore, surface treatment with 1 % and 2 % paraffin wax improved the water barrier properties of the film, increasing its water contact angle from 100°. Consequently, the controlled-release period of the coated urea was extended to 50 days, meeting the ISO 18644:2016 standard. This study is valuable for fertilizer production and provides a References for cellulose- coated fertilizers.

**ABSTRACT**

Declining soil fertility and the limited efficiency of conventional soil amendments are critical constraints to sustainable agricultural productivity in semi-arid ecosystems. Integrated soil fertility management (ISFM) offers a viable approach for restoring soil nutrient reserves and enhancing crop performance. This study investigated the effects of different fertilizer regimes on soil physicochemical properties and the productivity of onion (*Allium cepa* L.) and wheat (*Triticum aestivum* L.) under semi-arid conditions at the Usmanu Danfodiyo University Teaching and Research Vegetable Farm. Four treatments were evaluated: chemical fertilizer (Alelawa NPK 20:10:10), biofertilizer (Bio-NPK; NANDO product), a combination of both, and an unfertilized control, arranged in a randomized complete block design (RCBD) with three replications. Baseline soil analysis revealed a sandy loam texture, slightly acidic pH, low Nitrogen, organic carbon and available phosphorus, and high bulk density. Application of Bio-NPK alone slightly reduced soil pH (from 6.80 to 6.41) and bulk density (from 1.80 to 1.73 g $cm^{-3}$), while increasing organic carbon, Nitrogen and phosphorus contents. Similar but more pronounced improvements were recorded under combined Bio-NPK and chemical fertilizer application. Fertilizer treatments had a significant effect on crop yields. Onion yield was highest under the combined Bio-NPK treatment (13.25 t $ha^{-1}$), outperforming the sole applications and control (4.60 t $ha^{-1}$). Wheat grain yield ranged from 267.9 to 797 kg $ha^{-1}$, with the combined treatment producing the highest yield (797 kg $ha^{-1}$). These results demonstrate that integrating biofertilizers with conventional NPK fertilizers substantially improves soil quality and crop productivity in semi-arid regions, offering a sustainable pathway to enhanced food security.

## ABSTRACT

Yardlong bean (*Vigna unguiculata* subsp. *sesquipedalis*) is a nutritionally valuable and economically important vegetable both within Thailand and internationally. However, the application of chemical fertilizers to boost its production due to high consumer demand damages the soil environment. Therefore, this study aimed to evaluate the plant growth promotion (PGP) ability of rhizobia strains from yardlong bean root nodules as biofertilizer alternatives to boost sustainable yardlong bean production. All isolates from the initial pool of 19 isolates exhibited effective nodulation, however, isolates YL 1, YL 3 and YL 14 had the highest phosphate-solubilization (103.20 ppm), potassium-solubilization (22.55 ppm), and Indole-3-Acetic Acid production (52.20 ppm). Overall, isolate YL 14 had the best PGP traits. To confirm this, a split-plot Completely Randomized Design (CRD) experiment with four replications was conducted in the lab, where the PGP ability of the three rhizobia isolates (YL 1, YL 3, and YL 14) was tested at nine dilution levels: $10^{-1}$ to $10^{-9}$. The results showed that the $10^{-2}$ dilution of YL 14 produced the highest shoot fresh and dry biomass (3.86 and 0.4 g/plant, respectively). Furthermore, results from a subsequent CRD pot experiment in the greenhouse comprising control, chemical fertilizer (Urea - 46:0:0), and YL 14 powder inoculant treatments were consistent with those obtained in the lab: YL 14 significantly enhanced plant growth, yielding the overall highest average fresh and dry weight (110.27–117.73 and 21.96–22.89 g/plant, respectively), chlorophyll content (50.19), and nitrogen concentration (2.32%). Additionally, YL 14 improved all tested parameters compared to the control ($p < 0.05$), and increased shoot and root dry weights, root fresh weight, chlorophyll and nitrogen contents compared to the urea fertilizer treatment ($p < 0.05$). Collectively, these findings highlight the potential of YL 14 biofertilizer to replace urea fertilizer in enhancing the yield and supporting sustainable yard long bean production due to its multiple PGP traits.

**ABSTRACT**

Faba bean (*Vicia faba*) is a niche pulse crop in Western Australia (6000 tonnes per year[1)], largely targeting markets in the Middle East. This study focused on commercial production of carrier-based inocula, considering relative cost, efficacy, ease of use, and machinery availability. There were two segments: laboratory-scale inocula production and trialing the inocula efficacy in a glasshouse. In addition to non-inoculated control (treatment 1-T1), the consortia, a mixture of rhizobia species specific to different pulses and microbes used in this study (T2), faba bean-specific rhizobia strain SRDI969 (Group F) (T3), *Bacillus megaterium* (T4), mycorrhizae (T5), and *Trichoderma sp*. (T6) to assess the impact on growth. As the initial step, microbial strains were harvested at their log phase (>$10^8$ cfu $mL^{-1}$) and stored at 4 ºC until further processing. Then, microbial strains, were coated to carrier considering moisture retention and cell viability. Sterilised Hoagland solution (0.5-strength) was prepared without nitrogen and added to the pots containing presterilized soil as a basal nutrient supplement (0.1 L $kg^{-1}$) until reaching 60% of the water holding capacity. The surface sterilised faba bean seeds (cv. Samira) were placed in soil 1 cm deep together with the prepared bacterial inocula (1 g $seed^{-1}$). The pots were arranged in a randomised complete block design in a glasshouse; throughout the study, sterilised water was added to maintain the field capacity. The plants were grown until anthesis (~40 days), and the parameters measured were chlorophyll fluorescence, dry biomass, mineral nitrogen and dehydrogenase enzyme activity in the rhizosphere soil, shoot total nitrogen content, and root nodulation and morphological characteristics. One way ANOVA (n=3) was conducted using R, after Shapiro Willis test indicated the data were normally distributed. Significantly ($P \leq 0.05$) higher chlorophyll fluorescence ($P=0.001$) was observed in mixed inoculum treatment (T2) compared with the control (T1). Shoot dry biomass was higher in the inoculated treatments (T2-T6) than in the control. Mineral nitrogen in the rhizosphere soil ($P=0.000$) was significantly higher in T3 than the other treatments. Total root length and average root diameter were lower in the control compared to the other treatments, and a similar trend was observed in dehydrogenase enzyme activity. As expected, crown nodulation was observed only in T2 and T3. These findings suggest that the produced inocula positively influenced faba bean growth and the soil health parameters.

**ABSTRACT**

Sodic soils are widely distributed globally across semi-arid and arid regions, with agricultural productivity often limited due to structural instability caused by high concentrations of exchangeable sodium ($Na^+$). This instability is caused by clay dispersion and leads to reduced water infiltration, surface crusting, and poor seed germination. Although gypsum and other organic ameliorants are commonly used to address sodicity, the use of polyhalite ($K_2Ca_2Mg(SO_4)_4 \cdot 2H_2O$) is of potential interest given that it is a multi-element amendment that could potentially co-supply limiting nutrients at the same time as supplying Ca to aid $Na^+$ removal. We conducted a 60-day incubation study to examine the amelioration of sodic soils from Australia using both inorganic and organic amendments, being gypsum, polyhalite, chicken manure, pig manure, and polyacrylamide (PAM). Two application rates of polyhalite were used, with polyhalite supplied at a rate in which the Ca content was equivalent to that of gypsum, and a second in which polyhalite was supplied at a rate such that the combined Ca and Mg content was equivalent to that of Ca supplied in gypsum. It was found that the application of both inorganic (gypsum and polyhalite) and organic (chicken manure, pig manure) were effective in improving structural stability, Polyhalite was equally effective as gypsum in improving structural stability, but with the added benefit of nutrient co-supply (K and Mg). Nevertheless, it was observed for all amendments that effectiveness tended to decrease somewhat over time, highlighting the need for reapplication to ensure long-term effectiveness.

## ABSTRACT

The banding of potassium (K) fertilizers is becoming increasingly common and may disrupt K stratification within the soil profile. Although the movement and availability of K from these fertilizer bands are critical in determining subsequent plant uptake, much remains unclear in this regard. This study examined the movement and potential availability of K from fertilizer bands, using different K sources (sulfate of potash granules[SOP], and polyhalite granules as POLY4 ($K_2SO_4MgSO_42CaSO_4 \cdot 2H_2O$), three soils differing markedly in their properties (a calcareous Alfisol, an Ultisol, and an Oxisol, all with low levels of potentially available K) and co-application of P (monoammonium phosphate [MAP]). The diffusive gradients in thin-films (DGT) technique was used to visualize the movement of K and P into the soil from the fertilizer bands. In addition, synchrotron-based X-ray absorption near edge structure (XANES) spectroscopy was utilized for both K and P to determine changes in speciation. The results from the DGT and soil analyses showed that after incubation for two weeks, the distance that the K moved in all three soils was similar despite the three soils differing markedly in their properties (including cation exchange capacity [CEC] and clay content). Similarly, K movement away from the band did not differ markedly between the two K sources (SOP and POLY4) or with the co-application of MAP. However, it was observed that the application of K as POLY4 resulted in higher water-soluble K concentrations than SOP (by 41-130 mg K kg-1) and correspondingly lower exchangeable K (by 29-67 mg K kg-1) after incubation for two weeks, due to the competition of Ca and Mg with K for exchange sites. It was also noted that the co-application of P with POLY4 decreased water soluble K concentrations by 41-115 mg K kg-1 in the Alfisol (< 30 mm) and by 33-50 mg K kg-1 in the Oxisol (< 50 mm), but increased exchangeable K concentrations by 32-39 mg K kg-1 in the Alfisol (10-80 mm), 55-93 mg K kg-1 in the Ultisol (< 30 mm) and 123 mg K kg-1 in the Oxisol (0-10 mm). These effects were likely due to the formation of compounds, being Ca- and Mg-phosphates in the Alfisol, Fe-phosphates in the Oxisol, and Al-phosphates (e.g., taranakite) in the Ultisol. Indeed, XANES analyses for both P and K indicated the formation of taranakite-like compounds in the Ultisol following the co-application of P. The findings here suggest that deep banding of K fertilizers, including POLY4, may have the potential to overcome K stratification particularly in soils with high CEC. In addition, P co-application may slow K release in acidic soils with high concentrations of soluble Al. Further studies are warranted regarding how Ca and Mg in polyhalite will affect K movement and availability in strong K-fixing soils and in the presence of plants.

**ABSTRACT**

Rice production faces dual challenges of insufficient plant-available silicon (Si) in soils and environmental risks from conventional Si fertilizers. While diatoms, as bioactive silicon sources, show potential for soil amelioration and yield enhancement, their dose-response relationships and mechanistic roles in paddy ecosystems remain poorly understood. This study systematically investigated the synergistic effects of diatom (DI), natural diatomaceous earth (NDE), alkali-modified DE (ADE), and commercial Si fertilizer (CF). Three levels of Si application were established: low (0.0625 g $SiO_2$ $kg^{-1}$ soil, equivalent to 122 kg $SiO_2$ $ha^{-1}$) alleviated silicon deficiency stress, medium (0.125 g $SiO_2$ $kg^{-1}$ soil, equivalent to 244 kg $SiO_2$ $ha^{-1}$) and high (0.25 g $SiO_2$ $kg^{-1}$ soil, equivalent to 488 kg $SiO_2$ $ha^{-1}$) doses were employed to investigate potential effects of silicon excess on the soil-plant systems. We quantified key soil parameters (including pH, nutrient availability) and rice agronomic traits (including tiller number, plant height, panicle weight, grain yield). We employed Partial Least Squares Path Modeling (PLS-PM) and Principal Coordinate Analysis (PCoA) to conduct multidimensional dissection of the Si source-soil-crop interaction network. Results revealed that medium-rate diatom treatment (0.125 g $kg^{-1}$ soil) significantly enhanced soil available Si, alkaline-hydrolyzable N, and available K (by 4.6%, 10.7%, and 44.0%, respectively), reduced Cd and Pb bioavailability (10.3–7.6%), and increased rice yield (41.7%) via improved nutrient assimilation (total N: +13.4%; total K: +24.6%) and optimized agronomic traits (seed-setting rate: 94.8%; harvest index: 44.9%). PCoA and PLS-PM demonstrated that diatoms remodeled soil nutrient networks through sustained Si release, mediating heavy metal detoxification and yield synergism. As the first systematic exploration of silicon cycling dynamics mediated by living diatoms in paddy soils, this study clarifies clarifies the unique benefits of silicon uptake and stress tolerance in rice compared to fossilized sources, providing practical guidance for optimizing sustainable silicon management strategies in agriculture.

## ABSTRACT

Low use efficiency of conventional fertilizers creates significant environmental damage and impedes global food security, particularly given the 60-70% increase in food production needed by 2050 to support the population. Further confounding these efforts is climate change, which is forcing crop cultivation under more marginal conditions. The low efficiency of nitrogen and phosphorus use represents perhaps the most significant shortcoming of conventional agriculture, wasting tremendous resource inputs and causing significant environmental damage. We are exploring nano-enabled strategies to increase the efficiency and precision of macronutrient application. For nitrogen, efforts have focused on enhancing biological nitrogen fixation (BNF) to reduce use and increase yields. BNF relies on prokaryotic species fix N2 to NH3; these species form symbiotic relationships with legume roots. Enhancing BNF could reduce resource inputs for fertilizer production and subsequent greenhouse gas emissions. In fact, excessive use of synthetic nitrogen fertilizers likely severely limits BNF activity. We have demonstrated that nanoscale MoS2, Fe3O4, and NiO modified with sucrose, chitosan, and/or silica can enhance BNF by several mechanisms. For phosphorus, nanoscale tunable biopolymer-based strategies can control availability, including nutrient embedding in nanocellulose-based hydrogels that are modified with hydrophobic shells to tune release. Separately, different forms of nanoscale or conventional phosphorus have been blended with polymers biopolymers to control release and availability. Another project is investigating citrate-stabilized amorphous calcium phosphate nanoparticles that are doped with micronutrients as a fertilizer, as well as impacts on the rhizosphere microbiome. In all cases, phosphorus materials were used in plant-growth studies, with significant findings including up to 90% decreases in nutrient leachability/run-off, increased in planta phosphorus, biofortification of other micronutrients, and increased bioavailability of residual soil P. This work collectively demonstrates that nanotechnology-based solutions safely increase fertilizer use efficiency and crop yield, which is critical to reducing the negative environmental impacts of agriculture and for combatting global food insecurity in a changing climate.

**ABSTRACT**

A substantial proportion of the world's soils have undergone degradation, leading to increased dependence on mineral fertiliser application. Degradation increases the risk of aggregate breakdown and soil sealing under rainfall or irrigation. In productive agricultural soils, exchangeable cations are typically in the order $Ca^{2+} > Mg^{2+} > K^{+} > Na^{+}$. Depending on inherent soil characteristics, deviations from this can either promote aggregation or physico-chemical dispersion. This study quantified the effect of commercially available mineral fertilizers Sulphate of Potash, Muriate of Potash, LIMEX® and three forms of Polyhalite on soil erodibility and soil crusting. Dissolution of the mineral fertilizers tested and partitioning in the surface crust and sub-surface soil matrix were also investigated. Experimental soils were obtained from the United Kingdom, France, and Brazil in order to investigate the influence of contrasting physico-chemical soil characteristics and mineralogy.

Air-dried sieved (<2.0 mm) soils were uniformly packed into 100 mm internal diameter and 50 mm deep PVC microcosms and subjected to a single intensity storm event [80 (± 5.0) mm $h^{-1}$,14 min duration]. The experiment was divided into a wet and dry phase. During the wet phase, splash detached material was collected in a 300 mm diameter concentric ring collector and post-rainfall unsaturated hydraulic conductivity ($K_{un}$) measurements made using a Minidisk infiltrometer. Each microcosm was fitted with a type MOM, 10cm long, Ø 2.5mm Rhizon Sampler and soil solution extracted via evacuation tubes. The relative proportion of Ca, Mg, K, S and Na in the soil solution, soil matrix and soil crust was determined using a Perkin Elmer 950D ICP-MS. For the dry phase, penetrative resistance of the surface crust was evaluated using an Instron Bluehill® system. This study provides invaluable insights into the effect of Ca-Mg-K based mineral fertilisers on soil erodibility and soil crusting.

# Potassium Precipitation Efficiency at Different Dilution Ratios in Thai Sugarcane Molasses

**Karima Amphong[1*], Daojarus Ketrot[1], Saowanuch Tawornpruek and Chalermchart Wongleecharoen[1]**

[1] *Department of Soil Science, Faculty of Agriculture, Kasetsart University, Bangkok 10900, Thailand*

*E-mail Address of Presenting Author: karima.am@ku.th

**ABSTRACT**

Sugarcane (*Saccharum officinarum* L.) is an economically important crop worldwide, supplying the primary feedstock for sugar production, while its by-products support a range of downstream industries. Molasses, a viscous dark-brown by-product of sugar processing, contain high levels of potassium (K). Efficient K recovery from molasses has been demonstrated using a two-step precipitation process consisting of dilution followed by the addition of calcium acetate and sulfuric acid to form syngenite (Otani et al., 2023). However, it remains unclear whether Thai molasses, derived from different cane varieties and processing conditions, exhibits similar precipitation behavior. This preliminary study used molasses from a sugarcane mill in central Thailand to evaluate the effect of dilution ratios on K precipitation efficiency and identify the dilution level that maximizes K recovery. The molasses sample was first analyzed for pH, electrical conductivity (EC), and total K content, and then diluted with $H_2O$ at ratios of 1:0.3, 1:0.4, 1:0.5, 1:0.6, 1:0.7, 1:1.0, and 1:1.25 (w/w). Each dilution was reacted with calcium acetate and sulfuric acid in triplicate. Precipitates were collected, oven-dried, and weighed, and their total K contents were determined. The remaining supernatant was analyzed for pH, EC, and total K.

Preliminary analysis of the Thai molasses sample showed that it was slightly acidic ($pH_{1:2}$ water = 4.75) and had a high $EC_{1:2}$ water of 15.28 mS $cm^{-1}$, reflecting its concentrated ionic composition. The molasses was also rich in K, containing 30.29 g $kg^{-1}$, confirming its suitability as a K-rich feedstock for precipitation-based recovery. Dilution ratio had a significant effect on both the quantity and K concentration of the precipitates ($p < 0.01$). The highest precipitate yields were obtained at dilution ratios of 1:0.40 and 1:0.60. Total K concentration in the precipitates also varied significantly, ranging from 30.27 to 51.44 g $kg^{-1}$, with the highest concentration observed at the 1:0.70 dilution, followed by the 1:0.40 dilution. However, when considering the actual amount of K recovered, the 1:0.40 dilution ratio was the most effective, achieving the highest K recovery of 51.83%. The supernatant from this treatment had a pH of 2.84, an EC of 8.27 mS $cm^{-1}$, and a residual total K concentration of 12.73 g $kg^{-1}$, indicating efficient removal of K from solution. Overall, the results indicate that an intermediate dilution ratio of 1:0.40 provides the most efficient conditions for K recovery from Thai sugarcane molasses. However, further investigation is needed using molasses samples sourced from different regions of Thailand, as well as different calcium salts, to confirm the robustness and broader applicability of the process.

*eun3349731@naver.com

**ABSTRACT**

Poly butylene adipate-co-terephthalate (PBAT) is an aliphatic–aromatic copolyester-based biodegradable plastic derived from petroleum resources. Conventional non-biodegradable polymers used in controlled-release fertilizers (CRFs) effectively regulate nitrogen release but persist in soil for extended periods, leading to microplastic contamination. In this study, the effects of PBAT-coated urea and polyethylene (PE)-coated urea on soil available nitrogen concentrations ($NH_4^+$ and $NO_3^-$) and greenhouse gas ($CO_2$, $CH_4$, and $N_2O$) emissions were compared with those of uncoated urea and a non-fertilized control. Each treatment was applied at a rate of 0.4 g of fertilizer per 200 g of soil and incubated at 25℃ for one month under dark conditions. To evaluate the effects under upland and paddy conditions, two moisture levels (60% water-holding capacity (WHC) and continuous flooding) were maintained. Under 60% WHC, $NH4^+$ concentrations showed no significant differences among treatments at the initial stage but were highest in the urea treatment at the intermediate stage. Under flooded conditions, $NH_4^+$concentrations were initially significantly higher in the urea treatment due to rapid hydrolysis of urea, while PE- and PBAT-coated urea treatments maintained higher levels during the intermediate stage as a result of delayed nitrogen release. Although both coated fertilizers showed prolonged $NH_4^+$ retention in the late-stage, PBAT-coated urea showed earlier nitrogen release compared with PE-coated urea, which might be attributed to faster biodegradation of the PBAT relative to PE. Under 60% WHC, $NO_3^-$concentrations increased in a sigmoidal pattern due to nitrification whereas in flooded conditions, $NO_3^-$ accumulation was 91% lower. $CO_2$ emissions were greatest in the PBAT and PE coated urea treatment under 60 % WHC and flooded conditions, respectively, suggesting that microbial activity associated with degradation of the polymer coatings under aerobic conditions. $CH_4$ emissions were highest in the PE-coated urea under 60% WHC and in the urea treatment under flooded conditions. Under flooded conditions, urea promoted $CH_4$ emissions because nitrogen sources could enhance methanogenesis. Under 60% WHC, $N_2O$ emissions were elevated because aerobic conditions promoted active nitrification compared to flooded conditions. In flooded conditions $N_2O$ emission was highest in the urea treatment due to rapid urea hydrolysis enhancing denitrification. Overall, PBAT-coated urea retarded nitrogen release and reduced greenhouse gas emissions compared with PE-coated and uncoated urea fertilizers showing the potential of PBAT-coated urea as a sustainable alternative to reduce microplastic pollution and mitigate environmental impacts in agricultural soils.

# Chemical Gradients in the Fertosphere: Rethinking Fertiliser–Soil Interactions

**Enzo Lombi1, Casey Doolette1, Rodrigo C. da Silva1, Brigid McKenna2 and Peter M. Kopittke2**

[1]*Adelaide University (Future Industries Institute, Mawson Lakes 5095 SA, Australia)*

[2] *The University of Queensland (School of Agriculture and Food Sustainability, St Lucia 4072 QLD, Australia)*

**ABSTRACT**

Fertilisers underpin modern food production, contributing 40–60% of global crop yields. However, average nutrient use efficiency (NUE) remains low leading to economic inefficiency, depletion of finite resources, and pollution from nutrient runoff and greenhouse gas emissions. The cost and geopolitical concentration of resources, heighten the urgency of improving efficiency. Improving NUE requires rethinking how soil-fertiliser interactions are studied. Traditional approaches often overlook the steep chemical gradients that develop in the immediate zone of soil surrounding fertiliser granules (i.e. the fertosphere) where nutrient concentrations, pH, chemical reaction and speciation vary dramatically over millimetres. Understanding these gradients is crucial for designing fertiliser formulations that maximise plant uptake and minimise losses to the environment. Classic studies identified distinct reaction zones, from near-granule precipitation to outer adsorption zones, but limitations in analytical methods forced researchers to use indirect, ex situ chemical extractions that mask these dynamics. Recent advances now enable in situ and spatially resolved analyses, marking a paradigm shift. Techniques such as Diffusive Gradients in Thin Films (DGT) in conjunction with elemental mapping techniques allow mapping availability in the fertosphere in 2D. Synchrotron-based X-ray Absorption Spectroscopy (XAS) allows in situ solid phase speciation and planar optode imaging can visualise changes in pH in the fertosphere. Integrating these tools enables a mechanistic understanding of how soil and fertiliser properties interact, informing the “4R” stewardship principles: right source, rate, place, and time. This new analytical framework can guide the formulation of fertilisers with tailored dissolution behaviour, pH control, and nutrient compatibility. For instance, mapping of ammonium phosphate fertilisers shows that local acidification can drive calcium phosphate precipitation, limiting P availability in calcareous soils. At the same time, co-application of P and K fertilisers in acidic soils can lead to the formation of insoluble K, P and Al compounds. Hence, a paradigm shift is essential: fertiliser science must move from bulk to gradient-resolved approaches. This is especially urgent given the rise of recycled nutrient fertilisers derived from waste streams, which are central to circular economy initiatives. These recycled products often contain diverse chemical species with variable solubility and efficacy. Mechanistic understanding of fertosphere processes will ensure these innovations genuinely improve NUE and sustainability rather than being driven solely by waste-sector economics.

## ABSTRACT

Improving fertilizer use efficiency while reducing pesticide loads, soil contamination and labour demand is a key challenge for sustainable agriculture. Water-fertilizer integrated systems that simultaneously co-deliver fertilizers and pesticides and exploit pesticide-fertilizer synergism is an effective way to save labour and improve resource use efficiency. However, most hydrophobic pesticides are incompatible with aqueous fertilizers and therefore rely on organic co-solvents and heavy surfactant use when combined with fertigation, increasing costs, complicating operation and threatening soil biota and groundwater. This work presents a pure water-based nano pesticide-fertilizer co-delivery system (WNPFS) that couples crop protection with micronutrient supply in a single input, enabling simultaneous pesticide-fertilizer application to reduce labour operations and overall agrochemical input costs.

Formulation parameters are optimised to maximise micronutrient loading, colloidal stability and robustness. Physicochemical characterisation (size, morphology, zeta potential, loading efficiency) confirms well-defined, stable nanostructure. Using rice as a model crop, foliar and root applications of WNPFS are compared with commercial formulations and rigid nanocarriers for leaf retention, root uptake, translocation, pest control and plant growth. Rare-earth labelling plus multi-scale imaging and ICP-MS tracking quantify transport across the rhizosphere-root interface, leaf barriers and within tissues, linking formulation design to nutrient use efficiency and soil exposure.

Transcriptomic and metabolomic analyses identify plant pathways involved in nutrient assimilation, stress mitigation, xenobiotic detoxification and root exudation under WNPFS versus conventional inputs, providing mechanistic insight into pesticide–nutrient synergism and potential feedbacks on rhizosphere processes relevant to soil health. Overall, WNPFS defines a nano-enabled agrichemical that unifies crop protection and micronutrient delivery in a solvent-free, water-compatible, soil-friendly form, reducing reliance on solvent-based formulations that can disturb soil biota and structure, and providing a labour-saving, cost-efficient and scalable route to fertilizers that support input reduction, soil health and sustainable agricultural intensification.

**ABSTRACT**

Bio-based coated controlled-release fertilizers (CRFs) represent a sustainable alternative to petrochemical-based coatings; however, their application is often limited by loose pore structures that lead to imprecise nutrient release and reduced longevity. This study addresses these challenges by developing a novel biocomposite coating that integrates Metal-Organic Framework-303 (MOF-303) into a castor oil-based polyurethane matrix.

MOF-303 was synthesized and successfully grafted onto the bio-based coating via self-assembly, as confirmed by FTIR, XPS, SEM, and TEM characterizations. The incorporation of MOF-303 significantly improved the coating's surface morphology, transforming rough, irregular surfaces into smoother, hierarchically porous architectures with enhanced hydrophobicity.

Key findings demonstrate that MOF-303 acts as a regulator of pore structure. While low concentrations (0.5%) acted as pore-opening agents, optimized concentrations (1.0% and 1.5%) effectively reduced porosity and extended the nitrogen release period. Specifically, the release duration increased from 63 days for the unmodified coating (BCF) to 105 days for the 1.5% MOF-modified coating (MBCF3). Kinetic modeling revealed that the release mechanism shifted from non-Fickian diffusion to Case-II transport, indicating precise control over nutrient delivery.

In pot experiments with spinach (Spinacia oleracea L.), the MOF-modified fertilizers significantly enhanced agronomic performance. Compared to urea treatments, the modified CRF increased spinach yield by 37.51% and chlorophyll content by 20.4%, while reducing nitrate accumulation by 40%. Furthermore, the modified fertilizer maintained high yields even with a 20% reduction in application rate, demonstrating significant potential for improving nitrogen use efficiency (NUE) and reducing agricultural non-point source pollution. This work provides new insights into constructing pore-oriented biocomposite coatings for sustainable and precise agriculture.

**ABSTRACT**

The recent increase in climate change and grain price volatility has highlighted the importance of food security. However, due to various factors such as urbanization and limited land area, the food self-sufficiency rate in the Republic of Korea has been continuously declining. To address this issue, reclaimed lands have been developed along the west coast to secure arable land, with the Saemangeum Reclamation Project, the largest of its kind, designating one-third of its total area as an agro-bio zone. However, the reclaimed soils are unsuitable for upland crop cultivation compared to general agricultural soils due to high pH, high salinity, and low nutrient contents. This study was conducted to characterize the Saemangeum reclaimed soils and to develop a composite soil amendment using various soil materials, evaluating its effects on soil improvement and crop productivity through the cultivation of *Triticum aestivum* L. 'Saekuemgang'. Surface soils were collected and analyzed from Zones 1, 2, 4, 5, and 6 of the Saemangeum agro-bio area, and the field experiment was conducted at the test field of the National Institute of Crop Science located in Zone 5. The developed composite soil amendment consisted of cocopeat, black peat, biochar, zeolite, hydrogel, and byproduct gypsum. Application rates were set at 11, 21, and 42 bags per 50 L (50, 100, and 200%), respectively. Chemical fertilizers of $N–P_2O_5–K_2O$ were applied at rates of 8.9, 12.0, and 3.6 kg $10a^{-1}$ for all treatments including the control. Based on the agro-bio zone soil analyses, all soils were classified as non-saline normal arable soils. However, the soil fertility levels were substantially lower compared to the national average of upland soils. The field experiment results indicated that the application of the composite soil amendment significantly improved soil properties and fertility compared to the control, which consequently enhanced wheat yield across all treatment levels. Further long-term application trials and studies on various food crops are required, which are expected to contribute to strengthening national food security through the improvement of food self-sufficiency.

**ABSTRACT**

Metal-organic frameworks (MOFs) have gained considerable attention as promising candidates for controlled-release fertilizers (CRFs) due to their tunable structures and high porosity. However, the widespread application of MOFs in CRFs has been hindered by the limitations of conventional hydrothermal synthesis methods, which are time-consuming (requiring up to 24 hours for reaction) and energy-intensive. Additionally, these traditional approaches often limit the selection of metallic elements to iron (Fe), restricting the diversity of available CRFs. To overcome these constraints, we present a microwave-assisted approach for rapid synthesis of multi-metal MOF-enabled CRFs. Through a systematic analysis of reaction parameters, we identified several key factors that govern the formation of Fe-MOFs and their nutrient release kinetics. The modulator dosage (urea-to-phosphate ratio) was found to be the most influential factor, with an optimal range of 0.5–1, followed by reaction temperature (120–160°C), reaction time (1.25–2.5 hours) and microwave power (600–800 W). The microwave-assisted process was significantly faster (8–16 times) compared to traditional hydrothermal methods, enabling synthesis within hours rather than a day. Moreover, the incorporation of additional metals, such as zinc (Zn), calcium (Ca), or a Zn/Ca mixture, altered the coordination environment of Fe-MOFs while maintaining Fe-centered coordination as the dominant structure. Characterization techniques, including PXRD and XPS, along with stability constants of coordination (Ig $K_n$) and hard and soft acid-base (HSAB) theory, confirmed these structural changes. Among the various formulations, the Zn/Ca mixture (MW12) exhibited the most significant alterations in pore structure and morphology. Multi-metal MOFs showed enhanced nutrient release rates, with a 31.0% increase in release and an 18.3% improvement in space-time yield compared to single-metal Fe-MOFs, indicating their potential for large-scale production. Specifically, MW12 demonstrated the fastest nutrient release (~9.9% over 30 days), following the diffusion-erosion kinetics. Pot trials further demonstrated substantial agronomic benefits, including a 13.8% increase in pak choi biomass and a 25.8% increase in rice seedling biomass, particularly with MW12. In summary, these findings suggest that the microwave-assisted method offers a rapid route to advanced, multi-metal MOF-based CRFs with tailored nutrient-delivery profiles.

**ABSTRACT**

Polyhalite is a naturally occurring mineral containing potassium, calcium, sulphur and magnesium. It is crushed and granulated to create the slow-release, low-carbon, multi-nutrient fertilizer called POLY4, produced and marketed by Anglo American plc.

Crop roots are intrinsically sensing and seeking organs, searching the soil for water and nutrients to support growth. Despite germination and early growth stages being critical to crop yield, there is little information regarding how the application method of POLY4 affects crop rooting and establishment.

A pot experiment was used to investigate how the location of POLY4 influences the development or seedling root architecture, as well as the mobility and uptake of nutrients delivered by POLY4. Wheat seedlings were grown in columns containing POLY4 in different locations, representing different fertilizer application methods. X-ray Computed Tomography was used to quantify root development throughout germination and early establishment over 16 days. Additionally, inductively coupled plasma mass spectrometry (ICP-MS) was be used to investigate nutrient mobility in soil and uptake into plant tissues. The results of the study are important to inform effective application practices of POLY4 to the seedbed.

**ABSTRACT**

Soil fertility management is greatly improved when nutrients are supplied in alignment with the physiological demands of crops, and controlled-release fertilizers (CRFs) provide an effective approach for enhancing nutrient-use efficiency while minimizing environmental losses. In the present study, composite N–Zn fertilizers were developed using a polymer-based carrier engineered to regulate the release of urea and zinc oxide (ZnO). The primary objective was to synthesize, characterize, and evaluate N–Zn composites capable of sustained nutrient delivery through polymeric encapsulation, controlled swelling, and optimized nutrient loading. The composites were prepared via polymerization of partially neutralized monomers in a 1:3 ratio, incorporating a cross-linker, filler, and initiator, with ZnO introduced at varying levels (3%, 4%, and 5%) during synthesis. Nutrient loading was achieved by swelling the resulting superabsorbent polymer in aqueous urea solutions, yielding nitrogen contents ranging from 12.47% to 21.12% and zinc concentrations of 72.09 ppm to 90.86 ppm. Swelling behavior followed the order 5% N–Zn > 4% N–Zn > 3% N–Zn, demonstrating the influence of ZnO content on water absorption and release dynamics. FTIR analysis confirmed characteristic Si–O–Si and Si–O–Al vibrations of the bentonite framework, along with O–H, H–O–H, and C–H/N–H bands indicative of hydration and nutrient interaction, while Zn–O absorptions verified ZnO incorporation. Overall, the developed N–Zn composites exhibit strong potential as controlled-release fertilizers for improving nutrient retention and advancing soil fertility management.

## ABSTRACT

As global agricultural production increasingly relies on fertilisers, understanding the interaction between fertiliser formulations and soils is crucial for enhancing nutrient efficiency. When fertiliser is placed in soil, several reactions occur, often forming a high salt zone around the granules that affects nutrient diffusion and availability. These reactions are well studied for N- and P-containing formulations but vastly under-reported for conventional (e.g. KCl, $K_2SO_4$) and alternative potassium (K) sources (e.g., polyhalite - $K_2SO_4MgSO_42CaSO_4 \cdot 2H_2O$). To address this, we investigated nutrient release and reaction products of conventional and alternative K fertilisers in four contrasting soils. Polyhalite (as POLY4® a granulated polyhalite product of Anglo American plc. (www.poly4.com)) and sulphate of potash (SOP) fertilisers were incubated in an Aridisol, Oxisol, Alfisol, and Vertisol for 3 to 56 days. The granules were enclosed in a nylon mesh (<45 µm) attached to a 3D-printed support to position the granules in the centre of a vial filled with ~100 g of each soil at 80% water holding capacity. Unfertilised soils were incubated to account for background nutrients. At the end of each incubation period, the fertiliser-containing mesh was removed, and the remaining soil was dried, homogenised and analysed. A three-step sequential extraction then assessed various soil K pools: K directly available to plants from the soil solution (water extraction), readily exchangeable and plant-available K (ammonium acetate extraction) and, non-exchangeable K that may become slowly available for plant uptake (sodium tetraphenyl boron [TPB] extraction). Selected soil samples (14- and 56-d incubations) were also analysed for K and S solid-phase chemical speciation using synchrotron-based XANES analysis. Overall, most K released from both fertilisers was present in the readily available K pools (water and acetate extracts), with <10% recovered from the less plant-available pool (TPB extract). This distribution remained relatively consistent for the duration of the experiment (56 d) across all soil types. For all soils, 100% of the K and Mg applied as polyhalite was recovered in the soil, but <50% of the polyhalite S and <20% of the polyhalite Ca were recovered. Soil type influenced the release of these nutrients from polyhalite, where the alkaline Ca-rich soil had the least dissolution of fertiliser nutrients. This may be in part due to the common-ion effect, where the high concentration of $Ca^{2+}$ ions already present in the soil may limit the dissolution of granules and/or even lead to reprecipitation of Ca. Potassium XANES analysis suggests that differences in soil K speciation are more related to soil type than fertiliser source, where K is mostly associated with clays, iron oxide or to a lesser degree, organic matter. In soils dominated by 1:1 clays, iron oxides play an important role in K speciation.

**ABSTRACT**

Exudates are the medium through which plants adapt to complex soil environments, however, the mechanisms of how different types of root exudates increase maize yield and phosphorus (P) use efficiency (PUE) throughout the entire growth period remains unknown. In this study, we designed an experiment to examine the effects of continuous addition of exudate substances on maize growth and P uptake over the entire growth period. The addition of succinic acid, luteolin, and inositol significantly increased maize biomass, particularly root biomass. Specifically, the treatment with added succinic acid increased maize yield by 11.6% and PUE by 8%. Additionally, we found that different exudate substances significantly altered the soil bacterial and fungal communities, thereby increasing soil P bioavailability. The microbial co-occurrence networks revealed that Actinobacteriota and Proteobacteria keystone ASVs, enriched by the addition of succinic acid, luteolin, and inositol, were significantly associated with maize P uptake. Furthermore, at the V12 stage (Twelve leaves unfolded), the addition of exudate substances significantly increased alkaline phosphatase activity, and at the R6 stage (Maturity), soil available P content was significantly elevated, enhancing soil P bioavailability. These findings provide evidence for future exploration of the interaction mechanisms between plants and soil microbes and optimizing nutrient management strategies in farmland.The extension limit is 3000 characters with spaces in total, this including Acknowledgments and References if any.

## ABSTRACT

Potassium (K) fertilisers are necessary for sustaining crop productivity, yet their global manufacturing and supply chains remain geographically concentrated, raising concerns over price volatility, supply security, and environmental impact. Among emerging alternatives, polyhalite ($K_2SO_4.MgSO_4.2CaSO_4.2H_2O$) has attracted growing attention as a natural multi-nutrient mineral source ofK, Mg, Ca, and S. Despite its increasing worldwide commercial use, its dissolution mechanisms in soil environments remain poorly characterised, limiting our capacity to predict nutrient release kinetics and agronomic efficiency. This study investigated the temporal dissolution behaviour of polyhalite formulations - commercial granules (POLY4®, a granulated polyhalite product of Anglo American plc. (www.poly4.com)); polyhalite chips - compared with sulphate of potash (SOP) in four contrasting Australian soils (Calcarosol, Ferrosol, Kandosol, Vertosol). A novel, custom-designed 3D-printed incubation system was developed to trace granule solubilisation over 56 days under controlled moisture conditions. Residual fertilisers were recovered, weighed, and analysed using µCT, X-ray diffraction (XRD), SEM-EDS, and ICP-OES to visualise internal porosity, mineral transformations, nutrient distributions and release patterns. SOP dissolved completely within three days, whereas polyhalite-based fertilisers exhibited slower, incongruent dissolution. POLY4® released nearly all K and Mg within 56 days, but only ~50 % of S and <30 % of Ca, leaving behind material composed predominantly of gypsum ($CaSO_4.2H_2O$). The dissolution of the fertilisers was remarkably consistent across soil types, indicating that fertiliser formulation, rather than soil properties, governed the solubilisation behaviour. µCT and SEM imagery revealed that POLY4®'s high internal porosity facilitated a dual-phase dissolution pattern (rapid initial release followed by slower depletion), while the denser polyhalite chips dissolved gradually through a "weathering-front" mechanism from the chip surface inward. These findings elucidate how the physical structure and mineralogy of polyhalite fertilisers dictate nutrient release profiles. The incomplete short-term dissolution should not be interpreted as inefficiency: the gypsum-rich residues possess residual agronomic value through the slow release of Ca and S and potential mitigation of nutrient deficiencies and soil constraints. Overall, polyhalite fertilisers provide a sustained-release K source, representing a valuable component in integrated nutrient management strategies. The study underscores the need to tailor fertiliser formulation and particle architecture to match crop nutrient demand and soil conditions. It also highlights the relevance of advanced imaging tools (µCT, SEM-EDS) for resolving micro-scale processes governing nutrient release from the granules and their availability within the fertosphere.

## ABSTRACT

Sulphur (S) and nitrogen (N) fertilizer input increased in Canada and across the world, especially in canola-wheat cropping systems across Western Canada, the nation's central region for crop production. However, sulphate-S is susceptible to leaching, and urea can elevate nitrous oxide ($N_2O$) emissions, a potent greenhouse gas (GHG). Combining urea and S via the micronized elemental S technology (MST®), the co-granulated fertilizer products (e.g., UreaMST) were developed to improve season-long N-S availability, their use efficiencies, and reduce $N_2O$ emissions. It remains unclear whether urease inhibitors (UIs), weakening urease activity and potentially reducing $N_2O$ emissions, can impact $N_2O$ emissions when coated with UreaMST. In addition, concerns are rising about the differential influence of fertilizer placements on crop yields and $N_2O$ emissions for these fertilizers. A three-year field experiment was established in central Alberta, Canada, following a canola–canola–wheat rotation, and arranged in a randomized complete block design (RCBD) with four blocks and eight treatments (T1: no-N control, T2: no-S control, T3: side-band urea, T4: broadcast urea, T5: side-band UreaMST, T6: broadcast UreaMST, T7: broadcast urea + UI, T8: broadcast UreaMST + UI). Treatment effects on crop yields and growing-season cumulative $N_2O$ emissions were analyzed using linear mixed-effects models with year, treatment, and their interaction as fixed effects, and block and plot as random effects. Factorial effects were tested by two-way mixed-model ANOVA within the complete treatment subset: for no-UI treatments T3–T6, fertilizer (urea vs UreaMST) × placement (side-band vs broadcast); and for broadcast treatments T4/T6/T7/T8, fertilizer × UI (with or without). Controls (T1 and T2) were compared with N-S balanced fertilized treatments T3–T8 using Dunnett-adjusted contrasts ($\alpha = 0.05$). The result showed that crop yields varied strongly by year and showed significant treatment effects, with a significant year × treatment interaction: All N-containing treatments (T3-T8) significantly increased wheat yield (2025) relative to T1, and T3 and T8 significantly increased canola yield (2023) relative to T2. Within the no-UI subset (T3–T6), fertilizer effects were year-dependent (Year × fertilizer significant), while placement effects were not consistently significant across years. In the broadcast subset (T4/T6/T7/T8), UI treatments increased crop yields. The treatment and year × treatment effects on growing-season cumulative $N_2O$ emissions were significant and dominated by year effects with fertilizer and placement effects not consistent across years. In the broadcast subset, UI effects on $N_2O$ were detected ($p = 0.03$). Overall, UreaMST + UI showed 2.1% (canola) and 11.0% (wheat) higher yield than urea under broadcast, while the mean cumulative $N_2O$ emissions was 36.6% lower, indicating that the UreaMST + UI formulation is potentially a promising fertilizer strategy that mitigates $N_2O$ emissions and benefits crop yields in Alberta croplands despite varying impacts by year.

**ABSTRACT**

Urea is widely used as a nitrogen (N) fertilizer to improve crop yields worldwide; however, sustainable N management remains a major challenge due to its loss by volatilization, leaching, surface runoff, and denitrification. To improve N use efficiency (NUE), polymer-coated fertilizers are commonly used as controlled-release fertilizers (CRF), because they release nutrients gradually in accordance with plant demand. However, concerns regarding microplastic pollution have increased interest in sulfur-coated urea (SCU), which is expected to decompose completely in soil environments. This study investigated the stability of the coating and examined the controlled-release performance of the coated urea fertilizers. In this study, we compared the N and S release pattern of six fertilizers: (1) S-Coated Urea Fertilizer 90 days (SCU-90; N 34%), (2) S-Coated Urea Fertilizer 100 days (SCU-100; N 36%), (3) S-Coated Urea Fertilizer 80-90 days (SCU-80-90; N 34.5%), (4) S-Coated Urea Fertilizer 80 days (SCU-80; N 36%), (5) Bulk Blend Fertilizer (BB; N 13%), and (6) Polyolefin-Coated Urea Fertilizer (POCU; N 42%). A leaching test was conducted in distilled water at 30 °C for 1, 2, and 7 days. In addition, to understand the controlled release mechanism of the fertilizers in a soil (Inceptisol), triplicates of each treatment were applied at an equivalent rate of 70 kg N $10a^{-1}$ and incubated for 15 weeks in a pot at 30 °C, and the water level was kept 2 cm above the surface of the soil, simulating paddy environments. $NH_4$-N was measured using a $CaCl_2$ extraction solution, and total S was extracted using a $KH_2PO_4$ extraction solution and measured with ICP-OES. Leaching tests revealed the contrasting patterns: SCU-80, SCU-80-90, and SCU-90 showed rapid initial mass loss (74.1%, 65.3%, 40.9%, respectively), whereas POCU lost only 4.2% of its weight by Day 7. Soil incubation study also showed that POCU exhibited the most sustained release of $NH_4$-N, followed by SCU-100 and SCU-90, while SCU-80 and SCU-80-90 showed the least controlled release of N. Sulfur release showed similar results with SCU-80-90> SCU-80> SCU-90> SCU-100 in soil as well as soil solution. Notably, scanning electron microscopy (SEM) analysis after the leaching test showed that the coating surface of SCU-80 and SCU 80-90 became fragile compared to other fertilizers, suggesting that lower structural integrity led to rapid nutrient release. These results demonstrate that the coating efficiency and controlled release of POCU is much higher than those of the other fertilizers, as the coating was not degraded easily. This also suggests that the coating efficiency has a strong correlation with the release pattern of the nutrients of the coated fertilizers.

# Field evaluation of dual-inhibitor urea in baby spinach on clay soil: implications for $NH_3$ and $N_2O$ mitigation in high-input horticulture

**Brendon Costello[1*], Mei Bai[1], Shu Kee Lam[1] and Deli Chen[1]**

*brendon.costello@unimelb.edu.au

**ABSTRACT**

Intensive leafy-vegetable production systems often rely on split nitrogen (N) applications and frequent irrigation, creating conditions that can accelerate reactive N losses to the environment. These losses reduce fertiliser N use efficiency and contribute to air-quality impacts ($NH_3$) and climate change ($N_2O$). We conducted an on-farm field trial in irrigated baby spinach (*Spinacia oleracea* L.) on a clay soil in Victoria, Australia, to evaluate urea fertiliser with dual inhibitors (urease and nitrification inhibitors) compared with conventional urea under commercial raised-bed management.

Two large plots (60 × 20 m) were established to accommodate open-path Fourier transform infrared (FTIR) measurements, with open-dynamic chamber systems positioned within plots for complementary high-resolution flux quantification. Nitrogen was top-dressed as a split application (60 kg N $ha^{-1}$ followed by 30 kg N $ha^{-1}$). Ammonia ($NH_3$) and nitrous oxide ($N_2O$) fluxes were quantified using (i) open-dynamic chamber measurements coupled to a Picarro G2509, with intensive sampling daily for five days after each fertiliser application and tapered sampling thereafter, and (ii) continuous open-path FTIR monitoring across the 6-week production period. Soil mineral N ($NH_4^+$, $NO_3^-$) was measured on the same schedule as chamber fluxes, and crop yield was assessed at harvest.

Treatment effects were evaluated for emission dynamics (peak timing and magnitude), cumulative $NH_3$ and $N_2O$ losses, and soil mineral N transformations, and interpreted in the context of productivity outcomes. This study provides a field-scale, measurement evaluation of dual-inhibitor urea in an irrigated leafy-greens system, with findings intended to inform fertiliser product development and mitigation strategies for reactive N losses in high-input horticulture.

**ABSTRACT**

With the increase in world population and decrease in the arable land available, emphasis has been drawn to more effective fertiliser use, to reduce losses and improve outputs. When fertiliser is applied to the soil, it is not all stored and taken up by plants, but some is lost to the environment[1]. Using urea as an example it is estimated that between 40 – 70% of applied urea may be lost through leaching, immobilisation and volatilisation[2-4]. Increasing nitrogen use efficiency (NUE) of granular urea fertiliser is key in the maintenance of soil and plant health while also meeting global food demands.

The development of Enhanced Efficiency Fertilisers (EEFs), is an important goal, to increase the plant available nutrient amount available over time.[4].

Two studies are described involving two different formulation approaches to increase the efficiency of urea-based fertiliser. One approach involved blending the urea with lignite in various proportions to produce uniform granules[3]. A second novel approach involved using co-crystal noncovalent derivatives (NCDs) technology as a coating component of urea nitrogen fertilizer. These approaches both avoid polymer coatings on urea granules that produce microplastics as well as other potentially adverse effects.

Both fertiliser formulations were subjected to a series of evaluations including water dissolution, column leaching, nitrous oxide emissions, nitrate and ammonium in soils and limited plant growth trials. Both fertiliser formulations demonstrated significantly slower nutrient release in water compared to uncoated urea. Supporting evidence from silver beet pot trials and a strip plot field trial with corn, further demonstrated the potential benefits of both fertilisers in promoting plant growth.

**ABSTRACT**

A number of polymer-based formulations were tested in laboratory and field experiments as soil ameliorants focused to combat soil erosion and enhance soil properties. Individual synthetic and natural polyelectrolytes were tested: polycation polydiallyldimethylammonium chloride (PDDA), polyanion hydrolyzed polyacrylonitrile (HYPAN), xanthan gum (XAN), and natural polyanions of humic substances (HS), as well as complex formulations presented by interpolyelectrolyte complexes (IPECs) and binary polymer-humate compositions. Humic substances (HS) are natural polyanions that are widely used as soil conditioners and biostimulants in agricultural technologies and have a potential to enhance to positive effects of other polymers on soil properties and plant growth. The objective of this study was to examine the effects on anti-erosion resistance, soil hydrophysical properties, ecotoxicity, and detoxication ability of a number of individual polymeric soil ameliorants and to reveal advantages of two-component formulations compared to individual polymers. Model experiments were conducted using soil samples different in texture, pH, humus content, and salinity. Ecotoxicity of polymer formulations was assessed using standard toxicity bioassays using cultures of bacteria *Escherichia coli*, the ciliate *Paramecium caudatum*, earthworms *Eisenia foetida*, and plant species.

PDDA-based formulations were the most effective to decrease manifestations of wind and water erosion, but in some cases demonstrated ecotoxicity. HYPAN- and XAN-based compositions showed the lack of toxicity in soil media, were capable of forming protective soil-polymer coatings, decreased loss of soil affected by wind and water flow, and improved soil hydrophysical properties. In heavy metal-spiked soil-polymer mixtures, combinations of polymers (PDDA, HYPAN and XAN) with natural humic biopolymers decreased the content of mobile Cu, Zn, Pb, and Cd species and mitigated the toxicity of heavy metals for plants and soil microbial community.

Differences in the sorption capacity of polymer compositions were related to their molecular structure. Polymer macromolecules bind to the surface of soil particles through hydrogen bonds, van der Waals interactions, and electrostatic bonds between negatively charged sites on the particles and the polymer. HSs typically bind metals via carboxyl groups and polycationic bridges. They also exhibit redox activity due to the presence of highly condensed aromatic structures rich in quinone/hydroquinone fragments, which also facilitates chelation and binding of metals.

The effects on soil hydrophysical properties were mainly governed by synthetic polyelectrolytes, whereas the effects on soil chemical and biological properties were influenced by HS. The advantages of two-component compositions compared to individual polymers are determined by the limiting factor for the sustainable soil functioning (hydro-physical properties, humus status, level of contamination, etc.).

**ABSTRACT**

Although exogenous silicon (Si) is known to alleviate the significant inhibitory effects of salt ion stress on wheat growth, its synergistic mechanism with calcium (Ca) remains unclear. This study employed a Box-Behnken design with three variables: silicon (Si; 0, 1, 2 mM), sodium ($Na^+$; 50, 150, 250 mM), and calcium ($Ca^{2+}$; 5, 15, 25 mM), totaling 17 experimental treatments to investigate their interaction on root peroxidase (POD) activity and ion homeostasis. Results demonstrate that medium Si enhances salt tolerance primarily by regulating ion uptake and reinforcing POD-mediated antioxidant capacity, and this effect is most effectively synergized with medium $Ca^{2+}$, whereas suboptimal $Ca^{2+}$ levels strongly inhibit Si efficacy. Under high $Na^+$ stress (250 mM), plant biomass and root growth were severely inhibited, as indicated by the most significant suppression observed in the absence of Si and under low $Ca^{2+}$ conditions, likely due to a lack of synergistic protection against membrane lipid peroxidation. In contrast, the combination of medium Si (1 mM) and medium $Ca^{2+}$ (15 mM) optimally sustained ion homeostasis and enhanced antioxidant capacity under medium salt stress (150 mM $Na^+$), as demonstrated by restricted shoot $Na^+$ accumulation (56.65 g/kg), reduced root MDA, and concurrently enhanced root POD and leaf chlorophyll, suggesting improved membrane stability. High Si (2 mM) applied with low $Ca^{2+}$ significantly promoted plant growth, as shown by root length, root fresh weight, and plant height being 1.9, 1.8, and 1.3 times greater, respectively, than those in the medium Si-$Ca^{2+}$ combination at medium Na+ stress, potentially via activated growth pathways. However, Si benefits were negligible under the low $Ca^{2+}$ combination at high $Na^+$ stress (250 mM $Na^+$ + 5 mM $Ca^{2+}$), implying $Ca^{2+}$ deficiency may restrict Si mediated tolerance mechanisms. These findings provide crucial insights into Si-$Ca^{2+}$ interactive mechanisms and a theoretical basis for developing targeted Si amendment strategies to improve crop productivity in saline soil.

**ABSTRACT**

Controlled-release fertilizers (CRFs) can improve nutrient utilization efficiency, reduce waste and environmental pollution, aligning with green agricultural development. Developing bio-based coating materials has become a primary research focus. However, the preparation presents multiple challenges. Their susceptibility to water absorption, poor compactness, and insufficient toughness. Coating process technologies require refinement, and nutrient release struggle to precisely match crop requirements. Thus, enhancing the controlled-release quality and achieving efficient nutrient utilization have become critical issues.

To address these challenges, research has achieved innovations in coating modification, processes and specialized fertilizers for precise nutrient matching.

The superhydrophobic modification technology is based on the formation of an air layer at the water-coating interface, which effectively blocks water penetration. This innovation increased the hydrophobicity of the coating material by 90.5%. Furthermore, technologies for interpenetrating network densification and self-healing toughening were developed, reducing the coating porosity by 20.6%. These technologies overcome the bottlenecks in bio-based coatings. The development of multi-stage dynamic variable coating and bio-based material photocuring coating process technologies has addressed issues such as uneven coating and high coating material consumption, enabling efficient industrial production. Rapid and uniform coating curing under light conditions was achieved, overcoming the challenges of uneven coating and susceptibility to tearing in traditional processes for large particles. The curing time was shortened from 5 minutes to 3–5 seconds. Specialized CRFs for crops address low nutrient-release precision. Through multi-formula compounding and double-layer coating, they significantly improve the synchronization between nutrient release and crop demand. This increases nutrient use efficiency by over 10 percentage points, enabling one-time fertilization at sowing to meet the nutrient needs of crops throughout their growth cycle.

In summary, these technological breakthroughs have achieved efficient nutrient utilization in bio-based CRFs and elucidated the mechanisms, providing theoretical and technical support for industrial application.

# Effects of Chlorella Application on Soil Quality and Crop Productivity in Saline–Alkali Soils of Xinjiang, China

**Zhi QU*, Xiaoyang WANG, and Zixuan XI**

*State Key Laboratory of Water Engineering Ecology and Environment in Arid Area,Xi'an University of Technology, Xi'an, China*

*E-mail: zhiquzq@163.com

**ABSTRACT**

Saline–alkali soils severely limit agricultural productivity in arid regions of northwest China. In addition to conventional irrigation and drainage engineering, biological amendments may provide complementary approaches for improving soil quality and crop performance. *Chlorella*, a unicellular green alga characterized by rapid growth, high organic carbon and nitrogen contents, and strong stress tolerance, has emerged as a promising bio-amendment for saline–alkali soil improvement.

In this study, both soil incubation experiments and field trials under crop cultivation were conducted to evaluate the effects of *Chlorella* application on soil chemical and physical properties as well as crop growth in typical saline–alkali soils. Under non-planting conditions, *Chlorella* dry powder was applied at four rates (0.05–0.20 g $kg^{-1}$ dry soil). Higher application rates significantly reduced soil pH (0.13–0.35) and electrical conductivity (5.4–30.1%), while increasing soil organic carbon (6.6–21.0%) and total nitrogen (5.7–8.5%). *Chlorella* amendment markedly altered soil physical properties, decreasing the one-dimensional vertical water infiltration rate by 58.1–62.4% and significantly enhancing soil aggregate stability, as indicated by increases in mean weight diameter, geometric mean diameter, and water-stable aggregates (>0.25 mm). Structural Equation Modeling further revealed that improvements in soil structure and salinity were primarily mediated by enhanced soil carbon and nitrogen pools.

Field experiments with sunflower and wheat demonstrated that *Chlorella* application significantly improved soil fertility, reduced salinity, and promoted crop growth throughout the growing season. Among the application methods tested, foliar spraying produced the strongest effects, increasing crop biomass accumulation and grain yield by approximately 22–29% in sunflower and markedly improving yield components in wheat.

Overall, *Chlorella* amendment effectively enhanced saline–alkali soil quality by simultaneously regulating soil salinity, structure, and water infiltration processes, thereby promoting crop productivity in arid agroecosystems.

*remadayag@up.edu.ph

**ABSTRACT**

Layered double hydroxides (LDHs), widely studied for phosphorus (P) recovery from wastewater, have recently been proposed as slow-release fertilizers. This study evaluated the fertilizer potential of P-loaded Mg–Fe LDH compared with commercial recycled P sources (vivianite and struvite) and a conventional soluble fertilizer (triple superphosphate, TSP). A 28-day incubation experiment was conducted in two P-deficient soils (acidic and near-neutral) using $CaCl_2$-extractable P as an indicator of readily available P. Soil pH, $Fe^{2+}$ concentrations, and redox potential were also monitored to assess chemical changes influencing P dynamics. Synthetic Mg–Fe LDH consistently exhibited a slow-release pattern in both soils. In acidic soil, struvite and TSP released high soluble P early (0.167 and 0.109 mg P $L^{-1}$ on day 2) but declined sharply by day 28, whereas Mg–Fe LDH gradually increased to the highest final concentration (0.100 mg P $L^{-1}$). This trend coincided with a pH rise from 6.6 to 7.0, suggesting LDH's buffering effect facilitated sustained P availability. In near-neutral soil, Mg–Fe LDH maintained controlled release, rising from 0.127 mg P $L^{-1}$ on day 2 to 0.188 mg P $L^{-1}$ by day 14, then stabilizing near 0.178 mg P $L^{-1}$ at day 28, contrasting with struvite and TSP, which peaked early and declined. Vivianite showed minimal release in both soils. These results demonstrate the potential of Mg-Fe LDH as a sustainable slow-release P source that can enhance P availability while supporting nutrient management strategies.

## ABSTRACT

**Purpose:** Efficient nitrogen (N) management is essential for improving maize yield and resource use efficiency. The nitrogen nutrition index (NNI) is a common tool to assess crop N status. However, its response under controlled-release fertilizer (CRF) management is still not clear. This study evaluated how different N fertilizer types affect maize NNI. It also tested the use of UAV multispectral data for accurate N monitoring.

**Methods:** A two-year field experiment with five N treatments was conducted to evaluate the effects of fertilizer type on the maize's CNDC and the NNI at the V6, VT and R2 growth stages. CNDCs and NNI models were developed from leaf area index (LAI) and aboveground biomass (AGB) and compared using Akaike (AIC) and Bayesian (BIC) information criteria. A gradient boosting decision tree (GBDT) model was built from UAV multispectral data.

**Results:** CRFs significantly improved N distribution uniformity and model accuracy. CRF had stronger effects on LAI than on AGB, but NNI based on AGB better reflected actual N balance. Based on accumulated N deficit conditions characterised using AIC and BIC information criteria, a fertilisation range of 150-225 kg $ha^{-1}$ was determined. Furthermore, a CNDC model established using measured NNI_AGB was implemented to utilise unmanned aerial vehicles for predicting NNI. The GBDT model based on UAV multispectral data and by screening sensitive variables through variance inflation factors (VIF) achieved the highest accuracy and stability (R2 =0.88, RMSE =0.04, nRMSE=4.98%).

**Conclusion:** CRF management combined with UAV-based monitoring offers an effective way to diagnose maize N status. This approach supports precise N application and sustainable agriculture.

**ABSTRACT**

To investigate the effects of soil acidification amendments on microorganisms, enzyme activities, aggregates, porosity, and rice yield in red soil, a 3-year fixed-position field experiment with rice was conducted in this study, which set six treatments: no fertilizer (X0), NPK fertilizer (X1), lime + NPK fertilizer (X2), high-activity acidification amendment (1) + NPK fertilizer (X3), high-activity acidification amendment (2) + NPK fertilizer (X4), and high-activity acidification amendment (3) + NPK fertilizer (X5). Indicators including soil microbial biomass carbon and nitrogen, enzyme activities, aggregates, porosity, and rice yield were determined.The results showed that compared with X1 treatment, other treatments increased soil pH by 0.29-0.9 units under different treatments, among which X4, X2, and X5 treatments significantly increased by 0.61, 0.72, and 0.9 units, respectively. For aggregates with particle size >2 mm, X2 treatment significantly increased by 32.8%, while X4 and X5 treatments significantly increased by 14.30% and 16.76%, respectively. X3 treatment significantly increased the activities of BG, CBH, and NAG enzymes in the tested soil by 131.22%, 19.45%, and 20.44%, respectively, and X4 treatment exhibited an overall better enhancement effect than X3, with increases of 132.83%, 47.96%, and 30.27%, respectively.CT scanning results indicated that X4 treatment had a significant effect on the surface area, porosity, and volume of soil aggregates with different depths (0-15 cm shallow layer, 20-55 cm middle-deep layer) and different particle sizes (>1 mm, 1-0.5 mm, <0.5 mm), following a consistent pattern. In the middle-deep layer, the surface area of aggregates with various particle sizes (>1 $mm^2$, 1-0.5 $mm^2$, <0.5 $mm^2$) in X4 treatment was 747.14%-1013.08% higher than that in X1 treatment, the porosity increased significantly, and the volume increased by 384.09%-1014.39%.The thousand-grain weight of X4 treatment was higher than that of other treatments, and the yield was significantly increased by 17.7% compared with X1, reaching 6576 $kg \cdot ha^{-1}$. In summary, both high-activity acidification amendments and lime combined with NPK fertilizer can improve the physicochemical properties of red soil and enhance enzyme activities. Among them, high-activity acidification amendment (2) + NPK fertilizer shows the best effect, which can provide a favorable environment for rice growth by increasing soil pH, improving red soil physicochemical properties, enhancing enzyme activities, promoting the formation of macroaggregates and increasing the number of pores, thereby achieving yield increase. This study provides a technical References for improving the fertility of red soil paddy fields and high-yield and high-quality rice cultivation.

# Soil nitrogen deficiency and heat stress drive tissue-specific metabolic reprogramming governing nitrogen utilization in soybean

**Hamza Tariq[1], Muhammad Saqib Bilal[1], Lei Wang[1], Alisdair Fernie[2], Mohsin Tanveer[1]***

[1]*Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences, Urumqi, China*

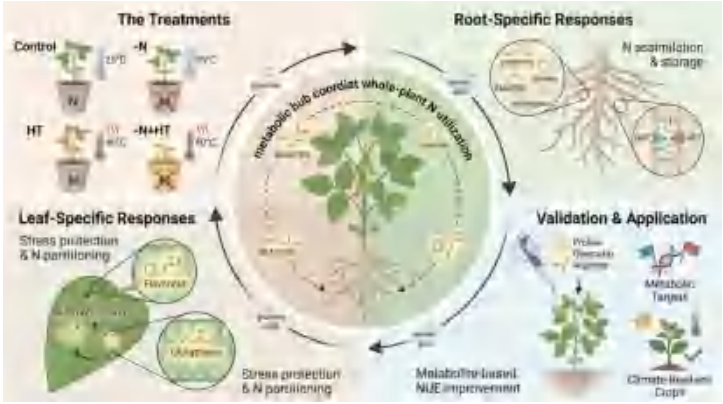
## ABSTRACT

**Introduction:** Soil nitrogen (N) deficiency is a primary constraint to crop productivity worldwide, and climate change is exacerbating this challenge through increased incidence of high temperature (HT) stress. The interaction between soil N availability and heat stress fundamentally alters how plants acquire and utilize N from soil, yet the metabolic mechanisms coordinating whole-plant N utilization under these combined stresses remain poorly understood.



**Objectives:** This work examined how N deficiency and HT stress, individually and in combination, drive distinct metabolic reprogramming in roots and leaves that regulates plant N utilization. We hypothesized that roots and leaves exhibit complementary N metabolic profiles in response to N deficiency, and that combined heat stress reveals unique N utilization hubs that determine whole-plant resilience.

**Methods:** Soybean plants were subjected to control, soil N deficiency (-N), HT, and combined -N+HT conditions. We assessed whole-plant physiological responses, with emphasis on N uptake from soil and N assimilation efficiency. Untargeted metabolomic profiling of roots (the primary soil interface) and leaves was performed, with targeted analysis of N-containing metabolites. Machine learning identified key metabolic regulators of N utilization under stress.

**Results:** Combined -N+HT severely inhibited plant growth and N utilization, reducing shoot length (67%), root fresh weight (52%), photosynthetic efficiency (47%), and tissue N content compared to control. Metabolomic analysis revealed tissue-specific N utilization strategies driven by soil N status: under -N alone, roots prioritized N assimilation and recycling, accumulating glutamate, proline, and aspartate, while maintaining expression of high-affinity N transporters to enhance N scavenging from soil. Under HT alone, leaves enhanced N remobilization into protective compounds (flavonoids, glutathione). Under combined -N+HT, roots focused on amino acid metabolism and N storage (proline, asparagine) to cope with limited soil N supply, while leaves directed N toward stress protection, indicating prioritized allocation of soil-derived N to protection over growth. Machine learning identified proline, flavonoids, and specific amino acids as top regulators coordinating soil N utilization with physiological resilience. Exogenous application of these metabolites partially restored N utilization efficiency under stress.

**Conclusion:** Soybean employs distinct N utilization strategies in roots and leaves to manage soil N deficiency and heat stress, with tissue-specific partitioning of soil-derived N. The identified metabolites represent hubs coordinating utilization of soil N under combined stress, offering targets for breeding climate-resilient crops with enhanced nitrogen use efficiency for sustainable production in N-deficient soils.

**ABSTRACT**

Impressive strides in the quantity and quality of grain production to meet world demands have been made thanks in large part to nitrogen (N) inputs, but often it has come at the expense of environmental degradation. As we try to solve the conundrum of environmentally sustainable and profitable agricultural production, it is clear that more needs to be done to better understand the impact of N management on crop production and its environmental footprint. Deliberate efforts have been devoted to establishing agronomic N best management practices (N-BMPs) for corn production. However, the same emphasis to determine the environmental outcomes of N-BMPs is lacking. Thus, studies of N-BMPs that integrate various N loss pathways with agronomic outcomes are chronically insufficient to determine whether N-BMPs to improve corn production are concomitantly sufficient to mitigate N loss. A number of studies, located on well-drained coarse-textured soils and on poorly drained fine-textured soils with subsurface drainage in the Upper Midwest region of the USA, will be summarized. The studies measured season-long $NO_3$ leaching, $NH_3$ and $N_2O$ emission along with corn grain yield, total crop N uptake, and residual soil N after harvest. Enhanced practices combining N source, rate, time, and application method were evaluated against traditional practices. The coarse-textured site also had no cover-crop, winter rye cover-crop, and kura clover living-mulch. Generally, crop N uptake and grain yield showed a quadratic-plateau response to N rate. Reducing N rates below the economic optimum resulted in less productivity and profitability and small reductions in environmental N loss. Applying N rates above the economic optimum resulted in nominal or no increase in productivity, reduced profitability, and increased environmental N loss. Using enhanced efficiency N (polymer-coated urea), often reduced N loss and maintained productivity and profitability. Splitting the N application in-season had agronomic and environmental advantages in the coarse-textured soil, but had generally only agronomic advantage in the fine-textured soil. Because of poor growth, the rye cover crop largely had no effect on agronomic or environmental outcomes, but kura clover substantially reduced $NO_3$ leaching, slightly increased $NH_3$ losses, but reduced grain yield, diminishing potential adoption by farmers. While the dual goal of improved corn production and environmental protection are attainable, precipitation after fertilization largely influenced N loss and diminished the otherwise attainable benefits of refining N management practices. Overall, the findings of these studies highlight that targeting the economic optimum N rate for corn production is also an environmentally sustainable practice, but realistic expectations must be set, realizing that adverse unpredictable weather conditions can ultimately negatively influence the outcome.

# Fertilizer-Driven Nitrate Availability and Waterlogging Resilience in Canola: Benefits and Micronutrient Trade-offs

## ABSTRACT

Waterlogging alters soil nutrient dynamics and constrains crop productivity. We evaluated four fertilization strategies—an inorganic chemical fertilizer (Base) and three organic amendments (biochar + Base, chicken manure + Base, fish blood & bone meal + Base)—in *Brassica napus* (canola) to assess impacts on nitrogen (N) availability and plant performance under waterlogging. The experiment was conducted in pots using Grey Chromosol (Australian Soil Classification) which is prone to seasonally waterlogging. Pre-waterlogging soil nitrate nitrogen ($NO_3^-$–N) was the strongest predictor of post-waterlogging biomass across spring- and winter-type cultivars (Spearman $\rho > 0.73$, $p < 0.01$). Inorganic fertilization significantly elevated pre-waterlogging $NO_3^-$ concentrations ($R^2 = 0.80$, $p < 0.001$), outperforming the organic amendments. Soil $NO_3^-$ was positively associated with shoot N uptake ($R^2 = 0.24$, $p = 0.016$) and biomass accumulation ($R^2 = 0.19$, $p = 0.036$), supporting a mechanistic pathway where fertilizer-driven nitrate enrichment before waterlogging is strongly associated with higher shoot N and greater biomass under stress. Furthermore, inorganic fertilizer also altered Fe and Mn accumulation in plant shoots. These results demonstrate nitrate's central role in maintaining biomass under waterlogging and highlight a practical trade-off: inorganic fertilizer enhances resilience via nitrate supply while increasing shoot Mn accumulation. The findings offer practical guidance on fertilizer timing and type selection to strengthen nitrogen resilience in waterlogging-prone canola systems.

## ABSTRACT

Ammonium ($NH_4^+$) efflux serves as a crucial mechanism in root responses to ammonium toxicity. Our previous investigations have demonstrated that both protein N-glycosylation and auxin homeostasis play pivotal regulatory roles in modulating $NH_4^+$ efflux, leading to the identification of key regulatory genes including AtVTC1, AtWRKY46, AtPIN5, and OsVTC1.3. However, fundamental questions remain unresolved, particularly concerning the initiation and recovery kinetics of $NH_4^+$ efflux under stress conditions and its relationship with ammonium use efficiency (AUE) and ammonium tolerance. To address these questions, we conducted pharmacological analyses using rice root protoplasts subjected to transient high-$NH_4^+$ treatment. Our results revealed that acute ammonium stress promptly induces sustained $NH_4^+$ efflux, potentially mediated by aquaporins, ABC transporters, and potassium channels. Screening of 99 rice cultivars demonstrated a significant negative correlation between $NH_4^+$ efflux and both root ammonium tolerance and AUE ($P < 0.01$), establishing efflux as a key limiting factor for nitrogen use efficiency. Furthermore, probenecid-mediated inhibition of efflux enhanced $NH_4^+$ uptake by 23.65% in high-efflux cultivars, underscoring the regulatory potential of $NH_4^+$ efflux. This study provides novel insights into the mechanisms underlying plant adaptation to ammonium toxicity and establishes a molecular framework for developing nitrogen-use-efficient crops through manipulation of $NH_4^+$ efflux pathways.

**ABSTRACT**

High ammonium ($NH_4^+$) inhibits primary root (PR) elongation in plants, but the underlying regulatory mechanisms remain poorly understood. In this study, we screened the PSKI015 activation-tagged mutant library and identified a novel dominant mutant, named Ammonium Sensitive 3D (amos3D), which shows increased sensitivity to high $NH_4^+$ in terms of PR elongation. Gene cloning revealed that amos3D is an overexpression mutant of IPT3, a gene involved in cytokinin biosynthesis. Pharmacological and genetic analyses revealed that the sensitivity of amos3D PR to high $NH_4^+$ is due to elevated levels of the active cytokinins iP and tZ. We furthermore identified ARR10 and ARR12, type-B ARRs, as key transcription factors in the cytokinin-mediated inhibition of PR elongation under high-$NH_4^+$ stress. Using CUT&RUN, yeast one-hybrid, and dual-luciferase assays, we show that ARR10 and ARR12 directly bind to the promoter of CAP1, a tonoplast-localized kinase, repressing its transcription. This repression reduces $NH_4^+$ transport from the cytosol to the vacuole, leading to increased Gln/Glu ratios, and enhanced $NH_4^+$ toxicity. Collectively, our identification of AMOS3 as a key regulator inhibiting PR growth under high $NH_4^+$ through the cytokinin-dependent ARR10/ARR12-CAP1 pathway not only reveals a novel $NH_4^+$-sensing mechanism but also offers promising agronomic potential for optimizing root architecture and improving nitrogen-acquisition efficiency in crops under ammonium-based fertilization systems.

**ABSTRACT**

Ammonium (NH4+) is toxic to root growth in most plants, and NH4+ toxicity has been linked to disruptions in plant Fe homeostasis. However, only a few genes have been linked to the disruption of Fe homeostasis under NH4+ nutrition, and pathway details have as yet to be resolved. Here, using RNA-seq analysis and RT-qPCR, we explore the response of different genes expressed in the roots of Fe-replete and Fe-starved Arabidopsis plants under NH4+ conditions. The Nitrate Transporter 1.1 (NRT1.1) gene, known to code for a dual-affinity nitrate transporter, but not other NRTs genes, was specifically induced in Fe-replete plants in response to NH4+ provision. NRT1.1 antagonizes NH4+-dependent Fe accumulation, and this antagonism requires NO3- supply. Constitutively expressing NRT1.1 confers higher NO3- uptake and reduces NH4+-dependent Fe accumulation by increasing pH in the rhizosphere. Building on previous evidence establishing the involvement of root Fe accumulation in the root growth response to elevated NH4+, our study shows that NRT1.1-mediated nitrate uptake curtails symptoms of NH4+ toxicity under elevated NH4+ and in the presence of NO3-, by increasing rhizospheric pH, offering new insights into possible pathways for improving the tolerance to NH4+ toxicity in plants.

## ABSTRACT

Nitrogen (N) is a fundamental macronutrient vital for sustaining plant growth, metabolism, and productivity. Among tropical crops, oil palm (Elaeis guineensis) is particularly nitrogen-demanding, yet its enzymatic mechanisms of nitrogen assimilation have received little scientific attention. In plantation practice, ammonium-based fertilisers are widely used due to their lower cost compared to nitrate-based sources. Nonetheless, the biochemical responses of oil palm to ammonium fertilisation remain inadequately characterised. This study examined the activities of key nitrogen-assimilating enzymes in oil palm roots and their influence on amino acid biosynthesis and biomass production under varying ammonium chloride (NH4Cl) fertilisation rates. We hypothesised that (1) nitrogen-assimilating enzyme activities in root tissue would peak under high ammonium fertiliser input; (2) Enzyme activities could serve as potential physiological indicators of nitrogen use efficiency (NUE). Three-month-old oil palm seedlings were supplied with four levels of N input: zero (0 g N), low (4.5 g N), medium (9.0 g N), and high (18.0 g N), and grown for eight months. Root tissues were analysed for nitrate content, total amino acids, and the activities of nitrate reductase (NR), nitrite reductase (NiR), glutamine synthetase (GS), glutamate synthase (GOGAT), and glutamate dehydrogenase (GDH). Increasing ammonium availability induced a metabolic shift from the NR/NiR-mediated nitrate reduction pathway toward the GS–GOGAT–GDH ammonium assimilation cycle. GS activity peaked under low $NH_4Cl$ input, reflecting the incorporation of $NH4^+$ into glutamine, but declined under higher inputs due to negative feedback inhibition. GOGAT activity was strongly suppressed at high $NH_4Cl$ rates, while glutamate dehydrogenase activity increased under elevated ammonium, functioning as a detoxification mechanism to maintain nitrogen homeostasis. Among treatments, medium $NH_4Cl$ application yielded the most balanced GS–GOGAT–GDH profile and the highest total amino acid accumulation. However, this treatment did not produce the greatest biomass. Both above- and below-ground biomass increased with higher N input, with the high-fertiliser treatment yielding the highest biomass (0.47 kg) compared to the medium treatment (0.39 kg), though the difference was not statistically significant. These findings indicate that enhanced enzymatic activity and amino acid synthesis do not necessarily translate into proportional biomass gains. Moderate ammonium application appears to promote a balanced and efficient nitrogen metabolism, optimising biochemical performance without inducing metabolic stress. In contrast, excessive fertilisation may enhance overall biomass production but reduce biochemical efficiency, triggering detoxification pathways. Further studies integrating both root and leaf enzyme profiling are needed to establish enzymatic activity as a reliable non-destructive indicator of NUE in oil palm.

# Responses of Rice Production, $NH_3$ and $N_2O$ Losses to Biochar Application at Different Growth Season of Rice-Wheat Rotation

**Haijun Sun[1*], Yu Zhang[1], and Yanfang Feng[2]**

*[1] College of Forestry and Grassland, Nanjing Forestry University, Nanjing 210037, China*

*hjsun@njfu.edu.cn (Sun H.); zhangyu@njfu.edu.cn (Zhang Y.); yfeng@jaas.ac.cn (Feng Y.)

**ABSTRACT**

Biochar (BC) application affects gaseous nitrogen (N) losses mainly via nitrous oxide ($N_2O$) emission and ammonia ($NH_3$) volatilization from paddy soils. However, in rice-wheat rotation systems, the impact of BC that being incorporated into soils at the initiation of different crop planting seasons on the two aforementioned gaseous N losses remains unclear. Therefore, we conducted a 2-year (2020 and 2021) soil column experiments with 5 t $ha^{-1}$wheat straw BC investigate the effects of BC that being applied during the rice season (BC-R) or wheat season (BC-W) and to on rice grain yield, $N_2O$ emissions, and $NH_3$ volatilization from rice paddy soil with three N supply levels (low: 160 kg N $ha^{-1}$, medium: 200 kg N $ha^{-1}$ and high: 240 kg N $ha^{-1}$). BC application during the wheat season had a significant effect on rice grain yield ($P < 0.05$), with the most pronounced response observed in 2020. Under 350 kg N $ha^{-1}$, the N200+BC-W treatment produced 12.4% higher grain yield than the N200 treatment. Moreover, wheat-season BC application significantly enhanced cumulative grain yield over the two-year period ($P < 0.05$). Notably, the effects of BC application on soil $N_2O$ emissions and $NH_3$ volatilization exhibited interannual variation, depending on the different crop planting seasons. Compared to N160, the N160+BC-R treatment significantly reduced $N_2O$ emissions by 15.9% in 2020. BC application during the wheat season in 2021 significantly decreased $N_2O$ emissions in the N160+BC-W and N200+BC-W treatments, with reductions ranging from 36.7% to 53.6% relative to N fertilization alone. In 2021, $NH_3$ volatilization in the N200+BC-R decreased by 28.7% compared with the N200, whereas the N200+BC-W achieved a greater reduction of 54%. BC application in this study did not yield significant reductions in net global warming potential (GWP) or greenhouse gas intensity (GHGI). Nevertheless, the N200+BC-W in 2021 showed a decreasing trend in both GWP and GHGI. Overall, the effect of BC on gaseous N losses was strongly influenced by the application season and the experimental year. in conclusion, the N200+BC-W represents the optimal management strategy for both emission reduction and high yields.

# MGP1-mediated Mitochondrial ROS Homeostasis Couples Carbon Metabolic Switching with Nitrate Adaptation

**Feng Zhihang[#], Hu Hailian[#], Chen Huiting[#], Yan Juanmei, Fu Chen, Li Baohai[*]**

*State Key Laboratory of Soil Pollution Control and Safety, College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, China.*

bhli@zju.edu.cn

**ABSTRACT**

Carbon–nitrogen (C/N) metabolic coordination is fundamental for plant growth. Mitochondria are central hubs of carbon oxidation and energy production. Electron transport across the respiratory chain and the associated generation/scavenging of reactive oxygen species (mROS) are crucial for maintaining mitochondrial metabolic stability. However, the contribution of mROS to plant energy metabolism and broader carbon metabolic reprogramming, and how such reprogramming feeds into plant nitrogen adaptation, remains largely unresolved.

Here, we characterized an uncharacterized glutathione S-transferase (GST) family member, namely Mitochondrial GST Protein 1 (MGP1). MGP1 homologs from unicellular algae to vascular plants localize to mitochondria, and high-resolution imaging shows MGP1 co-localizes with inner-membrane markers. Loss of MGP1 causes elevated mitochondrial swelling, indicating compromised mitochondrial integrity. Transcriptome profiling reveals robust upregulation of genes involved in mitochondrial organization, together with induction of compensatory ATP-producing carbon pathways (glycolysis and the pentose-phosphate pathway). In contrast, energy-demanding carbon sinks, including cell wall remodeling and sulfur-rich secondary metabolism, are consistently repressed, implying the role of MGP1 in shifting from growth/defense investment toward survival-oriented carbon utilization.

Notably, multiple high-affinity nitrate uptake/transport and nitrate-starvation signaling genes are constitutively upregulated in the *mgp1* mutant, suggesting that mitochondrial dysfunction-driven C-reprogramming triggers a persistent nitrogen-hunger state. Consistently, *mgp1* displays enhanced primary-root growth under low-nitrate conditions. Inhibition of mETC complexes I/III, applying mito-targeted antioxidants, or genetic accumulation of a peroxidase into mitochondria all markedly alleviate low-nitrate root growth inhibition, indicating that excessive mROS is a key determinant of nitrate starvation sensitivity.

We propose that MGP1 acts as a negative regulator of low-nitrate root growth by promoting ROS accumulation close to the inner-membrane mETC domain. mROS levels thereby tune the balance between mitochondrial and cytosolic carbon metabolism modes, which in turn gates nitrate uptake and assimilation programs. Our study implies a tight coupling between mROS homeostasis, carbon metabolic switching, and nitrate-response outputs, highlighting an unappreciated contribution of mitochondria to plant nitrogen adaptation.

**ABSTRACT**

Unlike diploid staple crops such as rice (*Oryza sativa* L.) and maize (*Zea mays* L.), modern wheat (*Triticum aestivum* L.; AABBDD) is a typical allohexaploid crop, derived from the natural hybridization between tetraploid wheat (*Triticum turgidum* L.; AABB) and its diploid ancestor *Aegilops tauschii* Coss. (DD). Early studies have shown that hexaploid wheat exhibits higher adaptability to saline-alkaline soils compared to tetraploid wheat, which is closely associated with the salt tolerance mechanism mediated by *TaHKT1;5-D* induced $Na^+$ efflux. However, whether soil microorganisms, regarded as the "second genome" of plants, are involved in the differential adaptation of wheat with different ploidy levels to saline-alkali soils remains unexplored. In this study, a set of genetic materials capable of simulating natural evolutionary processes was used, including artificially synthesized hexaploid wheat T093SHW, its diploid parent Aegilops tauschii T093, and tetraploid wheat LDN. Taking arbuscular mycorrhizal fungi (AMF), a symbiotic microorganism involved in the uptake of nitrogen and phosphorus and the improvement of plant nutrient use efficiency, as the entry point, we found that the abundance, community structure, and species richness of symbiotic AMF in the roots of hexaploid T093SHW in saline-alkali soils were similar to those of tetraploid LDN. However, at the operational taxonomic unit (OTU) level, T093SHW evolved the ability to be colonized by specific AMF taxa. More importantly, T093SHW showed a stronger capacity to recruit AMF in the rhizosphere. This study elucidates a novel mechanism underlying the enhanced adaptability of hexaploid wheat to saline-alkali soils, and provides a theoretical References for promoting the "coordinated adaptation between wheat and saline-alkali soils" by taking AMF as a bridge.

**ABSTRACT**

Intensive fertilization drives strong nitrification in acidic agroecosystems, accelerating nitrogen loss and $N_2O$ emissions. We tested whether the chemical class of biological nitrification inhibitors (BNIs) predicts efficacy and microbiome response by comparing six BNIs in an acidic-soil microcosm over 24 days: three phenolic acids (methyl 3-(4-hydroxyphenyl) propionate, syringic acid, methyl ferulate) and three fatty-acid BNIs (linoleic acid, linolenic acid, methyl linoleate). Nitrification rates were quantified, nitrifier gene abundances (AOA-*amoA*, AOB-*amoA*, NOB-*nxrA*/*nxrB*) were tracked by qPCR, and community composition and co-occurrence networks were resolved by high-throughput sequencing. Phenolic BNIs consistently suppressed nitrification, whereas fatty-acid BNIs showed little or no inhibition. Phenolic treatments produced an early decline in AOB-*amoA* and a sustained reduction in NOB-*nxrB* throughout incubation; in contrast, fatty-acid BNIs minimally affected *amoA* or *nxrB* and only transiently decreased *nxrA*. Community shifts under phenolic BNIs included reduced *Nitrosospira* cluster 3a.1 within AOB and *Nitrospira bockiana* within NOB-*nxrB*, alongside sparser, more competitive networks in which a single *Nitrospira* hub was replaced by multiple smaller hubs across nitrifier groups. These changes indicate selective down-weighting of efficient nitrifiers positively associated with process rates while permitting expansion of less efficient taxa (e.g., *Ca.* Nitrosocosmicus), thereby decoupling ammonia from nitrite oxidation and lowering community nitrification potential. Our results show that BNI chemical structure governs nitrifier network architecture in acidic soils, providing a mechanistic basis for deploying phenolic BNIs to limit nitrification and $N_2O$ risk.

## ABSTRACT

Biological nitrification inhibitors (BNIs) can reduce soil nitrous oxide ($N_2O$) emissions, but the inhibition strength depends on the type of BNIs and on soil properties. Phenolic acid methyl esters belong to a class of BNIs that occur in substantial amounts in plant tissues. However, the effects of these BNIs on moderately acidic soils with high $N_2O$ emissions remains unclear. Here, a soil incubation experiment was conducted to investigate the effects of three phenolic acid methyl esters on $N_2O$ emission, soil physicochemical factors, the abundance of nitrifying and denitrifying genes, and microbial communities in a moderately acidic soil. The results show that the three BNIs all significantly reduced $N_2O$ emission, and the inhibition rate of methyl cinnamate (CM) and methyl ferulate (FM) was about twice that of methyl 3-(4-hydroxyphenyl) propionate (MHPP). The three phenolic acid methyl esters significantly reduced the abundance of AOB-*amoA* while increasing the abundance of *nosZ* and the ratio of *nosZ*/(*nirK* + *nirS*). High-throughput sequencing revealed that the three BNIs altered soil microbial communities by promoting the abundance of Proteobacteria, particularly those belonging to the genera of *Massilia* and *Burkholderia-Caballeronia-Paraburkholderia*. Further, random forest and structural equation modelling indicated that these BNIs reduced $N_2O$ emissions by modifying the key factors of pH and dissolved organic carbon (DOC), targeting Proteobacteria, and affecting the abundance of AOB, *nirS*, and *nosZ*, thus suppressing nitrification and promoting complete denitrification. Our findings demonstrate that the application of phenolic acid methyl ester BNIs presents a promising nitrogen management strategy to mitigate $N_2O$ emissions from moderately acidic soils.

**ABSTRACT**

1,9-Decanediol, a biological nitrification inhibitor (BNI) identified from rice root exudates, effectively suppresses nitrification in both pure culture systems and soil environments. However, its physiological and transcriptional regulatory mechanisms against ammonia-oxidizing bacteria remain unclear. Here, we systematically investigated the model ammonia-oxidizing bacterium *Nitrosomonas europaea* through integrated physiological and transcriptomic analyses (RNA-seq). The results showed that 100 μg/mL 1,9-decanediol significantly inhibited nitrite production. The vitro enzymatic assays revealed that 1,9-decanediol directly targets ammonia monooxygenase (AMO) in a reversible manner. Additionally, 1,9-decanediol slowed the growth of *N. europaea* without causing significant membrane damage or increased cell mortality. Transcriptomic analysis further demonstrated downregulation of genes involved in oxidative phosphorylation and energy-consuming biosynthetic pathways, such as amino acid metabolism and ribosomal proteins, whereas genes associated with the two-component system, chemotaxis, and RND efflux pumps were upregulated. These findings indicate that under the stress of BNI 1,9-decanediol, energy metabolism and biosynthesis process in *N. europaea* cells are disrupted, thereby activating multiple stress response and escape signals for feedback regulation. This study provides a theoretical basis for developing BNI-based environmentally friendly strategies for nitrification management.

**ABSTRACT**

Sufficient nitrogen supply is essential to maximize rice yield. Nitrogen fertilizer has been used to supply N to rice, but due to increasing concerns on environmental degradation, rice production with reduced nitrogen supply without losing yield is required for future sustainability. Iron-reducing bacteria (IRB) have been documented as major nitrogen-fixing microorganisms in paddy field soils. As IRB abundance is affected by carbon. it is possible that rice cultivation also affects IRB abundance in paddy field soils. To test this, we developed a microcosm system using field-collected paddy soil to enable controlled evaluation of rhizosphere IRB and established a qPCR-based quantification method. We found that rice cultivation increases IRB abundance in paddy field soils. We also found that the extent of increase depends on rice cultivars. Applying this system to diverse rice accessions, we collected dataset of extents of IRB abundance increase for individual rice cultivars and the dataset was used for genome-wide association analysis. Genomic regions associated with IRB abundance were identified (Lin et al 2025), and within each LD block, genes carrying variants predicted to alter protein function and showing strong statistical association ($p \leq 0.001$) were selected as candidate genes that affect IRB abundance in soils. CRISPR–Cas9 knockout lines are being generated for these genes, and mutants have been obtained for several genes. These mutants will be evaluated to determine their effects on IRB abundance. At the congress we will present updates of our project. We believe that the results will facilitate elucidation of rice genetic factors involved in regulating rhizosphere IRB and provide a basis for integrating microbial functions into nitrogen management strategies.

## ABSTRACT

Biological Nitrification Inhibitors (BNIs) is the exudates from plant rhizosphere, 1,9-decanediol is a typical biological nitrification inhibitor from rice roots, promotes root growth in Arabidopsis and plays an important role on soil nitrification and nitrogen-loss reduction. However, the effects of Biological Nitrification Inhibitors (BNIs) on crop production and nitrogen（N）utilization in red soil in field are limited.

A field experiment was conducted and a typical BNIs 1,9-decane diol was used to investigate the effects of BNIs on maize yield and nitrogen use efficiency in red soil. Seven treatments were set: T1 (No, no N fertilization ), T2 (Conventional N application, 225 kg N /ha,), T3 (20% N reduction, 180 kg N /ha), T4 (Conventional N + 2% 1,9-decane diol), T5 (Conventional N + 5% 1,9-decane diol), T6 (20% N reduction + 2% 1,9-decane diol), and T7 (20% N reduction + 5% 1,9-decane diol). The maize growth and yield, N uptake, N translocation and N use efficiency were analyzed.

The results showed that, the addition of BNIs significantly increased maize yield and nitrogen use efficiency in red soil. Compared to conventional N application T2,20% N reduction (T3) decreased maize yield by 1.86%, but the reduction was not statistically significant.Under conventional N application, applying different concentrations of BNIs (T4 and T5) increased maize grain yield by 5.02% and 9.84% and biomass by 19.96% and 21.60%. Under the 20% N reduction condition, applying different concentrations of BNIs (T6 and T7),maize grain yield increased by 8.50% and 3.00%, and biomass increased by 14.39% and 5.58%. Among all treatments, the maize yield of T5 and T6 are the highest, T6 showed the best effect on yield increasing. Addition BNIs increased the maize N accumulation and N translocation from vegetative organs to grain. Under conventional N application and under N reduction,BNIs increased the plant N accumulation by 4.24%~8.87% (T4 and T5) and decreased it by -0.36% and -0.37% (T6 and T7)respectively. Simultaneously, the N translocation of BNIs from vegetative organs to grains increased by 14.26%~32.94% under conventional N application (T4 and T5) and by 12.38%~24.94% under N reduction (T6 and T7). The nitrogen agronomic efficiency (AE) increased by 20.94%~21.25% (T4 and T5) and 35.63%~48.10%(T6 and T7), respectively, while the nitrogen recovery efficiency (RE) increased by 49.65%~54.25% (T4 and T5) and 51.07%~59.71% (T6 and T7), respectively. Among all treatments, T5 and T6 showed the best effect on the N utilization increasing.

In conclusion, biological nitrification inhibitors (BNIs) can significantly enhance maize yield and nitrogen fertilizer use efficiency by promoting nitrogen accumulation and translocation in maize grown in red soil. BNIs addition maintains good performance both for maize yield and N use efficiency even under reduced 20% nitrogen application, demonstrating the potential as a green practice for synergistically increase both crop production and nitrogen use efficiency and achieving nitrogen fertilizer reduction.

## ABSTRACT

Nitrogen, although essential for the development of grasses, exhibits short residence time in the soil and high application costs, particularly in tropical regions. Moreover, nitrogen fertilizer use efficiency is low; it is estimated that approximately 50% of the applied N is lost through volatilization or leaching, contributing to environmental impacts such as soil acidification and water eutrophication (BANGER et al., 2017). Inoculation with plant growth-promoting bacteria (PGPB), such as *Azospirillum brasilense* and *Bacillus* spp., has emerged as an effective strategy to enhance the agronomic performance of forage grasses, especially under tropical conditions where nitrogen demand is high. The objective of this study was to evaluate the association between PGPB and nitrogen rates on nutritional efficiency and biomass production of *Urochloa brizantha* cv. Marandu Palisadegrass. The experiment was conducted under field conditions in a pasture-establishment area of *Urochloa brizantha* cv. Marandu during the 2023/2024 and 2024/2025 growing seasons, at the Experimental Farm ofUNESP (21°27’ S, 5l°36’ W; 42l m altitude). The soil was classified as a dystrophic Ultisol. Pasture establishment included the application of l0 kg ha_1 of pure viable seeds broadcast and incorporated, along with 200 kg ha_1 of 4-30-10 (N-P2O5-K2O) fertilizer. The experimental design was a randomized block design with four replicates. Treatments involving nitrogen fertilization (urea) and foliar bacterial inoculation were: T1) References (zero N and no bacteria), T2) 80 kg ha_1 N, T3) 40 kg ha_1 N, T4) T3 + *Azospirillum brasilense* Ab-V5 + Ab-V6 (AZ), T5) T3 + *Bacillus* S26 (S26), T6) T3 + *Bacillus* N72 (N72), T7) T3 + AZ + S26 + N72, T8) AZ + S26 + N72, T9) AZ, T10) S26, T11) N72. The combined canonical axes (Can1 + Can2) explained 86% to 95% of the variation in the integrated dataset across the two growing seasons. This outcome demonstrated that inoculation with *Azospirillum* and *Bacillus* S26 and N72, whether applied individually or in co-inoculation, enhanced plant metabolic activity, increased nutritional efficiency, and improved dry mass production. Co-inoculation, particularly when associated with the reduced N rate, yielded the best performance, sustaining high dry mass production even under declining residual soil fertility. In contrast, mineral nitrogen fertilization alone showed reduced efficiency over time. Thus, the use of microbial bioinputs represents a sustainable and effective strategy to maximize productivity in tropical pasture systems.

**ABSTRACT**

Nitrogen is a vital macronutrient that significantly affects rice growth, grain yield, and quality. The widespread use of N without proper management can lead to economic losses and environmental harm through leaching, volatilization, and greenhouse gas emissions (Swathy et al., 2024). To address these issues, the present study aimed to develop a machine learning-based protocol to optimize nitrogen nutrition in rice by combining graded nitrogen levels with foliar applications of Nano Urea and remote sensing derived vegetation indices. The field experiment was conducted during the 2023 and 2024 Rabi seasons at the Wetland Farms of Tamil Nadu Agricultural University, Coimbatore. The trial was arranged in a Split Plot Design with eleven graded nitrogen doses (0–150 kg N $ha^{-1}$, representing 0–100% of the recommended dose) in the main plots and four foliar nutrition treatments in the subplots: Nano Urea (16% N) at 0.7%, sprayed at active tillering, panicle initiation, and heading, along with a no-foliar-nitrogen control and each replicated three times. Growth, physiological, and yield attributes were recorded at critical growth stages, while high-resolution multispectral images were captured using a DJI Phantom 4 platform to compute key vegetation indices (NDVI, NDRE, GNDVI, GCVI, MCARI, SAVI, and EVI) as proxies for crop vigour and nitrogen status. The results indicated that both graded nitrogen levels and Nano Urea foliar sprays, as well as their interaction, significantly affected plant height, tiller number, panicle length, and grain yield. The highest yield (6228 kg $ha^{-1}$) was achieved with 100% of the recommended nitrogen combined with a Nano Urea spray at active tillering, while the control (0 kg N $ha^{-1}$, no foliar nitrogen) produced the lowest yield (3695 kg $ha^{-1}$). Importantly, 70% of the recommended nitrogen combined with Nano Urea spray at active tillering resulted in yields statistically similar to the 100% nitrogen treatment, suggesting that a 30% reduction in nitrogen input can be achieved without compromising productivity. Spectral analysis showed strong positive relationships between nitrogen level, chlorophyll content, and canopy reflectance, with NDVI and GCVI exhibiting the highest correlations with plant nitrogen content across stages. Linear regression models identified EVI as the most reliable predictor of nitrogen status during early growth, while NDVI performed better at panicle initiation, with good agreement between observed and predicted values. Based on these relationships, a Python-based Nitrogen Management Calculator was developed to offer real-time, index-based recommendations for nitrogen sufficiency or deficiency. Overall, the study demonstrates that integrating nanofertilizer-based foliar nutrition, multispectral sensing, and machine learning provides a strong framework for site- and stage-specific nitrogen management in rice, enhancing nitrogen use efficiency, supporting more sustainable and input-efficient rice production systems.

## ABSTRACT

Biodiversity can enhance ecosystem functioning not only through interactions but also through lasting legacies that shape future resource use. In agroecosystems, these legacy effects are extensively studied in topsoil but remain largely unexplored in subsoil layers despite their critical role in nutrient acquisition, drought resilience and carbon storage. Here, we combined a $^{13}C$–$^{15}N$ dual-labeling field experiment with microbial community profiling and metaproteomics to investigate how cover crop diversity influences carbon (C) and nitrogen (N) dynamics across soil depths (0-30 and 30-60 cm). We identified root channel legacies as a key pathway through which cover crop mixtures affect the fate of plant-derived C and N in deep soil layers. Cover crop mixtures that combine deep- and shallow-rooting species enhanced the recovery of plant-derived $^{13}C$ and $^{15}N$ in empty root channels relative to deep-rooting monocultures, with stronger effects in the subsoil (30–60 cm) than in the topsoil (0-30 cm). Reuse of legacy root channels by maize intensified microbial C and N processing in rhizosphere hotspots, with subsoil legacy processes dominating maize N acquisition. Microbial structural and functional dynamics further showed that cover crop mixtures reshaped microbial community composition and upregulated protein pathways involved in carbohydrate and N metabolism, with amplified responses in reused channels. Importantly, different mixtures expressed distinct functional effects, demonstrating that biodiversity effects in agroecosystems are functionally heterogeneous rather than uniform. Together, our findings expand biodiversity–ecosystem functioning theory by identifying subsoil legacies as an overlooked dimension of ecological memory. By imprinting the subsoil microbiome through root channel, plant diversity enhances and diversifies crop nutrient capture, suggesting improved resilience to increasing climatic fluctuations by global change.

## ABSTRACT

Soil nitrogen (N) mineralization is a critical ecological process that plays a significant role in maintaining soil fertility and sustainability of agroecosystems. Legume//cereal intercropping, particularly in wheat//faba bean systems, has been demonstrated to enhance the soil's nitrogen supply capacity. Nonetheless, previous studies have rarely addressed how intercropping affects soil net nitrogen mineralization rates and their temporal dynamics, as well as the associations with the soil carbon-to-nitrogen ratio, nitrogen-transforming enzyme activities, microbial community structure, and particularly the properties of microbial interaction networks. Here, we conducted a continuous wheat//faba bean intercropping field experiment and performed in-situ soil-core incubation over two growing seasons to assess monthly variations in soil ammonification, nitrification, gross mineralization and net mineralization rates during the growing season (December to May), and subsequently investigated the regulators of soil nitrogen mineralization. We systematically examined how intercropping drives N mineralization through stoichiometric, enzymatic and microbial pathways by integrating in-situ incubation, enzymatic profiling, high-throughput sequencing and microbial co-occurrence network analysis. We found that intercropping increased soil N mineralization rates, with a peak increase of 154.8% in March. Intercropping increased the soil C/N ratio by up to 11.62%, and enhanced the activities of N-acetyl-β-D-glucosaminidase and leucine aminopeptidase by 39.25% and 45.26%, respectively. Microbial network analysis showed higher proportions of positive links in the intercropping system than in Monocropped crops, reaching 95.6%. Path analysis revealed that intercropping increased soil N mineralization mainly through elevated soil C/N ratio induced microbial resource reallocation to N-acquiring enzymes and enrichment of nitrifying taxa, which stimulated the nitrification process (increase of 183.00%) and consequently enhanced overall N mineralization. In conclusion, crop diversity-driven changes in soil C/N stoichiometry induced a cooperative microbial network and enriched keystone functional taxa, which promoted mineralization efficiency. A new mechanism elucidating the positive crop diversity effect on N cycling is proposed.

## ABSTRACT

Regenerative viticulture (RV) is a vineyard management approach that aims to increase vineyard soil carbon (C) and restore vineyard soil health, improve ecosystem services and mitigate against extreme climatic events.

Biochar is one potential RV tool, however its impact on subtropical vineyard soils is minimal. This study aimed to investigate the short-term impacts of biochar application on total carbon (C), total nitrogen (N) and their isotope compositions ($\delta^{13}C$ and $\delta^{15}N$) in vine plant tissues (young and mature petioles, young and mature leaves, rachis and berries) during spring and harvest sampling at two Southeast Queensland vineyards of subtropical Australia.

Pine biochar (650°C pyrolysis) was applied at 0, 5.0, 10.0 and 20.0 t $ha^{-1}$ to the vine rows (VR) soil at two vineyards, Nuova Scuola (NS, clay-loam soil) and Ballandean Estate (BE, sandy soil) in August 2023. Soil and vine tissues were sampled two months later in spring at ~70% capfall, with the second sampling being the day before harvest about 5 months after biochar application. The total C, total N and their isotopic compositions($\delta^{13}C$ and $\delta^{15}N$) on the soil and vine tissues were measured.

The isotopic compositions responses strongly differed significantly with the site, with the yield parameters mostly unaffected over one growing season. In sandy soil, the 5 t $ha^{-1}$ biochar application enriched $\delta^{13}C$ in vine tissues and berries, indicating increased plant water-use efficiency (WUE), but 20 t $ha^{-1}$ biochar application improved soil microbial N transformations, producing enriched $\delta^{15}N$ in vine tissues and berries as well as evidence of potentially better yield and lower individual berry weight. In clay loam soil, biochar effects were not so significant, with negative $\delta^{13}C$ values of continual lower WUE, however increased $\delta^{15}N$ at 10 t $ha^{-1}$ was optimal for N use efficiency (NUE) with little discernible effect on the berry yield.

Biochar applications affected the soil – vine isotopic coupling primarily through soil microbial and vine physiological processes, with responses strongly governed by the site-specific soil texture. Dual isotopic analysis of using both $\delta^{13}C$ and $\delta^{15}N$ provided a sensitive diagnostic tool to fingerprint the impacts of biochar applications on soil microbial functioning and vine nutrient efficiency under the framework of regenerative viticulture (RV).

## ABSTRACT

Plant root–secreted compounds can act as biological nitrification inhibitors (BNIs), suppressing soil nitrification and improving nitrogen use efficiency, thereby reducing nitrogen losses through greenhouse gas emissions and leaching in agricultural systems. Despite their potential, the key drivers of BNI efficiency remain poorly defined, particularly in wheat. Addressing this knowledge gap is critical for optimizing nitrogen management, mitigating environmental impacts, and enhancing crop productivity.

In this study, we developed and applied multiple complementary approaches to quantify BNI efficiency and assessed the effects of plant growth conditions (hydroponic versus soil), developmental stages (tillering, stem elongation, booting, and flowering), and genotype (high-, mid-, and low-BNI wheat lines). A novel integrated BNI index revealed higher BNI efficiency under hydroponic conditions compared with soil, suggesting that soil mechanical constraints and rhizosphere microbial interactions modulate root exudation patterns.

BNI activity was observed across all genotypes and increased with plant developmental stage, consistent with rising nitrogen demand. Integrated metabolomic and microbial community analyses identified key mechanisms underpinning the BNI phenotype, including the exudation of specific benzoxazinoid compounds and the selective suppression of archaeal and bacterial ammonia-oxidizing populations in the rhizosphere.

Our findings demonstrate that BNI is a significant and regulated ecosystem function in wheat, driven by genotype-dependent root exudation that varies with growth conditions and developmental stage. Specific root metabolites differentially influenced rhizosphere microbial communities, thereby controlling nitrification rates and nitrogen availability. This work advances our understanding of BNI regulation in wheat and provides a foundation for developing sustainable nitrogen management strategies to reduce nitrogen losses and improve agricultural efficiency.

**ABSTRACT**

Context: Robust prediction of maize leaf nitrogen concentration (LNC) is essential for optimizing nitrogen (N) management strategies aiming for reducing fertilizer input and maintaining crop yield stability. However, how the spatial distribution patterns of N within individual leaves are associated with N deficiency and developmental senescence has not the fully understood. Advanced hyperspectral imaging (HIS) technologies, provide a high-throughput and non-destructive way to monitoring the spatial variability in LNC, which has the potential of offering new insights into explaining the spatiotemporal dynamics from super high-resolution hyperspectral scans across individual millimeters of a leaf surface. Objective: This study aimed to elucidate the physiological responses of N partitioning patterns in leaves to N stress and developmental senescence using HIS, and to achieve nondestructive, fine-scale monitoring of leaf N status through a band optimization algorithm. Methods: Field experiments were conducted in Inner Mongolia during the 2023 and 2024 growing seasons, involving maize cultivars subjected to varying N levels. HSI of the latest fully expanded leaves and the oldest leaves (V9 stage) were captured at vegetative (V9, V12) and reproductive (VT, R1) stages. LNC was measured in six pre-defined segments along individual leaf length. The stability of published spectral indices and the optimized spectral indices for spatial LNC prediction mapping were compared. Results: LNC exhibited a decreasing gradient from the tip to the base in the latest fully expanded leaves, whereas an inverse pattern was observed in the oldest leaves. In both cases, the N distribution displayed symmetrical patterns centered on the leaf venation. Excessive N supply and developmental senescence did not alter these spatial distribution trends. Compared to published indices, the optimized spectral indices (OSIs) significantly improved the accuracy of spatial LNC mapping along the leaf. OPT-NPDI demonstrated the highest stability (R2 = 0.80, RMSE = 0.27%). Conclusions: Neither excessive N application nor leaf senescence altered the intrinsic spatial distribution pattern of N within maize leaves. Senescence appeared to stabilize the spatial distribution of LNC. The accuracy of OPT-NPDI and its insensitivity to variations in bandwidth highlight its applicability across sensors with varying spectral resolutions. Significance: This study advances the application of HSI for fine-scale, non-destructive monitoring of leaf N status by developing a modeling framework. It provides methodological support for the broader deployment of hyperspectral imagers in precision nutrient phenotyping and management.

# From methodological to mechanistic frameworks: assessing BNI efficiency by integrating varying levels of plant growth realism

**Xiaoping Fan*, Jasmeet Kaur-Bhambra, and Cécile Gubry-Rangin**

*School ofBiological Sciences, University ofAberdeen, Aberdeen, UK*

xiaoping.fan@abdn.ac.uk

**ABSTRACT**

Quantifying biological nitrification inhibition (BNI) efficiency in crops is critical for advancing sustainable nitrogen management. However, current BNI phenotyping is constrained by methodological inconsistencies and limited mechanistic understanding of how plant growth conditions (hydroponics vs. soil), developmental stages and genotypes (high- vs. low-BNI wheat lines) interact to shape observed BNI outcomes, particularly in wheat.

Here, we establish an integrated methodological-mechanistic framework to assess BNI efficiency across contrasting plant growth conditions (hydroponics vs. soil), developmental stages, and genotypes (high- vs. low-BNI wheat lines). We combine complementary direct and indirect approaches, including culture-based bioassays (ammonia-oxidising archaea (AOA) and bacteria (AOB)) of root exudates, soil nitrification assays, molecular characterisation of rhizosphere nitrifier communities, and metabolomic profiling of root exudates, to determine how varying levels of plant growth realism drive BNI expressions.

Our results demonstrate that BNI efficiency differed between soil- and hydroponically grown plants, indicating distinct biochemical and microbial interaction regimes. Metabolomic profiles revealed growth condition and developmental stage dependencies in root exudate composition, providing mechanistic insight into observed discrepancies among BNI estimation approaches. BNI effects were demonstrated across tested genotypes, the capacity to discriminate between high- and low-BNI lines varied among BNI estimating approaches, indicating differential sensitivity to metabolite-mediated versus microbially mediated inhibition processes. Higher BNI lines maintained plant nitrogen acquisition, indicating no apparent trade-off between BNI expression and plant N uptake. Plant developmental stage affected BNI efficiency, but stage-dependent patterns diverged across approaches, highlighting trade-offs between mechanistic specificity, temporal resolution, and ecological relevance.

Together, these findings demonstrate that BNI efficiency is a plant strategy arising from coordinated shifts in plant metabolism, rhizosphere microbial communities, and growth context. By explicitly linking methodological choice to mechanistic interpretation, this framework provides a basis for more interpretable, comparable, and standardised BNI phenotyping, supporting both crop breeding strategies and nitrogen management applications.

## ABSTRACT

The globally highly problematic nitrogen (N) deposition in natural ecosystems is largely derived from losses of mineral fertilizer-derived N from agroecosystems. Thus, alternative strategies to tighten the N cycle in crop production are urgently needed, specifically for crops with high N demand such as maize (*Zea mays* L.). Cover crops (CC) can contribute to this through enhanced N input and stabilization within the soil N pool. Few studies, however, have fully quantified the N input into the soil from CC and the subsequent re-use of this N by the following main crop. CC species should bring N in organic form into the soil, ensure ongoing N transformation and turnover, and enable the release of available N for the following cash crop upon demand. However, there might be trade-offs between these optimal traits and individual species are unlikely to achieve all of them. Therefore, we aim to assess the effects of three different cover crop mixture (CCM, legume/grass, legume/brassica and brassica/grass) with deep- and shallow-rooting species on N input into soils, microbial N transformation and N turnover in top (0-30 cm)- and subsoils (30-60 cm), including the implication for subsequent maize N nutrition. To generalize or differentiate our results, we conducted our $^{15}N$ leaf-labeling field experiment at three sites with different soil types implying three soil fertility levels. The results revealed that CCM significantly increased N mineralization compared to fallow at the site with lowest soil fertility, but no significant CCM effect was identified at sites with higher soil fertility. The CCM containing deep-rooting brassica demonstrated a discernible beneficial impact on the N uptake of subsequent maize crop. In consequence, the main crop maize profited most from the pre-crops, showing highest CCM-derived $^{15}N$ uptake, under lower soil fertility, whereas maize growing on high-fertile soils exhibits a pReferences for the uptake of nutrients from the native soil. Consequently, the use of CCMs is of highest benefit in low-fertile soils and can only urgent be recommended there. Among them, whenever crop rotation allows, the use of brassica-based mixture will promote subsequent crop N uptake from the CCMs, and thus allows for reduced fertilizer N application. In consequence, the use of CCM represents a viable and effective management strategy for crop farming systems.

# Variation Patterns and Influencing Factors of Fine Root Uptake of Different Nitrogen Forms with Stand Age in Cunninghamia lanceolata

## ABSTRACT

Nitrogen (N) uptake of forest trees vary across different developmental stages, which exerts a significant impact on tree growth and carbon sequestration capacity. This study focused on Chinese fir (Cunninghamia lanceolata) plantations, the world's largest monoculture plantations, and selected stands of 11, 21, 24, 31, 42, 52, 58, and 68 years of age. Two in situ $^{15}N$ labeling experiments were conducted: an in situ hydroponic experiment and an in situ soil experiment. The objectives were to investigate how the fine root N uptake capacity for different N forms (both as an inherent trait and under natural conditions) changes with stand age and to identify the influencing factors.

The results showed that, regardless of the experimental condition, the uptake rates of ammonium ($NH_4^+$) and glycine by fine roots decreased with increasing stand age. This decline might be attributed to the reduced N demand in the later growth stages of the plantation, where the strategy for N acquisition shifts from direct root investment to a "cooperative outsourcing" model, potentially enhancing interactions with soil microorganisms. In contrast, the uptake rate of nitrate ($NO_3^-$) exhibited a unimodal pattern with stand age, peaking at 42 years. This pattern is likely the combined result of changes in fine root nitrate transporter expression, energy supply, tree N demand, and soil N availability. Furthermore, the complete ability to absorb glycine was only detected in the fine roots of 31- and 42-year-old stands, which may be related to energy supply and microbial competition.

Collectively, these findings reveal the patterns and underlying mechanisms of the age-dependent shifts in the N uptake strategies of Chinese fir fine roots, thereby providing a crucial scientific basis for the future management of plantations.

## ABSTRACT

Nitrogen (N) deposition can significantly influence plant hydraulic cycling through modifying plant functional traits, biomass allocation and resource use. Under scenarios of increasing N deposition and atmospheric drought, it is thus crucial to understand how nitrogen affects plant transpiration as vapor pressure deficit (VPD) rises for predicting ecosystem responses, i.e., water and carbon exchange to climate change. Particularly, grassland communities dominated by C3 or C4 plants may respond differently due to their distinct photosynthetic pathways, which influence water and N use efficiency under varying environments. Here we combine a controlled gravimetric chamber and an experimental field study to quantify plant responses to N addition and rising VPD levels. Our chamber study revealed higher N levels reduced transpiration sensitivity to rising VPD at both leaf and whole-plant scales. Our field study demonstrated this reduced sensitivity was due to N-induced decreases in stomatal conductance and, somewhat counterintuitively, belowground biomass allocation, which collectively suppress water transportation and plant transpiration. Moreover, in chamber study whole-plant transpiration decreased with high N levels for C3 species, reflecting a trade-off between water and N use efficiency. In contrast, C4 species maintained high whole-plant transpiration as N levels rose due to their simultaneous high water and N use efficiency and sharp increases in plant productivity. Together our studies suggest under rising atmospheric drought scenarios, N differentially modulates leaf-level and whole-plant transpiration of C3 and C4 grass species. Future studies should predict how these differences drive the hydrological and carbon cycling, particularly with changing relative abundance of C3 and C4 species under climate change.

**ABSTRACT**

Rhizosphere microbial communities are shaped by soil chemical properties, while how soil chemistry influence the core members recruited by plants remains unclear. We investigated the core rhizosphere microbiome of wild rice by comparing plants growth in three natural reserves (in situ) with those transplanted and cultivated ex situ for more than 40 years in soils of the same type but with different chemical characteristics. Using generalized joint attribute modeling (GJAM), we identified 44 amplicon sequence variants (ASVs) consistently shared across sites, including 35 bacterial and 9 fungal ASVs. These taxa mainly belonged to *Actinobacteria*, *Chloroflexi*, *Firmicutes*, *Nitrospirae*, *Ascomycota*, *Basidiomycota* and *Rozellomycota*. Several bacterial ASVs—particularly those from *Haliangium*, *Anaeromyxobacter*, *Bradyrhizobium* and *Bacillus*—were significantly enriched in ex situ soils, suggesting a strong influence of soil chemical factors on core microbiome structure. Functional predictions indicated roles in nitrogen fixation, manganese oxidation, chemoheterotrophy and iron respiration, highlighting their potential contribution to nutrient utilization and plant growth. Our results demonstrate that soil chemical properties can differentially regulate the core microbial community in wild rice rhizosphere microbiome and should be considered when designing strategies for soil and crop improvement.

# Developing an AI-based Precision Nitrogen Management Strategy for Corn

**Yuin Miao[1*], Dan Li[2], and Fabian Fernandez[1]**

[1] *Precision Agriculture Center, Department of Soil, Water and Climate, University of Minnesota, St. Paul, USA*

[2] *Key Lab of Guangdong for Utilization of Remote Sensing and Geographical Information System, Guangzhou Institute of Geography, Guangdong Academy of Sciences, Guangzhou, China*

*Presenter and corresponding author: ymiao@umn.edu

**ABSTRACT**

The optimal nitrogen (N) rates vary significantly from field to field and from year to year, affected by genetics, environmental conditions and management practices. The primary goal of this research was to develop an innovative in-season nitrogen (N) recommendation strategy for corn (*Zea mays* L.) across the U.S. Midwest using stacking ensemble machine learning (ML) and multi-source data fusion. Forty-nine site-years of N rate experiments conducted across the U.S. Corn Belt were used to evaluate the performance of five individual ML algorithms (Random Forest Regressor (RFR), Support Vector Regressor (SVR), Extreme Gradient Boosting Regressor (XGBR), CatBoost Regressor (CBR), and Multi-Layer Perceptron (MLP)) and stacking regression (STR) for in-season corn yield prediction under different preplant and split N application conditions using the active canopy sensor data along with genetics, environmental and management information. These models were further evaluated for their prediction of yield responses to sidedress N application rates and in-season estimation of site-specific economic optimal N rate (EONR) across the U.S. Corn Belt. The results indicated that the stacking model performed consistently well across all datasets for corn yield prediction, demonstrating robustness ($R^2 > 0.85$ for validation dataset). Preplant N rate, Sidedress N rate and normalized difference red edge (NDRE) were identified as key variables for predicting corn yield. For EONR estimation, the stacking regression 2 model (STR2) using RFR, SVR, XGBR, CBR, and MLP as base estimators and linear regression as the meta estimator performed the best for the full dataset ($R^2$=0.82 and root mean square of error (RMSE)=27.50 kg N $ha^{-1}$). It is concluded that the stacking regression and multi-source data fusion framework is a promising strategy for in-season site-specific corn yield prediction and sidedress N recommendation. It can be improved by adding more plot and on-farm N experimental data collected across diverse environmental conditions to guide in-season site-specific N management in the U.S. Midwest. It can also be adapted and improved for different crops, regions and dynamic price environments using UAV and satellite remote sensing and more advanced ML models with user-friendly interfaces to make greater contributions to the improvement of N use efficiency, farm profitability and agricultural sustainability.

## ABSTRACT

Nitrous oxide ($N_2O$) has a global warming potential equivalent to 298 times that of $CO_2$ over a 100-year horizon and is the dominant ozone-depleting substance in the 21st century. However, there are large uncertainties because it is still unclear whether all the sources have been well identified. Plant-mediated nitrous oxide ($N_2O$) emission is a crucial component of the terrestrial nitrogen cycle, yet its response to nitrogen (N) and phosphorus (P) nutrient additions and the microbial driving mechanisms remain unclear. This study aimed to investigate the $N_2O$ flux from *Leymus chinensis*, a dominant grass in temperate grasslands, to clarify the effects of N and P addition, and to reveal the roles of epiphytic and endophytic microbial communities.

A three-year field manipulation experiment was conducted to monitor the growing-season $N_2O$ flux from *L. chinensis*, with treatments including control (CK), N addition (N), P addition (P), and combined N and P addition (NP). Concurrently, laboratory incubations with non-sterilized and sterilized (simulating an endophyte-dominated, microbe-free internal environment) plant materials were performed to differentiate the contributions of epiphytic and endophytic microbes. Quantitative PCR (qPCR) was used to quantify the abundance of the epiphytic ammonia-oxidizing archaea (AOA) and bacteria (AOB) *amoA* genes, and the endophytic denitrification functional gene *cnorB*. High-throughput sequencing was employed to analyze the endophytic bacterial community structure.

The field experiment confirmed *L. chinensis* as a source of $N_2O$, with flux rates ranging from 0.8 to 6.3 ng $g^{-1}$ $h^{-1}$, peaking in late July coinciding with peaks in temperature and precipitation. Single N or P addition showed an increasing but non-significant trend, whereas NP co-addition significantly enhanced emissions (+63.1% in 2022, +142.3% in 2023). Laboratory incubations further confirmed the strong stimulatory effect of NP (non-sterilized: +179.6%; sterilized: +291.5%). N addition significantly increased the abundance of epiphytic AOA and AOB; P had a significant effect only on AOA. NP treatment increased AOA abundance by 212.7%. Sterilization attenuated microbial effects, but N addition still significantly increased *cnorB* abundance (+241.7%) and the Shannon index. NP addition markedly altered the composition of key denitrifying genera: e.g., increasing the relative abundance of *Brevibacillus* from 5.1% to 20.58% under non-sterilized conditions, and that of *Sphingomonas* from 2.22% to 44.54% under sterilized conditions. Random Forest analysis revealed that under non-sterilized conditions, epiphytic AOA abundance and the endophytic Shannon index were the most important variables for predicting $N_2O$ emissions. Under sterilized (endophyte-dominated) conditions, the relative abundance of endophytic *Sphingomonas* and the *cnorB* gene abundance became the dominant factors.

This study demonstrates that *L. chinensis* is a source of $N_2O$ in grassland ecosystems. Synergistic N and P addition strongly promotes $N_2O$ emissions, an effect far exceeding that of single nutrient additions. The mechanism involves the co-regulation by NP addition of both epiphytic ammonia-oxidizing microbes on plant surfaces and endophytic denitrifying microbial communities (specifically functional gene abundance and key genus composition) inside plants, thereby driving increased $N_2O$ production. This research highlights the necessity of considering plant-mediated emissions and the interactive effects of N and P nutrients underpinned by microbial mechanisms when assessing greenhouse gas budgets in grassland ecosystems.

## ABSTRACT

The complex network of interactions between plants and microbial communities play a vital role in regulating nutrient cycling, plant health, and ecosystem function, which are critical for maintaining ecological balance and sustaining agricultural productivity(Trivedi et al. 2020; Philippot et al. 2024). The rhizosphere provides an ideal environment for a diverse microbial community, which can be regarded as one of the most composite microbial ecosystems on earth. In the rhizosphere, plant roots secrete sugars, organic acids, coumarins, benzoxazinoids, plant hormones to regulate the rhizosphere micro-environment and recruit plant growth-promoting rhizobacteria to cope with various biotic and abiotic stresses(Sasse et al. 2018) (Yu et al. 2020).

Plant hormones are important signal molecules produced in very low concentrations but have diverse functions in cell elongation, cell differentiation, organogenesis, reproduction, and responses to abiotic and biotic stresses. Plant hormones are classified into nine categories, including encompasses auxins (IAA), cytokinins (CK), strigolactones (SL), brassinosteroid (BR), gibberellins (GA), ethylene (ET), abscisic acid (ABA), jasmonic acid (JA), salicylic acid (SA). Plant hormones—in particular, IAA is considered to be one of the most key regulators in regulating plant growth, shaping plant microbiota, and protecting plants from pathogens (Kou et al. 2022; Nakano et al. 2022). The major define phytohormones of SA and JA have been extensively studied in their function in plant – microbe interactions. The epiphytic and endophytic root microbiome community composition appears to be strongly driven by SA accumulation/insensitivity mutants (Kniskern et al. 2007; Lebeis et al. 2015). In addition, exogenous SA also application affected bacterial composition in bulk soil, suggesting that the effect of SA on microbial communities is independent of plant signals (Lebeis et al. 2015). Exogenous treatment with JA has recently been shown to increase Arabidopsis rhizosphere alpha diversity along with an enrichment of several potentially beneficial microbial taxa(Carvalhais et al. 2013). SLs are known not only as plant hormones, but also as molecular signals facilitators specific plant symbioses(Mashiguchi et al. 2021). The nodule number has been shown to decrease in strigolactone biosynthesis mutants in pea, soybean, and M. truncatula (Rehman et al. 2022; Van Dingenen et al. 2023; McAdam et al. 2017). Additionally, exogenous rac-GR24 treatment could reverse the reduced nodule phenotype in ccd7 mutant and rms4-mutant lines in pea (Foo and Davies 2011; Foo et al. 2013). Phytohormones signaling and biosynthesis affect composition and abundance of plant microbiota, while the unraveled phytohormones-optimised microbiome recruitment mechanism requires further investigation.

n this study, we first investigated the molecular mechanisms of soil microbiome recruitment by the application of exogenous nine categories phytohormones. Three categories (IAA, ZT, and SL) markedly influenced microbial respiration and their structure and function in topsoil. The application of JA and SA marginally altered the dynamics of microbial populations. Four other phytohormones (GA3, ACC, EBL, and ABA) treatments were not affected the microbial metabolism and community assembly both in topsoil and subsoil. Amplicon sequencing identified 20,604 bacterial and 6,900 fungal amplicon sequence variants (ASVs) in the topsoil, and 16,743 bacterial and 3,573 fungal ASVs in the subsoil. Microbes in the surface soils were dominated by Proteobacteria, Actinobacteria, Chloroflexi, andAcidobacteria. It has been suggested that the higher abundance of Proteobacteria in the surface layer may be linked to elevated levels of carbon and nutrients. To discern disparities in microbial diversity among soil strata, we first determined the alpha diversity indices, including the Shannon index, Chao1 index and Simpson index, and beta diversity metrics such as the Bray-Curtis distance based on the amplicon data.

Our results indicated a decline in microbial alpha diversity under both JA and ZT treatments in topsoil and subsoil. In contrast, bacterial beta diversity (spatial variations) increased across both soil layers, whereas fungal beta diversity remained unchanged. Overall, our study provides clear evidence for plant hormones-driven microbiome assembly. Next, we aimed at modulating the plant hormone levels by the engineering of PGPBs to promote plant growth and development.

## ABSTRACT

Background

Current average nitrogen fertilizer use efficiency (NUE) is suboptimal, leading to significant environmental pollution.

Methods

As part of the Global Ion-Moleculeome Project (GiP), we are constructing a global "live dynamic functional database" (GiPDatabase). This database integrates large-scale NMT-derived imOmics data on crop-specific $NH_4^+/NO_3^-$ uptake dynamics under varied soil and climatic conditions.

Results

Machine learning models trained on this database can predict real-time crop nitrogen demand with high spatio-temporal resolution. Preliminary simulations indicate that this GiP-enabled "Smart Agriculture" module can effectively increase NUE and reduce nitrogen runoff.

# Crop improvement for nitrogen and phosphorus use efficiency in rice

**Nandula Raghuram**[1*]

[1] *Centre for Sustainable Nitrogen & Nutrient Management, School of Biotechnology, Guru Gobind Singh Indraprastha University, New Delhi 110078*

* raghuram@ipu.ac.in

**ABSTRACT**

Poor agricultural nutrient use efficiency adds to the triple planetary crisis of pollution, biodiversity integrity and climate change, as most of the nitrogen (N) and phosphorus (P) inputs are lost to the environment. N/P use efficiency (NUE/PUE) is therefore a huge economic and environmental issue for sustainable agriculture. Rice is an ideal target to improve NUE/PUE in India due to its highest fertilizer consumption and huge genetic and genomic resources. We characterized the phenotype for NUE separately for urea/nitrate and identified some of the most contrasting genotypes among a thousand released Indian rice varieties. We also characterized the phenotype for PUE in popular Indian rices and found some common traits for both NUE and PUE. The late-germinating, late-flowering, long duration rice varieties assessed had higher yield and NUE/PUE than the early-germinating, early-flowering, short duration varieties, with only one exception each so far. The common high-ranking traits common for NUE and PUE were, photosynthetic rate at the reproductive stage, number of tillers, root–shoot ratio, culm thickness, leaf width of flag leaf, shoot biomass, and straw weight. Transcriptomic analyses of contrasting rice varieties for N-responsive genes associated with the NUE phenotype, QTLs and yield, revealed the genes/pathways associated with NUE. They include G-proteins, transporters, transcription factors (TFs), microRNAs (miRNAs), kinases and phosphatases. Though over 70% of the rice N-responsive genes contain G-quadruplex sequences (G4Qs), indicating epigenetic regulation, over 83% of the NUE-related genes lacked G4Qs, indicating their direct genetic regulation and potential for genetic improvement. Physiologically, high NUE is associated with better photosynthetic performance, transpiration efficiency and internal water-use efficiency, relative to low NUE in rice. We also found some common genes for nitrogen and phosphorus use efficiencies. We are currently genome-editing candidate genes for crop improvement of NUE/PUE in popular Indica rices. We also used comparative RNAseq of contrasting NUE genotypes to identify SNPs and are developing markers for alternative selection/breeding strategies for NUE.

# The power of the less productive: understanding the links between diversity and belowground traits of wild, landrace and modern crops

**Llorenç Cerdà [1*], Cristina Valero-Asencio[1], and Catherine Preece[1]**

[1] *IRTA (Sustainability in Biosystems, Cabrils, Spain)*

*llorenc.cerda@irta.cat

**ABSTRACT**

Crop genetic erosion has been a major concern to ensure the stability and resilience of agronomic systems. The widespread use of modern crop cultivars favoured by conventional agronomic practices have led to a steady decline in crop diversity over the last century. Furthermore, traditional varieties of crops (landraces) and non-domesticated crop wild relatives (CWRs) remain a large untapped pool of genetic diversity often dismissed because of their lower productivity compared to modern crops. Still, comparisons in the functional traits of crops and CWRs have emerged as a critical research direction to increase our understanding of how plant domestication syndromes have reshaped relationships among yield and plant traits. Plant root exudation constitutes the chemical interface through which plants communicate with the rhizosphere microbiome. The associations between plants and rhizosphere microbes influence their root system and belowground soil nutrient-acquisition strategies. These associations can help crops access nutrients beyond their root-depletion zone to different pools of resources such as recalcitrant or organic nutrient forms not normally easily available to the plant. We expect modern crop roots to have lower rates and diversity of exudation than their wild relatives, due to lower relative investment in these processes and lower genetic diversity, leading to less diverse crop rhizospheres. To explore this hypothesis, we designed an experiment to collect root exudates, rhizosphere soil and root tissue of 20 different modern crop species and their respective landrace and CWR varieties. We assessed root nitrogen content, exudate quantity and composition using untargeted metabolomics and characterised the composition and diversity of root-associated soil microorganisms. Studying relationships between domestication syndromes in root traits and nutrient acquisition strategies may reveal the possibility of new directions in breeding programs to achieve more efficient yet sustainable agricultural practices.

# Maintaining sulfur supply to rhizobia delays nodule senescence in soybean

**Zhichang Chen[1*], Yuan Li[1], and Renfang Shen[1]**

*zcchen@issas.ac.cn

**ABSTRACT**

Symbiotic nitrogen fixation (SNF) in legume-rhizobia represents a sustainable and eco-friendly alternative to chemical nitrogen fertilizers in agriculture. Identifying key factors involved in nodule senescence, is crucial for enhancing SNF by effectively extending the lifespan of nodules. Here, we reveal that sulfur, an essential element for SNF, plays a major regulatory role in the senescence of soybean (*Glycine max*) nodules. Blocking sulfur input into the symbiosome by knocking out either sulfur transporter genes *SULTR2;1* or *SULTR3;5*, resulted in a significant decrease in glutathione levels. This reduction impaired the capacity for reactive nitrogen species scavenging, thereby accelerating nodule senescence. Notably, reducing reactive nitrogen species (RNS) production in rhizobia or increasing sulfur input in soybean nodules through genetic manipulation, can effectively mitigated high nitrogen-induced nodule senescence. Our findings demonstrate that SULTR-mediated sulfur input is a pivotal step in regulating nodule senescence, and provide new insights for developing strategies to enhance SNF in legumes by delaying nodule senescence.

**ABSTRACT**

Conventional split broadcasting (CSB) of nitrogen (N) fertilizer often leads to low N use efficiency (NUE), and substantial environmental N losses, threatening fragile ecosystems such as that in the plateau regions of southwestern China. A 2-year field experiment was conducted to explore the effect of one-time root-zone fertilization (ORZ) method on the production of faba bean (*Vicia faba L.*) in Yunnan Province, southwestern China. Two N application methods (CSB, ORZ) with 6 N rates (0, 36, 72, 108, 144 and 216 kg $ha^{-1}$) were involved in the experiment. The results showed that ORZ significantly enhanced faba bean yield by 5.8–11.3% and economic benefits by 11.4–17.6% compared to CSB at the same N rates. N agronomic efficiency (NAE) and N apparent recovery efficiency (NARE) were also increased by 46.8–208.1% and 4.4–99.0%, respectively. The higher N recovery was observed with 11.8-12.5 and 5.3-7.7 percentage points by plant or soil, respectively, and lower N loss with 17.8-19.5 percentage points using $^{15}N$ tracing method in the treatment of ORZ compared to CSB. Correspondingly, higher soil $NH_4^+$-N and $NO_3^-$-N contents remained in the root zone when N was applied with ORZ. What's more, although increasing N fertilization generally inhibited nodulation and nitrogenase activity of faba beans, ORZ alleviated this inhibitory effect. The N application with ORZ seemed to be an efficient and promising way on N nutrient management for multi-wins of yield, NUE, economic and environmental benefits.

**ABSTRACT**

Agroecosystems typified by soybean intercropping reinforce crop interactions with gains in productivity and profound consequence on soils, yet the cascade from metabolites to microbes to functions remains insufficiently resolved. We established controlled rhizobox experiment that contrasted soybean neighboring oat with single soybean, integrating *in situ* zymography and glucose imaging with untargeted metabolomics and metagenomics. Daidzein was tested for its differential induction of distinct carbon substrate decomposition using substrate-induced respiration, as a key rhizosphere metabolite.

With oat as a neighbor, the soybean rhizosphere shows enhanced isoflavonoid and coumarin production and activation of the phenylpropanoid pathway. These metabolites act as selective chemical cues and substrate contexts that jointly enrich and stabilize decomposer oriented bacterial lineages, for example *Flavobacteriales*. Reliance on central carbon metabolism such as the TCA cycle, one carbon metabolism, and gluconeogenesis is attenuated, while the potential for degrading polymeric substrates such as hemicellulose and pectin is increased. Exogenous daidzein provides causal support for this mechanism. It broadly promotes utilization of labile carbon, yet it amplifies decomposition of the recalcitrant substrate arabinogalactan only within the community and metabolic framework created by soybean with an oat neighbor. Daidzein raised soil metabolism of arabinogalactan by 1.2 times only in soybean rhizospheres neighboring oat, with no response in single cultivation. In contrast, glucose induced respiration increased 1.4 times over seven days after daidzein addition under both cultivation regimes.

Taken together, soybean with an oat neighbor reconstructs the rhizosphere metabolite microbe function axis, shifting carbon cycling from a central metabolism dominated regime to one dominated by polymer decomposition and conferring context dependent sensitivity to the specific signal daidzein. These results outline a biochemical route by which crop interactions redirect rhizosphere carbon fluxes and influence short term turnover and long-term soil carbon stability.

**ABSTRACT**

A comprehensive understanding of crop strategies for soil resource acquisition is critical for achieving sustainable food security as climate change progresses. Root and rhizosphere traits are central to the acquisition of water and nutrients, yet variety-specific rhizosphere strategies, their plasticity, and their responses to changing water availability remain largely obscure. Here, we investigated root and rhizosphere traits of maize (Zea mays L.) along two contrasting belowground strategies – do-it-yourself vs. outsourcing – and how these strategies respond to drought severity and duration in soils of varying texture. In a controlled greenhouse experiment, six maize varieties previously characterized as do-it-yourself strategists (e.g. by high specific root length, reduced root-derived C input into the rhizosphere) or outsourcing strategists (e.g. by larger root diameter, higher arbuscular mycorrhization, and greater rhizosheath formation) were grown in two contrasting soils (silt loam vs. loamy sand). Plants were exposed to five distinct water availabilities: optimal (1), moderate (2), and low (3) water availability, as well as reciprocal shifts shortly before sampling - dry-down of initially well-watered plants (4) and rewetting of initially drought-stressed plants (5). We quantified root morphology and chemistry, root exudation, arbuscular mycorrhization, rhizosheath properties - including specific rhizosheath mass and microbial biomass carbon (MBC) and nitrogen (MBN) - and integrated these traits using multivariate statistics to identify strategy–environment interactions. Preliminary results showed that soil texture was the dominant factor influencing root morphology and microbial biomass responses under both optimal and low water availability, with stress responses being more pronounced in the sandy soil. Drought led to opposite root trait adaptations depending on soil texture: root diameter increased under drought in sandy but decreased in loamy soil, indicating that the direction of trait plasticity is co-determined by soil physical constraints rather than intrinsic to the plant. A modification of the rhizosphere strategy, particularly of do-it-yourself-strategists in sandy soils and of outsourcing-strategists in loamy soils, can therefore be assumed, but only if sufficient phenotypic plasticity is present at the variety level. Microbial biomass responses were consistent across soils, with drought causing declines in MBN while MBC remained stable. Specific rhizosheath mass was highest in plants exposed to early drought followed by rewetting, especially in sandy soils, and was significantly greater under continuous severe drought than under initially optimal and late severe drought conditions. This pattern suggests that drought severity and duration promote rhizosheath formation, largely independent of soil texture and soil water content at the time of sampling. Our findings highlight the role of soil texture and drought dynamics in determining root and rhizosphere trait combinations and their plasticity in maize, with implications for breeding drought-resilient crops to specific soil environments.

# Genotype-Specific Rhizosphere Strategies for Phosphorus Acquisition in Tea Plants under Organic Substitution

**Lizhi Long*, Yanyan Jiang, Chen Zhu and Jianyun Ruan**

*Tea Research Institute, Chinese Academy of Agriculture Sciences, Hangzhou, P.R. China*

*E-mail Address of Presenting Author: longlizhi@tricaas.com

**ABSTRACT**

Phosphorus (P) limitation in acid soils leads to high dependency on mineral fertilizers, resulting in low P-use efficiency. Although organic sources offer a sustainable alternative, how their utilization is governed by the interplay between plant genotype and the rhizosphere microbiome remains poorly understood. *Camellia sinensis* is typically grown on acid soils that readily fix phosphorus, and genotypes vary considerably in their phosphorus use traits. We characterized cultivar-specific P acquisition strategies by growing an albino 'Huangjinya' (HJY) and a green-leaf 'Longjing 43' (LJ43) in P-deficient soil under three fertilization treatments: no P (CK), mineral P (Pm), or organic P (Po). A comprehensive dataset was generated, including plant P accumulation, root morphology, soil chemical properties, rhizosphere metabolites, and the microbial community's structure and function, to elucidate genotype-specific acquisition mechanisms.

Organic phosphorus (Po) substitution significantly boosted shoot P accumulation in both tea cultivars relative to the no-P control (CK), with performance comparable or superior to mineral P (Pm) application, while shoot biomass remained consistent across treatments. Under Po amendment, HJY markedly increased the availability of soil P, alongside elevating soil organic carbon and total nitrogen concentration. In contrast, LJ showed a minimal response in soil available P but exhibited a pronounced increase in root length and surface area. Notably, root morphological traits were negatively correlated with shoot P concentration in HJY, a relationship absent in LJ. These divergent responses indicate cultivar-specific P-acquisition strategies: rhizosphere-driven solubilization in HJY versus root proliferation-based exploitation in LJ.

The rhizosphere microbiome was reconfigured by organic P fertilization in a genotype-specific manner. Po fertilization in HJY restructured bacterial and fungal communities, enriching bacterial metabolic pathways for carbohydrate, nucleotide, glycan, and cofactor metabolism. These pathways correlated positively with soil available P (SAP). We identified succinic acid as a key metabolite, specifically elevated by Po in HJY and uniquely correlated with SAP, SOC, and TN. Network analysis indicated greater complexity in HJY, associating the Po-enriched fungus *Rhizopus* and putative P-solubilizing bacteria (e.g., *Arthrobacter, Mesorhizobium, Acidibacter*) with succinic acid and available P. In contrast to HJY, the green-leaf cultivar LJ exhibited stable bacterial functions but enriched fungal guilds (e.g., mycorrhizal and saprotrophic fungi) and the *Burkholderia–Caballeronia–Paraburkholderia* cluster, which correlated with root growth. Our results demonstrate that organic P can effectively substitute for mineral P in tea cultivation, with efficiency governed by distinct genotype-specific rhizosphere processes: a solubility-based strategy in HJY versus a root foraging-based strategy in LJ.

We demonstrate that plant genotype dictates the recruitment of specific rhizosphere consortia, which deploy complementary P-acquisition strategies through functional microbiome-metabolome interactions. This finding challenges the view of universal fertilizer efficacy, showing it is instead co-determined by plant genetics and the microbiome. Thus, integrating host genotype and microbial traits into agriculture is essential for developing precised fertilization strategies that enhance nutrient efficiency and reduce environmental impact.

# Diversified cropping systems with complementary root growth strategies improve crop adaptation to and remediation of hostile soils

**ABSTRACT**

Hostile soil conditions have a global impact on crop production. While root traits of individual plant species adapted to specific hostile soils are well studied, a comprehensive synthesis of how to use diversified cropping systems with complementary root growth strategies to adapt to and remediate hostile soils is lacking. We begin by providing definitions, categorizations, and global distribution of hostile soils, followed by a synthesis of recent advances in below-ground niche complementarity or facilitative root interactions among crop species in diverse cropping systems across various hostile soils. Lastly, we highlight the significance of cultivating a robust understanding of root adaptations for crop diversification in hostile soils for future research. Diversified cropping systems that incorporate complementary root growth strategies can efficiently utilize nutrients and mitigate abiotic stress in hostile soils, such as nutrient deficiency, aridity, and waterlogging conditions. Furthermore, intercropping hyperaccumulator plants or halophytes with crops is effective in reducing metal or salt accumulation in target crops grown in contaminated or saline-alkali soils, respectively. Cover crops could create biopores for succeeding crop roots in compacted soils, while diversified cropping systems aid in preventing additional soil erosion in eroded areas. Leveraging diverse root traits can also contribute to the suppression of soil-borne diseases and pests within intercropping setups. Enhancing diversified cropping systems necessitates the application of novel methods and technologies for root studies. This multifaceted approach is crucial for sustaining yield under the challenges posed by multiple hostile soil conditions, especially within the context of climate change.

**ABSTRACT**

Mycorrhizal symbioses are pervasive interkingdom interactions established between land plants and soil fungi. Among them, the association between plants and arbuscular mycorrhizal (AM) fungi is well acknowledged for its dramatic impacts on plant performance and ecosystem functioning. Only recently, AM fungi-associated bacteria have been identified as cooperative actors which participate in the two-partner symbiosis; the bacteria which colonize the hyphosphere (the thin soil area surrounding the extraradical hyphae) are named hyphospheric bacteria to distinguish them from bacteria living inside the AM hyphae. We develop the novel concept of plants-AM fungi-bacteria (PAMFB) continuum to summarize the current advances and discuss future perspectives in soil microbiology. First, we describe the top-down carbon flow and the bottom-up mineral (especially phosphorus and nitrogen) flow in the PAMFB continuum as well as how AM fungi-bacteria interaction influences biogeochemical cycling of nutrients (e.g., carbon, phosphorus and nitrogen). Second, we discuss how AM fungi interact with hyphospheric bacteria or endobacteria to regulate the nutrient exchanges between plants and AM fungi, and the possible molecular mechanisms underpinning this continuum. We focus on future perspectives for studies on the hyphosphere to facilitate applications of AM fungi and hyphospheric bacteria in the current context of sustainable agriculture. We present the most recent advances in our understanding of how plants, AM fungi, and their associated bacteria exchange host plant–derived C and soil-derived minerals. These exchanges provide energy to the heterotrophic partners and economically convenient nutrients to plants.

**ABSTRACT**

Legume-grass intercropping is considered a planting system that improves crop nutrient use efficiency; however, the contribution of returned straw to crop nutrient uptake in such intercropping systems remains unclear. The study employed a field frame experiment to quantify nitrogen utilization rates of maize straw by subsequent crops, traced using $^{15}$N-labeled maize straw incorporated into the soil, and integrated metagenomic sequencing to identify key driving microorganisms. In a field frame experiment, five kinds of straw incorporated into soil treatments were designed: maize straw alone (M), 2:1 mixture of soybean and maize straw (2MS), 1:1 mixture of soybean and maize straw (MS), soybean straw alone (S), and without straw (CN). Each returning patterns were set with three kinds of planting patterns: monocropping maize (M), intercropping maize/soybean (IM/IS), and monocropping soybean (S). Compared with the M treatment, the average utilization rate of maize straw $^{15}$N by maize grains in the MS and 2MS treatments was significantly increased by 1.7 times and 1.2 times, respectively; the MS treatment was significantly increased by 3.7 times in soybean grains. Compared with monocropping, under the M, 2MS, and MS treatments, the average utilization rate of maize straw $^{15}$N by maize grains increased by 100.20%, 82.53% and 74.86% respectively, after intercropping. Compared with other returning patterns, the soil bacteria and fungi diversity in the MS treatment was significantly increased. Furthermore, intercropping significantly increased the abundance of *Rubrobacter* and *Entrophospora* and enhanced the abundance of *glnA* and *GLIL* in the soil. This led to an acceleration of the nitrogen cycling rate in the soil and an increase in the utilization rate of maize straw $^{15}$N by grains. Moreover, intercropping can directly promote denitrification, indirectly promoting nitrogen transport and organic nitrogen metabolism processes, thereby accelerating the inorganic Phosphorus solubilization and organic Phosphorus mineralization, and ultimately accelerating the polyphosphate synthesis. The results indicate that intercropping facilitates the return of combined crop straws, which enhances the combined straw decomposition effect and strengthens the selection and complementarity effects of underground microorganisms. This mechanism effectively promotes crop uptake of returned maize straw, thereby improving soil N-P coupling capacity and maintaining the productivity and stability of the system.

## ABSTRACT

How plant genotypes shape their rhizosphere microbial communities and jointly influence phenotypes is a core issue in the field of plant-microbe interactions. This study aims to systematically analyze the influence of soybean host genotypes on the structure of rhizosphere bacterial communities and quantify the relative and synergistic contributions of genotypes and microbial communities to key agronomic trait variations. Using 176 soybean varieties as materials, this study employed a strategy combining multi-omics and statistical modeling: 1) Analyzing the correlation between host genetic distance and microbial community Bray-Curtis distance through Mantel test; 2) Calculating the heritability ($H^2$) of bacteria at different taxonomic levels (phylum to genus) to assess host dependence; 3) Constructing linear models based on SNP (Single Nucleotide Polymorphism), based on genetic marker ASV (Amplicon Sequence Variant), and their combination, and evaluating their phenotypic variance explanation rates for traits such as plant height, number of main stem nodes, number of branches, hundred-grain weight, and seed yield per plant through cross-validation. The main results show that host genetic distance is significantly positively correlated with the similarity of rhizosphere bacterial communities (r=0.083, p=0.013). The bacterial heritability shows hierarchical dependence, with the highest at the genus level ($H^2$= 0.452), and core bacterial genera such as *Geodermatophilus* exhibit strong host dependence. The average explanatory rate of the genotype model for five traits is 31.74%, while the average explanatory rate of the rhizosphere genetic marker bacterial model is higher (44.53%). Among them, the bacterial explanation rate for the number of main stem nodes is as high as 69.24%. The combined model of genotype and microbial community has an average explanation rate of 66.64%, which is significantly higher than either of the individual models, indicating a synergistic effect and joint shaping of phenotypes. Through microbial community association analysis, 359 genetic marker ASVs related to traits were identified. Among them, *Pseudomonas* and *Bacillus*, which have high heritability and multi-trait association, were determined as key candidate functional genera. This study demonstrates that host genotypes can specifically recruit rhizosphere bacteria, especially a group of core functional bacteria with high heritability, and interact with these microorganisms, jointly explaining most of the variation in soybean agronomic traits. This provides empirical evidence for the regulatory path from "host genotype→rhizosphere microbial community→plant phenotype" and identifies *Pseudomonas* and *Bacillus* as key targets for subsequent microbial community-assisted breeding and functional validation.

**Key words:** Host genotype, Root-associated bacterial community, Phenotypic variation, Microbiome-assisted breeding

**Genetic variability of root-associated bacteria in different genotypes of soybeans**

**Figure 1. a Bacterial heritability across taxonomic levels. b Top 10 core bacterial genera ranked by heritability.**

Bacterial heritability shows a hierarchical dependence at different taxonomic levels, indicating that the host genotype has limited influence on higher-level communities, but has a significant regulatory effect on specific core bacterial communities. At the phylum level, the heritability of *Acidobacteria* is the highest ($H^2$=0.2409); at the family and genus levels, bacterial communities such as *Geodermatophilaceae* ($H^2$=0.3403) and *Geodermatophilus* ($H^2$=0.452) exhibit strong host dependence, while various known beneficial and stress-resistant functional bacteria such as *Pseudomonas* and *Sphingomonas* also have moderate heritability, suggesting that the host genotype can selectively recruit bacterial groups related to metabolic adaptation, forming a rhizosphere microbial community with genotype characteristics.

**Association patterns between host genotype and rhizosphere bacterial community structure**

**igure 2. Association between host genetic relationships and rhizosphere bacterial genetic patterns**

To investigate the influence of soybean host genotype on rhizosphere microbial community structure, a Mantel test was performed to assess the relationship between host genetic distance and microbial community Bray-Curtis dissimilarity. The results revealed a significant positive correlation between host genetic distance and the Bray-Curtis distance of rhizosphere bacterial communities (r=0.083, p=0.013), indicating that genetically similar soybean cultivars more similar rhizosphere bacterial community compositions. These findings demonstrate that host genotype exerts a significant influence on the structure of rhizosphere bacterial communities.

**Effects of genotype-rhizosphere bacterial community covariation on agronomic traits**

**Figure 3. Contribution of rhizosphere bacteria to phenotypic prediction**

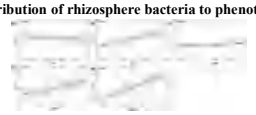

**Figure 4. Simulated effects of genetic and microbiome variation on agronomic traits**

To elucidate the contribution of genetic variation to the formation of key agronomic traits, we first constructed linear regression models to evaluate the effects of host genotype on major growth traits (plant height, number of main stem nodes, and branch number) and yield-related traits (hundred-grain weight and Seed yield per plant) across 176 soybean cultivars. Using thirty rounds of five-fold cross-validation, SNP-based models explained, on average, 31.97%, 24.64%, 57.27%, 34.25%, and 10.59% of the phenotypic variance in plant height, number of main stem nodes, branch number, hundred-grain weight, and single-plant yield in the test sets, respectively (Figure 3).Given that rhizosphere microorganisms have been shown to enhance plant stress tolerance and promote growth and yield formation, we further assessed the contribution of the rhizosphere microbiome to trait variation. Amplicon sequence variants (ASVs) with a prevalence≥90% across all samples and a relative abundance>0 were selected as candidate features to construct rhizosphere bacterial predictive models, which were evaluated using the same thirty rounds of five-fold cross-validation. The results showed that genetically tagged rhizosphere bacteria explained 49.49%, 69.24%, 33.69%, 47.70%, and 22.52% of the phenotypic variance in plant height, number of main stem nodes, branch number, hundred-grain weight and seed yield per plant, respectively. To further disentangle the synergistic effects between host genotype and the rhizosphere bacterial community, candidate SNPs and candidate ASVs were jointly incorporated into linear mixed models to assess their integrated contribution to phenotypic variation. The combined models explained 68.70%, 80.77%, 75.24%, 74.56%, and 33.91% of the phenotypic variance in plant height, number of main stem nodes, branch number, hundred-grain weight, and seed yield per plant, respectively (Figure 4). Overall, the combined genotype-rhizosphere microbiome models significantly outperformed models based on either host genotype or rhizosphere bacteria alone.

**Rhizosphere genetically tagged bacteria associated with soybean agronomic traits**

**Figure 5. The 359 genetically tagged bacteria associated with soybean agronomic traits**

Through microbiome association analysis, a total of 359 genetically tagged ASVs significantly associated with agronomic traits were identified within the bacterial community, predominantly belonging to 11 phyla and 89 genera. The most abundant phyla were *Proteobacteria*, *Actinobacteria*, *Firmicutes*, *Bacteroidetes*, and *Planctomycetes*. Among the highly heritable key genera, *Geodermatophilus* ($H^2$=0.4520), Acidiphilium ($H^2$= 0.2002), *Pseudomonas* ($H^2$=0.1842), *Bacillus* ($H^2$=0.1628), and *Carnobacterium* ($H^2$=0.1563) showed close associations with soybean agronomic traits. Notably, *Pseudomonas* and *Bacillus* were significantly associated with key traits such as plant height and yield. Based on their high heritability, strong trait associations, and potential predictive capacity, *Pseudomonas* and *Bacillus* were selected as core candidate genera for subsequent functional validation.

**Conclusion**

Soybean host genotype significantly shapes rhizosphere bacterial community structure, with host genetic distance positively correlated with bacterial community similarity, indicating a clear host genotype dependency of the rhizosphere microbiome. The host dependency of rhizosphere bacteria exhibits a pronounced hierarchical pattern across taxonomic levels, with the highest heritability observed at the genus level. Core genera such as *Geodermatophilus* display high heritability, suggesting that host genotype primarily influences the rhizosphere microbiome by modulating specific core functional taxa. Host genotype and the rhizosphere microbiome jointly exert a significant synergistic effect on the variation of key soybean agronomic traits, with combined models explaining a substantially higher proportion of phenotypic variance than models based on either factor alone. Notably, *Pseudomonas* and *Bacillus*, characterized by high heritability and multi-trait associations, serve as key functional taxa and act as critical regulatory hubs connecting the “host genotype–rhizosphere microbiome–plant phenotype” pathway.

**ABSTRACT**

Global production of high-yielding, nutritious crops depends upon judicious application of fertilizers to meet crop demands and replenish soil nutrient reserves. Ideally, this approach should maintain soil fertility and food security. In reality, incomplete nutrient use by crops and nutrient loss from soils is responsible for inefficient nutrient cycling in agroecosystems. Here, we discuss the design of closed loop crop systems with an optimized internal nutrient recycling process. The key characteristic of these designed crop systems is high nutrient retention in the plant and soil compartments, which requires an efficient nutrient flux between physicochemical and biological pathways. The physicochemical reactions for nutrient retention involve sorption on reactive soil surfaces, as well as nutrient occlusion and precipitation with soil organo-minerals, including aggregates. On the biological side, the nutrient transfers are mediated by roots and their rhizobiome partners. Roots and their rhizobiome, which include root-associated and endophytic microorganisms, produce and respond to chemical signals. This cross-talk involves the exchange of hundreds of metabolites that alter plant growth, development and nutrient acquisition at the genetic, cellular, physiological and morphological levels. This allows the root-rhizobiome partners to engineer their shared rhizosphere and optimize nutrient transfers for their joint benefit. We will discuss how these fundamental partnerships can inform soil management in designing closed loop crop systems with enhanced nutrient use efficiency.

**ABSTRACT**

Soil calcareousness is the major growth limiting factor in many arid and semiarid regions, which naturally limits plant growth and yield due to poor soil organic matter, deficient nutrient availability and high pH. On the other hand, fixation of nutrients in calcareous soils is an inevitable problem that corresponds to very low use efficiency of applied fertilizer nutrients due to various chemical reactions like precipitation, fixation and adsorption (Chitdeshwari&Brindhavani,2023, Rukmani *et al.,* 2023). In this context, evaluating the inherent potentials of the crop genotypes for calcite dissolution potentials and nutrient efficiency is essential to avoid crop loss and to reduce cost of fertiliser inputs.Hence a set of greenhouse screening experiments were conducted with ten groundnut genotypes viz., CO 6, CO 7, TMV 2, TMV 10, TMV 13, TMV 14, VRI 7, VRI 8, ALR 2 & BSR 2 to assess the phosphorus (P), Zinc (Zn) and Iron (Fe) efficiency and their calcite dissolution potentials on calcareous soils having the free $CaCO_3$ content of <5, 5-10, 10-15, 15-20 and > 20%. The experiment was conducted on a factorially completely randomised block design with three replications for 45 days and harvested. The plant growth attributes, dry matter production, nutrient availability, content and uptake were estimated and reported. The nutrient efficiency of genotypes and their calcite dissolution potentials were also computed to screen the tolerant crop varieties suitable for calcareous soils.

Increasing soil calcareousness reduced the growth,dry matter production, nutrient availability, absorption and utilisationwhich varied widely with the groundnut genotypes. Further omission of P, Zn and Fe in the fertiliser schedule considerably reduced the growth attributes of all the groundnut genotypes by 40-50%. Among the ten genotypes tested on five different calcareous soils, the genotype CO 6 recorded higher plant height, root length and SPAD index in both nutrient omitted and supplied pots which was followed by CO7 and TMV 10. Lesser growth attributes were noted with BSR 2 and ALR 2 genotypes indicating their sensitiveness to soil calcareousness. Similar to growth attributes, the dry matter production of the groundnut genotypes also showed greater reduction with increasing soil calcareousness which varied from 18.8 to 43%, 46 to 48 %, 40-50% for skipping P, Zn and Fe respectively. Increasing calcareousness reduced the DMP of all genotypes and the impact was lesser with CO 6 > CO 7 >TMV 10 > TMV 2 > TMV 13 > VRI 8= TMV 14 > VRI 7 > ALR 2 > BSR 2.

Differential behaviour of groundnut genotypes was noticed in absorbing and utilising the applied phosphorus, zinc and iron which decreased with increasing soil calcareousness. Higher nutrient absorption and uptake was noted with CO 6 followed by CO 7 in all the calcareous soils. Lesser nutrient content and uptake was observed with BSR 2, VRI 7 and TMV 13.The greenness index of the genotypes is the indicator of photosynthetic efficiency which decreased markedly with increasing soil calcareousness. Higher greenness index was registered with CO 6 (0.87 to 0.98) and CO 7 (0.85 to 0.93) and the lowest index was observed with BSR2 (0.70 to 0.78). The DMP efficiency was also reduced significantly with increasing soil calcareousness and better efficiency was noticed withCO 7 (76.5 to 80.6%), CO6 (73.2 to 82.1%) and TMV 10 (75.4 to 77.4%). Lesser DMP efficiency was registered in ALR 2 (58.8 to 64.5%) followed by BSR 2 (64.3 to 71.8%).With regard to nutrient absorption and utilisation efficiency by the genotypes, higher P, Zn& Fe absorption and utilisation efficiency was recorded with CO 7 > CO 6 =TMV 10 and the values varied from 75.5 to 89.9%, 75.5 to 89.1% and 73 .3 to 83% respectively. The lowest nutrient absorption and utilisation efficiency was registered with BSR 2 (53.2 to 77%.

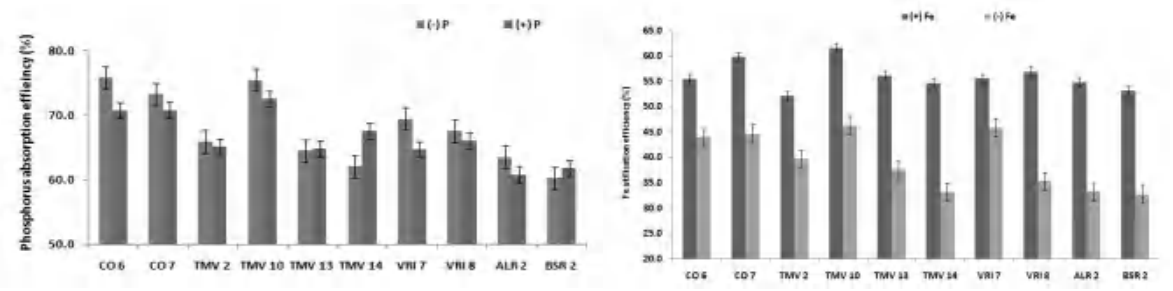

*Fig. 1. Phosphorus absorption and Fe Utilisation efficiency of groundnut genotypes*

To conclude, the groundnut genotypes CO6, CO7, and TMV 10 were found to be efficient in tolerating the soil calcareousness upto 12.5% and possess higher P, Zn, Fe efficiency to grow on calcareous soils which was well correlated with the higher amount of phytosiderophore production, rhizosphere acidification and calcite dissolution hence forwarded for further field studies.

**ABSTRACT**

Sweet potato, a potassium (K) -favoring crop, strongly relies on arbuscular mycorrhizal fungi (AMF) symbiosis for K nutrition. However, the interactive effects of soil K availability and AMF inoculation on plant performance and rhizosphere microecology of sweet potato remain unclear. We integrated plant growth, nutrient uptake, root exudate metabolomics, and bacterial community profiling to elucidate the regulatory roles of soil K and AMF, and to identified shared and differential strategies under contrasting K levels. Soil K availability dominated rhizosphere microecology remodeling, enriched Chloroflexi, Methylomirabilota, Desulfobacterota, Latescibacterota, Nitrospirota, MBNT15, and NB1j involved in carbon, nitrogen, and sulfur cycling, and simultaneously upregulated signal transduction, primary and secondary metabolic pathways, thereby enhancing root growth and defense capacity. Whereas, AMF fine-tuned rhizosphere microecology and played a central role in improving root growth and nitrogen, phosphorus, and K uptake of sweet potato. In low-K soil, AMF primarily enhanced root growth and nutrient uptake (especially more K uptake), supporting plant adaptation to low-K condition and enriching beneficial microbes like *Haliangium*. Conversely, in high-K soil, AMF further promoted whole plant growth and nutrient uptake (especially more P uptake), while modulating root exudates to optimize resource allocation. Across both K levels, AMF consistently activated auxin biosynthesis, and enriched Planctomycetota via root exudates (indole-2-carboxylic acid, L-arabitol, tropic acid), thereby promoting root growth and nutrient uptake. AMF-mediated adaptation exhibited soil K-dependent plasticity, adopting stress adaptation in low-K and growth optimization in high-K soils. By integrating nutrient uptake, metabolic reprogramming, and microbial enrichment, AMF improved sweet potato adaptability and performance, providing a theoretical basis for AMF inoculation combined with targeted K management.

**ABSTRACT**

Significant intraspecific variation exists among sweet potato genotypes in potassium (K) uptake, utilization efficiency (KIUE), and growth response to varying K supplies. Field screening identified genotypes such as Xu28 and Wan5 as K-efficient genotypes, and Ji22 as K-inefficient genotype. K-efficient genotypes demonstrate superior K accumulation dynamics, characterized by peak uptake during early growth stages under deficiency and effective partitioning and redistribution of K at maturity, leading to higher root: shoot K ratios and reduced K concentration in roots at harvest. KIUE is negatively correlated with whole-plant K concentration but positively linked to the K harvest index and relative root growth from the expanding stage to maturity, rather than directly with total root dry matter yield. The interaction between K availability and arbuscular mycorrhizal fungi (AMF) critically modulates root morphology, nutrient uptake, and plant performance. AMF inoculation, particularly with *Claroideoglomus etunicatum*, synergizes with K application to optimize root architecture (e.g., increasing root tip number, length, and surface area) in high-KIUE genotypes like Xu28. This synergy enhances dry matter allocation to roots and promotes root K accumulation while limiting excessive aboveground K allocation. Soil K availability dictates rhizosphere microecology remodeling, enriching microbial taxa involved in nutrient cycling. AMF further fine-tunes this environment, enhancing plant adaptation to low-K stress by boosting K uptake and enriching beneficial microbes (e.g., *Haliangium*), while under high-K conditions, AMF prioritizes phosphorus uptake and growth optimization. Consistently, AMF activates auxin biosynthesis and enriches phyla like Planctomycetota via specific root exudates, promoting root development and nutrient acquisition across K regimes. In conclusion, achieving high K-use efficiency in sweet potato involves a complex interplay of genotypic selection for optimal K partitioning and redistribution, coupled with strategic AMF inoculation that tailors root morphology and rhizosphere microbial communities in a K-dependent manner. This integrated approach provides a theoretical foundation for improving sweet potato cultivation through genotype selection and synergistic nutrient-microbe management.

## ABSTRACT

Being a raw material for P-fertilizers, insoluble phosphate rock (PR) is less available for plants, unless with arbuscular mycorrhizal (AM) helpers. This also occurs in arsenic (As) hyperaccumulator *Pteris vittata*, yet the underlying mechanisms behind mycorrhizal P acquisition and As accumulation remain unclear. Using PR as the sole P source and *Rhizophagus irregularis* inoculation in a sand-culture system, As exposure at 10 and 100 μM accentuated mycorrhizal colonization and responsiveness of growth and P uptake compared to no-As control. We further investigated mycorrhizal associated trade-offs and P-transporter expressions in *P. vittata* symbiont after growing for 60-day in a contaminated soil containing 75 mg $kg^{-1}$ As, and 1% mass ratio of AM inoculum and/or PR addition. Compared to the PR-alone addition, *P. vittata* biomass and frond P content were rose by 15−26%, while As accumulation in the fronds was increased by 70% to 1190 mg $kg^{-1}$ in the AM+PR treatment. Following lower allocation of root biomass and exudation (6−8%), mycorrhizal *P. vittata* probably activated a scavenging strategy in P and As acquisition, resulting in their 15−29% depletion of available contents in the rhizosphere. As evidences, AM symbiosis upregulated inherent *PvPht1;3* by 2.0-folds in *P. vittata* roots. Whereas PR enhanced gene expressions of *RiPT1* in AM fungi (2.7-folds) and *PvPht1;6* in *P. vittata* symbiont (2.2-folds), corresponding to the 15% greater hyphal density in the AM+PR compared to AM treatment. By linking mycorrhizal traits to *P. vittata* uptake of P and As, this study provides valuable strategies for As-phytoremediation.

**Keywords:** *Rhizophagus irregularis*, mycorrhizal responsiveness, AM colonization and hyphal density, root biomass and exudation, inherent *PvPht1;3* and symbiotic *PvPht1;6* P-transporters

# Bioprospecting soil bacteria to increase sulfate release from elemental sulfur in tropical soil

**Fernanda Miotti [*1], Gladys Angélica Apaza-Castillo[2], Ana Paula Bettoni Teles[1], Guilherme Kenichi Hosaka[2], Pedro Henrique Pedron Mattiuzzi [2], Maria Carolina Quecine[2], Tiago Tezotto[1]**

*fernanda.miotti@usp.br

**ABSTRACT**

Given the increasing sulfur (S) deficiency in tropical soils, mainly due to reduced atmospheric deposition and the growing use of S-free fertilizers, and considering that soil S cycling is largely mediated by specialized microorganisms, it is necessary to investigate microbial strategies that improve S availability to plants. Thus, we aimed the isolation, characterization and selection of bacterial strains able to oxidize elemental sulfur (ES) and make it available in soil as sulfate ($SO_4^{-2}$,). First, eight soil with different residual concentration of S were sampled and incubated for 15 days to enrichment of S-oxidizing strain in a sodium thiosulfate medium. From 44 obtained isolates, four high-performing strains were selected and identified as belonging to the genus *Thiomonas* based on 16S rRNA gene sequencing. After, a destructive soil incubation experiment was conducted in a completely randomized design arranged as a 6 × 4 factorial (treatment × time), with four replicates per combination (n = 96). Treatments were: control without $S^0$ (C), $S^0$ without inoculation ($S^0$), and $S^0$ inoculated with strains S02B1-R3 (T1), S01B5-R1 (T2), S01B1-R3 (T3), or S01B4-R2 (T4). Elemental S was applied at 3 mg $kg^{-1}$ to a dystrophic Oxisol (medium texture, low fertility). A common baseline at day 0 was obtained from the characterization of the soil used. Samples were collected at 10, 20, 40 and 60 days, and sulfate was extracted with calcium phosphate and quantified as $SO_4^{-2}$ (mg $kg^{-1}$). Were observed that sulfate accumulation was affected by treatment, time and their interaction, evidencing time-dependent inoculant effects. The control remained at background levels throughout. $S^0$ showed progressive $SO_4^{-2}$ accumulation, confirming basal oxidation. Inoculation enhanced ES oxidation in specific windows: at 10 days, T2 and T4 produced significantly more sulfate than $S^0$; at 20 days, T2 exceeded $S^0$; at 40 days, T1 and T4 exceeded $S^0$. By 60 days, T1 oxidized about two times more ES than the non-inoculated $S^0$ treatment, indicating a clear increase in the oxidation rate. Overall, bacterial inoculation can accelerate ES oxidation, but performance is strongly time-dependent, while demonstrating that selected bacterial strains can increase the oxidation rate of ES, making them a sustainable alternative for supplying S to crops.

## ABSTRACT

**Background**
Rhizosphere pH is a key determinant of soil phosphorus (P) availability. However, how different nitrogen (N) forms shape the root-segment-specific rhizosphere pH over space and time, and thereby regulate P mobilization and uptake along growing roots remains poorly understood.
**Objectives**
This study aimed to elucidate how N forms regulate pH dynamics in the rhizosphere and to clarify the mechanisms by which these rhizosphere pH influence P mobilization and root P acquisition.
**Methods**
Non-invasive micro-test technology (NMT) and diffusion gradient technique in thin films (DGT) were combined in hydroponics and rhizo-box experiments to quantify rhizosphere pH regulation by different N forms and its contribution to the activation and uptake of distinct P sources.
Experiment 1 (Hydroponics):
Ion fluxes of maize roots were measured using NMT, and P uptake rates of root segments were quantified with a collection device under three N treatments: ammonium (A), ammonium–nitrate mixture (AN), and nitrate (N).
Experiment 2 (rhizo-box):
A factorial design combining two N forms (A and AN) and three P treatments (no P, $KH_2PO_4$, and sodium phytate) was used to visualize root-segment-specific P mobilization using DGT imaging.
**Results**
Distinct root-segment-specific pH microenvironments developed under different N forms. Ammonium nutrition induced pronounced acidification at the root apex-up to 0.4 pH units lower than basal root regions (Fig. 1). DGT imaging showed strong spatial heterogeneous in P mobilization along the root apex. Among treatments, A+KDP markedly enhanced single-root DGT-P flux, increasing it by 1.1-35.4 fold relative to other treatments (Fig. 2).

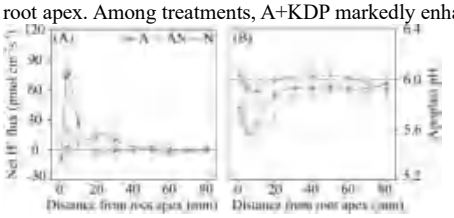

**Fig. 1** $H^+$ flux and apoplast pH in different root segments. Positive on the y-axis = net outflow; negative = net inflow.

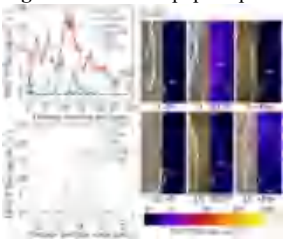

**Fig. 2** Rhizosphere DGT-P fluxes. White arrows mark the positions of transverse line scans; longitudinal profiles extend from the arrow to 30 mm.

**Conclusions**
Ammonium-induced $H^+$ release led to strong acidification at the root apex, yet maximal P uptake occurred in basal root regions characterized by moderate acidification rather than extreme pH reduction. These findings demonstrate that N form regulates P acquisition not simply through rhizosphere acidification, but via the root-segment-specific rhizosphere pH that differentially control P mobilization and uptake. (Fig. 3).

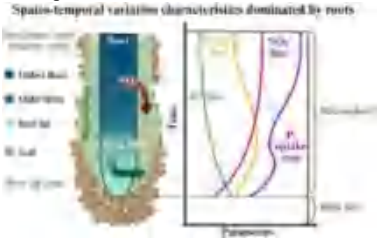

**Fig. 3** Conceptual model. Red arrow represents zones with higher $NO_3^-$ release compared to other root segments; green arrow: higher $H^+$ and $NH_4^+$ release.

**ABSTRACT**

Intercropping, as a classic sustainable agricultural practice, has attracted widespread attention for its potential to improve nitrogen use efficiency (NUE) and crop productivity. However, a comprehensive and mechanistic understanding of the underlying N acquisition and allocation processes and its drivers in intercropping remain poorly quantified at the global scale. Here, we conducted a global meta-analysis by synthesizing 786 data records from 97 peer-reviewed studies related to N dynamics in intercrops and showed that intercropping globally accumulated an additional 25.55 ~ 39.37 kg N·ha$^{-1}$, while reducing land requirement by 22.48% ~ 23.31% for equivalent N uptake compared with sole crops. The additional N uptake can be amplified by adopting maize/legume strip intercropping, increasing N input and raising planting density. Intercropping did not lower the N harvest index and N concentration of species in intercropping compared to sole cropping, indicating all extra acquired N was channeled into biomass and yield gains without decreasing the grain quality. Our findings confirm that intercropping is a sustainable agricultural practice for safeguarding food security and increasing NUE without compromising yield quality, particularly in maize/legume strip intercropping systems under optimized N input and planting density regimes.

# Mild to moderate drought stress reinforces the role of functional microbiome in promoting growth of a dominant forage species (Neopallasia pectinata) in desert steppe

**Zhenzhen Huang [1*], Hui Gao [1], and Haigang Li [1]**

[1] *Inner Mongolia Key Laboratory of Soil Quality and Nutrient Resources, Key Laboratory of Agricultural Ecological Security and Green Development at Universities of Inner Mongolia Autonomous Region, College of Grassland, Resources and Environment, Inner Mongolia Agricultural University, Hohhot, Inner Mongolia, China.*

*E-mail Address: huangzz628@163.com

**ABSTRACT**

Desert steppe ecosystems are prone to drought stress, which influences the ecological balance and sustainable development of grasslands. In addition to directly restrict plant growth, drought stress indirectly impacts plant fitness by altering the diversity and function of root-associated microbiomes. This begs the question of whether the functional microbiome of forage plants, represented by synthetic microbial communities (SynComs), can be leveraged to mitigate drought stress in desert steppes and promote the ecological restoration of these fragile ecosystems. A pot experiment was conducted to evaluate the role of SynComs in improving the plant growth and drought stress resistance of *Neopallasia pectinata* (Palt.) Poljak in desert steppe in Inner Mongolia, China. Six SynComs were derived from the rhizosphere and root endosphere of 12 dominant forage species in the desert steppe. Each SynCom comprised two to three bacterial genera (*Bacillus*, *Protomicromonospora*, and *Streptomyces*). We examined the capacities of different SynComs for nutrient solubilization, phytohormone secretion, and enzymatic activity. Under no water stress (75% soil water holding capacity, WHC), single strains performed better than SynComs in promoting plant growth in terms of stem diameter, root length, and plant dry weight, with the greatest effects observed for *Streptomyces coeruleorubidus* ATCC 13740 ($P<0.05$). However, under mild to moderate drought stress (55% and 35% WHC), SynComs outperformed single strains in enhancing plant biomass accumulation and inducing the production of resistance-related substances ($P<0.05$). No significant effect of single strains and SynComs emerged under extreme drought stress (20% WHC). This study underscores the potential of SynComs in facilitating forage plants to combat drought stress in the desert steppe. Mild to moderate drought stress stimulates SynComs to benefit the growth of *N. pectinata* plants, despite a soil moisture threshold (21% WHC) exists for the microbial effect. The use of SynComs provides a promising strategy for the ecological restoration and sustainable utilization of desert steppes by manipulating the functional microbiome of forage plants.

**ABSTRACT**

Microbial-mediated soil phosphorus (P) mobilization and immobilization processes directly and strongly influence the soil available P pool and plant P uptake. A quantitative description of the microbial-mediated soil P mobilization or immobilization driven by soil carbon (C):P stoichiometry change is a critical task in soil science. We hypothesis that microbial-mediated P mobilization and immobilization will decrease but microbial biomass P (MBP) turnover will increase as soil C:P ratio decreases. In this study, we verified the quantitative relationship between soil C:P ratio and microbial-mediated P mobilization, immobilization, and MBP turnover fluxes by a $^{32}$P-labelling experiment with decreased soil C:P ratio gradients. The results showed that microbial-mediated gross P immobilization was reduced by 54% with decreasing soil C:P ratio, while gross and net P mobilization and MBP turnover were increased by 141%, 252%, and 790%. We verified that declines in the soil C:P ratio decreased microbial-mediated gross P immobilization but increased gross and net P mobilization and subsequently enhanced P bioavailability. Our results provided an ecological intensification opportunity by which soil microbial activity and P fluxes can be quantitatively manipulated by altering the C:P ratio in calcareous soil.

## ABSTRACT

Drained peatlands used for agriculture are hotspots of nitrous oxide ($N_2O$) emissions, yet national greenhouse gas inventories often rely on default IPCC emission factors (EFs), which carry large uncertainties. In Ireland, where over 95 % of its ~20 % peatland cover has been degraded, there is a critical need for country-specific EFs to improve reporting accuracy and inform mitigation strategies. This study aims to quantify the impact of nitrogen (N) inputs and water table depth (WTD) on $N_2O$ fluxes from managed grasslands on peat soil, and to derive Irish-specific Tier 2 EFs.

The aim of this study was to assess the impact of agricultural management practices including N amendment and WTD management on $N_2O$ emission from agricultural grass-based peat soil and to contribute to the derivation of Irish-specific Tier 2 EFs. The experiment was conducted at two different peat soil sites on grassland in the Irish midlands (TB and CR). Each site included plots with contrasting water regimes (a drier and a wetter side) to represent different WTD conditions. Four treatments were applied to the soil in a fully randomized block design: control (C), calcium ammonium nitrate (CAN) fertilizer, sheep urine (SU), and cattle urine (CU). The C and CAN treatments were applied in spring, while SU and CU treatments were applied across three growing seasons. $N_2O$ fluxes were monitored continuously for three months post-application using automated chambers, with year-round monitoring on control plots. Key site-specific characteristics that drive GHG production were also monitored to serve as proxies for emissions.

Average $N_2O$ EFs ranged from 0.07% to 5.36% across all treatments and sites. While EFs were consistent across application seasons, they differed significantly between sites, underscoring the importance of site-specific conditions. Notably, EFs from urine treatments were generally lower than IPCC Tier 1 defaults (0.77% for cattle urine, 0.39% for sheep urine). A critical exception was the wetter area of the CR site, where EFs surged to 2.11–5.36%. At this location, substantial emission peaks were not only observed immediately after N application, but also during rainfall events up to two months later. This suggests that rewetted conditions, coupled with residual N, can create hot moments for $N_2O$ production, potentially via enhanced denitrification during fluctuating water tables. Our findings demonstrate that the hydrology and nutrient status of agricultural peatlands are key determinants of $N_2O$ emissions. The findings will also contribute to the development of nutrient management strategies that balance agricultural productivity with ecosystem functionality.

**ABSTRACT**

Soil phosphorus (P) activation is a global challenge and crucial for sustainable agricultural production. The coupling between water and P has been widely studied, while the response of soil P cycling to temporal variability of soil moisture and the potential biotic and abiotic mechanisms involved are largely unknown, which limits our understanding of strategies to regulate soil P availability and boost crop yield via water management. We combined metagenomics with sequential P fractionation to explore soil P cycling traits and P availability across moisture regimes with differing temporal variability. Reduced soil moisture temporal variability increased labile P but decreased moderately labile P. This shift was driven by transformations in microbial community structure and function. Lower soil moisture variability increased the abundance of P-solubilizing genes (e.g., *gcd*, *ppk*, *ppx*, *phoA*, *phoD*, and *phy*) and enriched beneficial bacterial genera such as *Sinorhizobium*, *Sphingobium*, and *Arthrobacter*. Specifically, stable soil moisture enhanced soil phosphatase activity by regulating microbial P cycling, thereby significantly promoting the conversion of organic P into available forms. Among these, the *phoA* gene and *Sinorhizobium* were identified as key predictors of labile inorganic P (Pi) during organic P mineralization. Concurrently, the increase in soil labile Pi significantly improved plant productivity and P uptake. In conclusion, this study reveals that a soil moisture stabilization strategy effectively enhances soil P availability and crop productivity, offering a pathway toward eco-friendly and sustainable P management.

# Phosphate rock and microorganisms as a sustainable alternative to soluble P fertilizers in tropical soil

**Fernanda Miotti [*1], Mikaella Meira Monteiro[1], Carlos Andrei Teza Cadeti[1], Ana Paula Bettoni Teles[1], Paulo Sergio Pavinato[1], Tiago Tezotto[1]**

*[1]Department of Soil Science, Luiz de Queiroz College of Agriculture, University of São Paulo, São Paulo, Brazil*

*fernanda.miotti@usp.br

**ABSTRACT**

The increasing demand for phosphate fertilizers in tropical agricultural systems, coupled with the global dependence on finite and externally sourced inputs, underscores the need to explore alternative phosphorus (P) sources for cultivated soils. In this context, the application of phosphate rock (PR), particularly when combined with phosphate-solubilizing microorganisms, may offer a sustainable alternative to improve P dynamics in soil–plant systems. However, the actual effectiveness of phosphate rocks and phosphate-solubilizing microorganisms in releasing P and matching the efficiency of soluble fertilizers remains poorly understood under tropical conditions. This study aimed to assess the efficiency of different P sources and the use of PSM associated with PR in improving soil P availability and maize growth. A greenhouse experiment was conducted using 5 kg pots filled with an Oxisol and supplied with 50 mg P $kg^{-1}$ of soil. Maize plants (B2782PWU) were cultivated in a completely randomized design with four replicates and nine treatments: Control (no P), Bayovar PR alone or combined with Probiom, Blindagem T, Biofree, or Biotrinsic Simplex, Bayóvar PR + phosphogypsum, single superphosphate (SSP), and triple superphosphate (TSP). Plant growth was evaluated through biometric measurements (height, stem diameter, and number of leaves) and by determining shoot and root dry matter. Nutrient accumulation in the shoot was quantified after acid digestion of plant tissue. Following harvest, soil samples were analyzed for pH, available and total P contents, and acid phosphatase activity to assess P dynamics and soil biochemical responses. At 35 days after emergence, all the P sources and microbial inoculations showed distinct effects on maize growth and soil P status. Phosphate rocks promoted maize growth comparable to soluble sources, although biomass accumulation was generally higher under TSP. The Bayovar PR showed the best agronomic response, particularly when combined with Biotrinsic Simplex, achieving shoot dry matter and P accumulation similar to SSP. All P sources increased soil available and total P relative to the control, but with Bayovar PR treatments reaching levels close to SSP and TSP. These findings indicate that, although the phosphate rock remain less efficient than soluble fertilizers in the short term, Bayovar PR demonstrated higher reactivity and greater potential for use in sustainable fertilization strategies. Future studies should focus on longer-term and field-scale assessments to clarify the residual and microbial effects on P release from phosphate rocks. Because these sources dissolve gradually, they may become more effective over time, supplying nutrients in synchrony with crop demand and contributing to sustained soil fertility. Understanding these processes is essential to confirm their agronomic efficiency and environmental advantages compared with soluble fertilizers in tropical soils.

# Phosphorus mineralization potentials of some soil amendments applied to degraded tropical Ultisol

**Nnaemeka H. Okoli, and Chioma M. Ahukaemere**

*Department of Soil Science and Technology, Federal University of Technology Owerri, Nigera*

*Email address of Presenting Author: nnaemeka.okoli@futo.edu.ng

**ABSTRACT**

Information on phosphorus (P) mineralization pattern of soil amendments is germane for proper P fertilizer management. This study was conducted to determine the phosphorus mineralization potentials of some soil amendments applied to degraded tropical Ultisol. The experiment was a 4 × 10 factorial experimental set-up fitted in a Completely Randomized Design. Treatments were soil amendments (Control, poultry manure, biosolids, and biochar) and period of incubation (0, 10, 20, 30, 40, 50, 60, 70, 80, 90 days after incubation (DAI)).The properties of both the soil amendments and the experimental soil were determined prior to the incubation experiment. Soil samples were treated with these amendments equivalent to 60 kg P ha-$^{1}$ under field capacity moisture condition and incubated for a period of 90 days. During the incubation period, soil sample was collected at 10 day interval for determination of available P. Results obtained were subjected to analysis of variance and means separated using LSD at 5% level of probability. Also, simple linear correlation analysis was employed to determine relationship between P mineralization and selected soil properties. Results showed that P mineralization varied significantly across the days of incubation and among the soil amendments. In the control soil, available P increased gradually from 10.5 to 25.8 mg kg-$^{1}$ (0 - 70 DAI), then slightly declined to 24.6 mg kg$^{-1}$ at 90 DAI. In contrast, poultry manure amended soil showed rapid rise in available P (42.8 to 67.2 mg kg$^{-1}$) from 0 – 60 DAI, then declined to 58.3 mg kg$^{-1}$ at 90 DAI whereas in biosolids amended soil, steady increase from 14.2 to 41.9 mg kg$^{-1}$ (0 – 80 DAI), stabilizing to 40.5 mg kg$^{-1}$ at 90 DAI. However, in biochar amended soil, there was continuous increase in available P (27.5 – 59.2 mg kg$^{-1}$) throughout the 90 day incubation period, indicating ability of the amendment to support long-term P supply. Results also indicated strong relationship between P availability and soil pH as well as exchangeable calcium. Conclusively, application of the soil amendments 40 - 60 days before planting is germane for optimal P availability in the acidic Ultisol.

# Biotechnological Strategies to Enhance Phosphorus Use Efficiency in Soybean/Maize Cropping Systems

**Mikaella Meira Monteiro*[1], Fernanda Miotti[1], Carlos Andrei Teza Cadeti[1], Ana Paula Bettoni Teles[1], Paulo Sergio Pavinato[1]**

[1] *PhD Student (Department of Soil Science, Luiz de Queiroz College of Agriculture, University of São Paulo, São Paulo, Brazil)*

**ABSTRACT**

The limited availability of phosphorus (P) in agricultural soils, coupled with the global dependence on highly soluble mineral fertilizers, represents one of the main constraints to food security and sustainable agricultural production. Moreover, a significant portion of the applied P rapidly becomes unavailable to plants, reducing phosphorus use efficiency (PUE). In this context, the combined use of low-solubility phosphate rocks and P-solubilizing microorganisms has emerged as a promising strategy to enhance PUE and decrease dependence on soluble fertilizers. This study evaluated the ability of P-solubilizing microorganisms to mobilize P from phosphate rock to improve PUE and crop productivity in a soybean/maize succession system established on an Oxisol in Mato Grosso, Brazil. The experiment followed a randomized block design with seven treatments and four replications: T1: control; T2: 268 kg ha$^{-1}$ Bayovar (BY); T3: BY + 0.2 L ha$^{-1}$ BiomaPhos; T4: BY + 0.4 L ha$^{-1}$ Phos UP; T5: BY + 0.4 L ha$^{-1}$ Meli-X Turbo; T6: 444 kg ha$^{-1}$ SSP; and T7: 154 kg ha$^{-1}$ MAP. P was applied at soybean sowing and topdressed in maize, while inoculants were applied five days after emergence (DAE). Plant height, stem diameter, number of leaves, grain yield, thousand-grain weight, leaf nutrient contents, and soil chemical attributes were evaluated. Soybean yield showed no statistical differences between BY and soluble P sources, regardless of microbial inoculation. At 30 DAE, BY treatments promoted plant growth and yields comparable to those obtained with soluble sources. Other growth parameters (plant height, stem diameter, number of leaves, and leaf nutrient contents) were not significantly affected by treatments. In maize, no significant yield differences were observed, although P treatments tended to outperform the control. Leaf P concentrations did not differ among treatments. All P sources increased soil available and total P contents compared with the control, with BY + Meli-X Turbo and SSP showing the highest mean values. Soil pH and exchangeable cations (Ca, Mg, and K) were also influenced, with soluble sources and BY combined with microorganisms generally showing better results than the control. Overall, the results indicate that low-solubility phosphate rocks associated with P-solubilizing microorganisms can enhance soil P availability and sustain yields comparable to soluble fertilizers. However, application methods, residual effects, and crop-specific P uptake dynamics likely influenced the responses, highlighting the importance of long-term studies under different production systems.

## ABSTRACT

Effective governance of agricultural phosphorus (P) non-point source pollution is undermined by episodic, high-magnitude export events, yet the quantitative thresholds triggering these shifts and their scale-dependent transport pathways remain poorly understood (Gao et al., 2014; Khan et al., 2025; Sun et al., 2026). Approaches to optimizing P management must account for how transport mechanisms and ecosystem functionality vary with catchment scale (Chen et al., 2025). This study investigated P export dynamics across four nested catchments (3.2–1236 ha) in a representative agricultural headwater catchment in the purple soil region of the Sichuan Basin, China (Wang et al., 2016). Employing high-frequency automated sampling during storm events (18.2–134 mm) and partial least squares structural equation modeling (PLS-SEM), this study quantified dynamic changes in P speciation. Results revealed a strong nonlinear P export relationship defined by a critical rainfall threshold of 30–50 mm. Below this threshold, export was transport-limited and primarily governed by hydrological leaching, with dissolved total P (DTP) as the dominant fraction. Above it, the system shifted to a detachment-limited regime where pollutant loads increased exponentially driven by erosion, with particulate P (PP) comprising > 95% of the total P load and exhibiting a pronounced first flush effect. This response was highly scale-dependent: small catchments (3.2 ha) showed rapid, slope-dominated responses tightly coupled with rainfall peaks, while larger catchments (> 100 ha) exhibited buffered, delayed hydrographs due to channel network processes (Liu et al., 2017). Critically, this scale-dependent transit altered biogeochemical functionality, as the proportion of bioavailable $PO_4$-P relative to DTP systematically increased with catchment size, attributed to the mineralization of dissolved organic P (DOP) induced by longer hydrological residence times. This work provides the scientific basis for shifting from traditional load-based strategies to spatio-temporal interventions, targeting erosion control in key source areas before critical rainfall thresholds are exceeded.

**ABSTRACT**

Phosphorus (P) is a critical nutrient limiting farmland productivity and crop growth. Low phosphate fertilizer use efficiency, coupled with excessive P accumulation in soils, has become an urgent issue to address in agricultural production across China. Moving away from the traditional agricultural model characterized by heavy reliance on high phosphate fertilizer inputs and fully harnessing the inherent potential of plants for efficient P acquisition constitutes a new direction in modern agricultural development.

Root morphology and physiological traits of plants are regulated by neighboring plants. To explore the responses of the gramineous crop maize to neighboring crops (maize or alfalfa ) under varying soil P supply intensities, this study used maize as the target crop and established three planting regimes: Maize was grown alone (single maize) or with maize (maize/maize) or alfalfa (maize/alfalfa). A pot experiment was performed under six distinct soil P supply levels to assess the effects of different neighboring crops on the growth, P uptake, root morphology, and rhizosphere processes of the target maize.

The results demonstrated that under low P (P0, P50) and medium P (P100, P200) conditions, neighboring alfalfa significantly increased the aboveground biomass and P content of the target maize by improving its root morphology and rhizosphere environment, there by exerting a positive promotional effect. Alfalfa exhibited strong responses in both root morphological traits and rhizosphere physiological processes, whereas neighboring maize had no significant impact. In the maize/alfalfa intercropping system, maize promoted the rhizosphere processes of neighboring alfalfa, and root-rhizosphere interactions between maize and alfalfa enhanced soil P availability. This finding highlights that interactions between maize and alfalfa are pivotal for improving soil P use efficiency and productivity in intercropping systems.

# The Art of Breeding Microbial Communities: Unlocking Soil Phosphorus through Artificial Selection

**ABSTRACT**

Microbial communities, acting as key drivers of ecosystem processes, harbour immense potential for sustainable agriculture practices. Phosphate-solubilising microorganisms, for example, can partially replace conventional phosphate fertilisers, which rely on finite resources. However, understanding the mechanisms and engineering efficient communities poses a significant challenge. In this study, we employ two artificial selection methods, environmental perturbation, and propagation, to construct phosphate-solubilising microbial communities. To assess trait transferability, we investigate the community performance in different media and a hydroponic system with *Chrysanthemum indicum*. Our findings reveal a distinct subset of phosphate-solubilising bacteria primarily dominated by *Klebsiella* and Enterobacterales. The propagated communities consistently demonstrate elevated levels of phosphate solubilisation, surpassing the starting soil community by 24.2% in activity. The increased activity of propagated communities remains consistent upon introduction into the hydroponic system. Additionally, we demonstrate that the propagation approach is reproducible and also effective when applied to recycled phosphate compounds, including struvite and vivianite. Together, our work demonstrates that propagation-based artificial selection can reliably enhance microbial communities to solubilize phosphorus from a wide range of sources, opening new opportunities for sustainable phosphorus management.

**ABSTRACT**

Phosphorus (P) availability is a critical concern in tropical agriculture, particularly in highly weathered Oxisols. Because soil functions are governed by hierarchical and self-organising structures, land use affects P availability and legacy through changes in soil aggregation. However, the impact of integrated agricultural systems (IAS) on P cycling at the aggregate scale remains unclear. Therefore, the objective of this study was to evaluate the relationships between P lability and soil structural parameters—water-stable aggregates (WSA; large, macro, and micro), aggregate stability (AS), and maximum Padsorption capacity (Qmax)—in three Oxisols of contrasting textures under long-term land uses: Integrated Crop–Livestock–Forest (ICLF), Integrated Livestock–Forest (ILF), Integrated Crop–Livestock (ICL), No-Tillage (NT), Conventional Tillage (CT), Rotational Grazing (RG), Extensive Grazing (EG), Permanent Pasture (RP), and Native Vegetation (NV).

At the clayey Site 1, IAS (ICL, ILF, ICLF) increased large-WSA andAS in surface layers, achieving macro- WSA contents like NV (~50%), while EG showed the lowest AS. At the heavier-textured Site 2, ICL and NT increased large-WSA (~50%) compared with CT (29.4%), which also had the highest micro-WSA and lowest AS, indicating structural degradation. In the sandy Site 3, RP and EG markedly enhanced large-WSAandAS, whereas CT again showed the weakest structural stability and highest micro-WSA. Across all sites, micro-WSA acted as the main sink for total and non-labile P—consistent with mineral–organic protection mechanisms in microaggregates (Six et al., 2000)—with microaggregates frequently accumulating >500–700 mg $kg^{-1}$ non-labile P under NT and CT.

Qmax generally decreased from large to micro aggregates and was highest in the clay-rich Site 2 (up to ~1330 mg $kg^{-1}$ under NV). In sandy soils, Qmax was lower (≈200–390 mg $kg^{-1}$) but remained greatest under RP. DNLP ratios showed that conservative systems (NV, RP, EG) retained more non-labile P in surface aggregates, whereas CT consistently displayed negative DNLP across aggregate classes, indicating vertical redistribution of legacy P linked to structural breakdown (Barrow, 2017).

Principal component analysis confirmed that IAS, NT and CT clustered with higher total P, non-labile P and Qmax, while NV, EG and RP were associated with higher AS and WSA but lower mineral P pools. Overall, IAS preserved or restored soil structure comparable to NV and, particularly in sandy Oxisols, enhanced the structural protection of P while supporting improved P-use efficiency and food security. These findings highlight soil aggregation as a key moderator of P legacy, buffering P transformations under contrasting land uses. Integrated systems provide a structural pathway to improve P-use efficiency and long-term sustainability in highly weathered soils.

**ABSTRACT**

Poultry litter is a useful fertilizer material. In Taiwan, it is estimated that the annual production of poultry litter about 2.5 million tons. To reduce environmental concerns from the raw litter materials disposal and direct application, converting raw litter to biochar is a promising recycling method. Biochar application in agricultural production is a potential resolution for plant nutrient supply and waste recycling. The effectiveness of biochar application to a soil on plant growth would be dominated by characteristics and application rates of biochar. In this study, two batches of soil incubation testing were conducted with different durations after application of poultry-litter biochar (PLC) for 30 and 90 days separately to access the effects of PLC application on soil available P. Pinchen series soil, which is an Oxisol in Taiwan, was used for illustration. The PLCs were derived with 6 different pyrolysis processes, which are the combinations of 3 pyrolysis temperatures (250℃, 350℃, and 550℃) and 2 annealing conditions (sealed and purged). The properties (i.e. pH value, EC, PZC, total P content, carbonate, and surface functional groups) of the PLCs were analyzed. Each PLC mixed with 100 g soil sample was added in each pot for incubation. The PLC application rates were 0%, 1%, 2%, 5%, 15 and 30%. The pots were placed in an incubator to keep the temperature at 25℃ and to maintain water content of soils in pots under field capacity about 0.7-fold soil saturated capacity. After incubation, the pH, EC and available P of incubated soil samples were analyzed. The results revealed that the pH, EC, total P and carbonate of PLC were increased with rising pyrolysis temperatures, but the CEC and functional groups of PLC decreased. The pH values of PLC were highly correlated with the carbonate; especially the pH of PLC exceeded 10 by 550℃ pyrolysis temperature. Compared with sealed annealing, purged annealing would enrich more CEC and surface functional groups of PLS. This reveals that the purged process shortened annealing to reduce the decomposition of functional groups on PLC surface. In addition, under the lower PLC applications (1% and 2% and 5%), the soil pH values significantly increased; even 15% and 30% PLC applications resulted in the pH being higher than 7. Also, the soil EC values were increased with PLC application rates and due to rising PLC pyrolysis temperatures. While the PLC application rates were higher than 15%, soil EC would exceed 2 dS $m^{-1}$. Furthermore, soil available P varied simultaneously with the changes of pH and EC, due to the PLC applications. Under the PLC application lower than 5%, soil available P would be increased with rising pyrolysis temperatures; however, while the application rates of PLC were approaching to more than 5%, soil available P continuingly increased with the additional applications of 15% and 30%.

## ABSTRACT

Maize and soybean intercropping plays an important role in enhancing crop yield, phosphorus (P) use efficiency and soil P activation in red soil. Soil microbial and mycorrhizal are critical for mediating soil P transformation under intercropping. However, the AMF-Bacteria interaction and the underlying mechanisms of intercropping driving soil P activation in red soil remains poorly understood. Based on a 7-year consecutive field experiment, two plantation models: maize monoculture and maize//soybean intercropping under four phosphate application rates (0, 60, 90, and 120 kg $P_2O_5 \cdot ha^{-1}$) on dryland red soil in Yunnan were compared, the effects of maize//soybean intercropping on maize yield, soil P fractions, the rhizosphere microbiome community, the arbuscular mycorrhizal fungal (AMF) and the phosphate solubilizing bacteria (PSB) were analyzed by integrating Illumina HiSeq sequencing and real-time quantitative PCR (qPCR). The underlying mechanisms of intercropping driving rhizosphere AMF-PSB synergistic interactions to promote soil P activation in red soil were discussed.

The results showed that, maize//soybean intercropping significantly increased maize yield, improved phosphorus use efficiency, increased the proportion and content of soil liable P pools, and enhanced soil P activation in red soil. Compared to maize monoculture, the grain yield of intercropped maize average increased by 45.97%, the yield sustainability index average increased by 58.87%, while the agronomic efficiency (AE) and apparent recovery efficiency (RE) of phosphorus fertilizers increased by an average of 48.53% and 28.68% across the 4 P levels. The proportion of the soil liable P pool average increased by 16.3%, in which the content of resin-extractable P (Resin-P) increased by 27.1%, the content of sodium bicarbonate-extractable inorganic P ($NaHCO_3$-Pi) increased by 16.9%, and the content of sodium bicarbonate-extractable organic P ($NaHCO_3$-Po) increased by 15.6%. Consequently, the soil phosphorus activation coefficient (PAC) average increased by 30.5%.

Maize//soybean intercropping reshaped the rhizosphere microbiome community. Intercropping significantly altered the rhizosphere AMF community structure, enhancing AMF diversity and enriching the *Glomus* genus with an relative abundance increase of 135.98%, enhancing the stability of the AMF co-occurrence network. Intercropping enhanced bacterial community diversity, significantly enriching phosphate-solubilizing bacteria (*Bacillus*) and antagonistic bacteria (*Streptomyces*), and strengthened the stability of cross-symbiotic networks between differential functional bacteria and AMF. This synergistic effect significantly upregulated key genes of soil P activation *phoD* and *pqqC*. Variance Partitioning Analysis (VPA) confirmed that the most important contributors to P activation was the synergistic effect of functional bacteria and AMF interaction, functional bacteria, and AMF, in order.

In conclusion, maize//soybean intercropping can synergistically promote soil P activation by reshaping the rhizosphere microbial community structure, enriching the abundances of both AMF and PSB, enhancing AMF-PSB cross-kingdom synergistic interactions, and upregulating the expression of key P activation genes, ultimately increasing maize yield and P use efficiency in red soil.

**ABSTRACT**

Phosphorus (P) phytoavailability in soils located in semi-arid regions, including Mediterranean areas, is commonly constrained by the presence of carbonates, which buffer soil pH around 8.0. Moreover, around 65% of these soils are degraded (low organic matter content, high soil erosion rates) resulting in a negative impact on soil functionality. Besides that, the increasing pressure on global phosphate rock reserves emphasizes the need for sustainable alternatives to mineral fertilizers to increase the resilience of agriculture. Recycled organic amendments may enhance soil functionality, particularly under the highly variable rainfall regimes typical of Mediterranean agroecosystems but their ability to supply P remains poorly understood. This study aimed to evaluate how different organic amendments improve the functionality of a Mediterranean agricultural soil, with emphasis on P cycling (as this is one of the most limiting nutrients under semi-arid conditions) and microbial communities (bacteria, archaea, and enzyme activities). A field experiment including a wheat–sunflower rotation in Andalusia (southern Spain) was conducted during two consecutive seasons to evaluate the immediate and residual effects of the organic amendments. A selection of composted organic amendments (including olive mill pomace, digestate, vermicompost, and urban solid residue), and stabilized amendments (based on plant residues) were compared with diammonium phosphate (DAP) and an unfertilized control. Additionally, pot experiments focused on evaluating how root traits and P uptake are modified after the application of organic amendments as a function of soil physicochemical properties were developed. Composted olive mill pomace and composted urban solid residue produced the largest increases in soil organic matter two years their application to the soil. Composted olive mill pomace triggered the strongest shifts in soil microbial community structure, followed by composted solid urban residue, whereas the latter most effectively enhanced nutrient cycling, improving the performance of mineral fertilizers (DAP) in terms of P use efficiency. Despite the drought-driven lack of significant yield differences, certain amendments increased aboveground biomass production and improved soil root exploration relative to CON. Enzyme activities related to C and P cycling were also stimulated by organic amendments, indicating improved biochemical soil functioning even under moisture-limited conditions. Overall, the results demonstrate that composted organic amendments can substantially modify soil functionality in Mediterranean agroecosystems, enhancing microbial processes, nutrient cycling and P-use efficiency despite severe drought, and support the transition toward more resilient cropping systems.

## ABSTRACT

**Introduction**

High legacy soil phosphorus inputs from slurry and organic manures are an issue in intensively managed agricultural areas within Northern Ireland, Ireland and North America, reducing water quality. However, rapid fixation of manure supplied P to soil constituents causes between 70-90% of the applied phosphorus becoming unavailable to plants. Therefore, solutions are required to both retain excess phosphorus in the soils, thereby protecting freshwater and coastal habitats, and act as a slow-release fertiliser to provide plants with sufficient phosphorus during growth. Biochar, a carbonaceous material produced from the thermochemical conversion of biomass, can absorb phosphorus, and its capacity to do so is increased by modification with metals, such as iron (Fe). This experiment aimed to test the effects of Fe-doped biochar versus unmodified biochar on crop production, soil P availability and water quality.

**Method**

Fe-modified and pristine biochar were loaded with P and applied in a pot scale experiment at a rate equivalent to 10 t $ha^{-1}$ and compared to a biochar-free control. At 40-, 80- and 120- days following sowing, pots were leached with deionised water and the leachate measured for total (TP) and soluble reactive (SRP) phosphorus. Following leaching, crop and soil samples were taken and measured for available P.

**Results and Discussion**

Laboratory analysis is still ongoing, but preliminary results show a significant effect by modified biochar reducing TP leaching losses, however soil available P was unaffected between treatments. Modified biochar reduced the tiller number of the crop. This is potentially due to the slow release of P from the biochar during the establishment phase of the crop growth (~0-30 days), which is a crucial time for tillering. Whilst modified biochar did not increase soil P availability during the growing season, it did reduce P leaching losses, demonstrating its potential to mitigate excess P losses from agricultural soils.

# Effects of organic fertilizer substitution on soil inorganic phosphorus (P) fractions and dynamics at the aggregate level: evidence from P fractionation and $^{33}P$ isotopic exchange kinetics

## ABSTRACT

Effective phosphorus (P) management during organic fertilizer substitution requires more knowledge of how P pools are cycled within soil aggregates. The main objective of this study was to investigate the effects of two organic substitution types (i.e., animal- and plant-derived composts) of equal-N input on soil inorganic P fractions and dynamics at the soil aggregate scale in a two-year wheat-maize rotation system. To examine this objective, a combination of Hedley sequential P fractionation and $^{33}P$ isotopic exchange kinetics (IEK) was used. Results showed that the animal-derived fertilizer (i.e., pig manure, PM) presented the significantly highest soil available P ($NaHCO_3$-Pi, 31.6 ± 3.4mg $kg^{-1}$), due to 10-39 times higher P inputs compared with chemical fertilizer (CF) and plant-derived fertilizer (i.e., fruit tree pruning, FP) equivalents. In contrast, the FP treatment significantly improved $NaHCO_3$-Pi (25.1 ± 3.0 mg $kg^{-1}$) as compared to the CF treatment (16.6 ± 3.1 mg $kg^{-1}$) but with very little P input (16.8 *vs.* 65.7 kg $ha^{-1}$ $year^{-1}$). P cycling within soil aggregates can be better described by P dynamics derived from the $^{33}P$ IEK method rather than P pools derived from Hedley P fractions. Specifically, < 0.25 mm aggregates showed higher inorganic P transformation ability than > 0.25 mm aggregates as indicated by larger IEK parameters including water-extractable P, $r_{1min}/R$, m and extrapolated E-values. These results indicated that smaller fraction can largely bind free P, and this P is also highly exchangeable and can be transferred to the available P pool. Organic fertilizer shortened the time difference of P dynamics between aggregates (e.g., non-significances detected after 4 and 5 days in PM and FP but after 19 days in CF, respectively), indicating that organic substitution can buffer the robust P dynamics and reduce P mobility likely by soil aggregation because of the introduction of C-rich materials. In terms of crop production, both crop grain yields and P uptake were not significantly affected by different fertilization regimes. Plant-derived fertilizer could be a balanced organic substitute due to its low P input and surplus, and maintenance of P supply, whereas the animal-derived fertilizer may lead to imbalance, surpluses and environmental losses in well P-supplied soils.

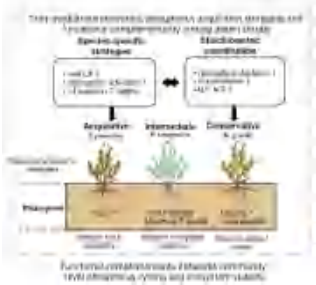
## ABSTRACT



**Background and Aims** Phosphorus (P) limitation is a pervasive constraint in desert ecosystems, fundamentally shaping plant nutrient strategies, community structure, and biogeochemical cycling. However, the trait-based mechanisms that enable plant coexistence and ecosystem stability under chronic P scarcity remain poorly understood.

**Methods** In this study, we investigated rhizosphere and bulk soil P fractions, organ-level C: N: P stoichiometry, and $\delta^{13}C$ signatures in three co-dominant desert shrubs—*Kalidium gracile*, *Reaumuria soongarica*, and *Salsola passerina*, —to identify divergent P acquisition strategies and assess their ecological implications.

**Results** Our results revealed distinct functional strategies among species. *S. passerina*, a *$C_4$ chenopod*, employed a P-acquisitive strategy, characterized by rhizospheric enrichment of labile P (resin-P). *K. gracile* adopted a conservative strategy, marked by limited P mobilization, high leaf C: P ratios, and reliance on organic P mineralization and increased phosphatase activity. *R. soongarica* exhibited an intermediate buffering strategy, uptake moderate labile P with stem P storage, likely facilitated by root–microbial interactions. These species-specific strategies corresponded to differential root–soil–trait linkages and spatial variation in P availability. Despite divergence in rhizospheric processes, organ-level stoichiometric traits remained relatively conserved, indicating phylogenetic or biomechanical constraints on internal nutrient allocation. The coexistence of acquisitive, conservative, and intermediate strategies reflects functional complementarity in phosphorus use, which enables rhizospheric niche differentiation, minimizes interspecific competition, and supports community-level phosphorus cycling.

**Conclusion** Trait-mediated rhizosphere P strategies support plant coexistence and community stability in P-limited deserts, offering insights for biodiversity conservation and ecosystem management under resource stress.

**Keywords** Phosphorus acquisition strategies; Rhizosphere niche partitioning; Stoichiometry; Desert shrub coexistence; Functional complementarity

**Conceptual model** illustrating divergent rhizospheric P acquisition strategies among coexisting desert shrub species and their ecological consequences. The diagram integrates root–soil–plant interactions and organ-level stoichiometry to depict three distinct strategies: P-acquisitive (*Salsola passerina*), P-conservative (*Kalidium gracile*), and intermediate (*Reaumuria soongarica*). Each species mediates different rhizosphere P fractions, leading to functional differentiation in carbon–phosphorus trade-offs, tissue stoichiometry, and spatial niche partitioning. This functional complementarity supports more efficient phosphorus use and promotes community stability under extreme aridity.

**ABSTRACT**

To nourish humanity, vast quantities of phosphorus (P) have been applied to agroecosystems. Yet phosphate rock, a finite resource, dwindles rapidly. This P dilemma urgently requires sustainable solutions. To address this critical challenge, we conducted two major investigations: a global meta-analysis exploring the fate of P added to terrestrial ecosystems, and a systematic nationwide sampling of agricultural soils across China in 2024. Our global meta-analysis revealed alarmingly low plant P use efficiency, averaging a mere 12.6% in fertilization experiments. Concurrently, 4.4% of applied P fertilizer was lost from ecosystems. Over two-thirds of the added P accumulated in soils, predominantly locked in non-labile inorganic forms. Our extensive soil sampling across China uncovered striking spatial variations in P status and significant regional shifts, pinpointing alarming hotspots of both P-depletion and P-loss. Collectively, these findings underscore the critical necessity to improve our predictive understanding of soil P dynamics, and develop and implement sustainable P management approaches within agroecosystems.

**ABSTRACT**

Cropland phosphorus (P) is essential for global food security, yet its management faces significant challenges due to low phosphorus use efficiency (PUE), leading to resource depletion and nutrient loss from agricultural fields. The effectiveness of PUE-enhancing practices varies with local conditions, and the lack of a predictive framework has impeded the assessment of their global potential and their role in meeting food demand while staying within planetary boundaries. Here, we develop a machine-learning model to map global PUE geospatial variations for maize, rice, and wheat at 5 arc-minute resolution and quantify potential gains under optimized management. The model integrates key management, soil, and climate drivers to identify where P recovery is most constrained and where improvements are most attainable. Our results reveal global average PUEs of 23.9% for maize, 25.3% for rice, and 23.6% for wheat, with pronounced spatial heterogeneity across agroecological zones. Targeted management interventions could achieve absolute PUE gains of 9.5-10.2%, with exceptional potential in regions facing acute P deficits, particularly in Africa, where improved P recovery can simultaneously alleviate nutrient limitations and increase the effectiveness of scarce inputs. We further translate these spatially explicit PUE gains into implications for future P requirements and the global P budget under mid-century food-demand trajectories. Implementing these strategies could reduce global P demand by approximately 29% (6.3-7.7 Tg P $yr^{-1}$) by 2050, while constraining the planetary P surplus to 8.7 Tg P $yr^{-1}$, thus maintaining global P usage within planetary boundaries. Our spatially explicit framework illustrates how strategic agricultural management tailored to local constraints and opportunities can balance food security with planetary boundary compliance. It also provides a quantitative basis for prioritizing interventions that deliver the largest sustainability benefits.

**ABSTRACT**

Phosphorus (P) limitation constrains agricultural productivity, particularly in drained paddy soils converted for soybean cultivation in South Korea. This five-year field study evaluated P dynamics at three soil depths (0–20, 20–40, and 40–60 cm) under three fertilization treatments: control, mineral fertilizer (NPK), and combined NPK plus manure compost (NPK + compost) in both paddy and drained paddy soils. Detailed P fractionation revealed distinct changes by treatment and depth. The NPK + compost treatment significantly enhanced available P, reaching 90.68 mg/kg in drained paddy soils and 68.24 mg/kg in paddy soils at 0–20 cm depth. Fe-bound P was the dominant inorganic fraction, peaking at 268.4 mg/kg with compost application in surface layers, accompanied by increases in Ca-bound and Al-bound P. Organic P similarly increased with compost addition, notably to 279.8 mg/kg at 20 cm in drained soils. Oxalate-extractable P ($P_{ox}$) and associated amorphous Fe and Al oxides ($Fe_{ox}$, $Al_{ox}$)—key in P binding—more than doubled under compost treatment. These increases declined with depth but remained significantly higher than control, indicating vertical stratification of P stabilization. The degree of phosphorus saturation ($DPS_{ox}$) rose to 20.3% in compost-treated surface soils, reflecting improved P retention but potential mobilization risks. Multivariate analysis confirmed fertilization and depth as primary drivers of P speciation, with organic amendments promoting stable organo-mineral complexes and enhancing P bioavailability. These findings highlight the critical role of integrated nutrient management in sustaining fertility and guiding phosphorus management in paddy-soybean cropping systems.

# Characteristics of soil phosphorus profile distribution in degraded black soil areas and effects of tillage patterns on root zone phosphorus supply barriers

**Huajie Zhang**

[1] *Huajie Zhang. Author (China Agricultural University)*

**ABSTRACT**

As an important food production base in China, the long-term degradation of black soil in Northeast China has led to a decrease in soil phosphorus effectiveness, which seriously restricts crop productivity. In this study, different degraded black soil areas (wind-sand black soil area, thin black soil area, infertile black soil area and dry thin black soil area) in Songnen Plain and Liaohe Plain were taken as the objects of the study, and Hedley phosphorus grading method was adopted, and correlation and principal component analysis were applied to reveal the effects of soil phosphorus profile distribution characteristics of degraded black soil areas and cropping patterns on soil phosphorus effectiveness in the root zone through regional survey and long-term positioning tillage experiment (plowing and clearing, rotary ploughing and return to the field, tilling and returning to the field, deep loosening and returning to the field, and no-tillage and returning to the field) in the dry thin black soil area. The correlation and principal component analysis were used to reveal the distribution characteristics of soil phosphorus profile in degraded black soil area and the influence of tillage pattern on soil phosphorus effectiveness in the root zone. The main research results are as follows:

(1) There are significant differences in the phosphorus profile characteristics of different degraded black soil areas. The wind-sand black soil area is affected by high pH (9.06-10.05) and high calcium carbonate content (3.88%-5.08%), the active phosphorus percentage of each soil layer is extremely low (<10%), and the medium-stable and stable phosphorus dominates (>85%), which shows typical calcium and phosphorus fixation characteristics; the thin black soil area is affected by the neutral to weakly alkaline environment (pH 5.96-8.25) and high organic carbon content (14.08 g/kg), which is the main cause of the degradation of the soil. 14.08 g/kg), but the accumulation of calcium carbonate in the deep layer exacerbated phosphorus fixation; the soil in the barren black soil area was acidic (pH 4.72-6.32), with a prominent proportion of Residual-P, and phosphorus effectiveness was mainly regulated by nitrate nitrogen; the soil in the dry and thin black soil area was neutral to weakly alkaline (pH 6.28-7.48), and the surface layer (pH 6.28-7.48) showed typical calcium and phosphorus fixation characteristics; the soil in the thin black soil area was neutral to weakly alkaline, and the surface layer (pH 6.28-7.48) showed typical calcium and phosphorus fixation characteristics. 7.48), the surface layer (0-10 cm) of the soil promotes the release of reactive phosphorus due to the mineralization of organic matter, while the deep layer (60-80 cm) of the soil HCl-Pi accounted for a sharp increase (208.34 g/kg), and the distribution of phosphorus showed the synergistic regulation characteristics of calcium fixation and organic matter input.

(2) Tillage pattern significantly affected the effectiveness of soil phosphorus in the root zone. Due to the low carbon and nitrogen inputs and high pH, the active phosphorus in each soil layer was the lowest, and the proportion of stabilized and stabilized phosphorus in the deep layer was more than 80%. Compared with the tilled stubble, no-tillage, deep-pine and rotary tillage significantly increased the active phosphorus in the 0-20 cm layer, and the active inorganic phosphorus in the no-tillage treatment showed obvious epimerization; deep-pine and rotary tillage improved the aeration of the middle layer and synergized with quick-acting nitrogen to activate the active phosphorus in the 20-40 cm layer (the proportion of Resin-P increased by 14.29%);and tilled stubble only enhanced the active organic phosphorus in the 10-20 cm layer (the proportion of NaOH-P increased by 14.29%). Tillage can only enhance the active organic phosphorus (NaOH-Po) in the 10-20 cm soil layer, and the overall phosphorus activation effect is weak.

In conclusion, the distribution of phosphorus components in the degraded black soil area of Northeast China was dominated by soil degradation types, and no-tillage, rotary tillage, and deep-pine tillage significantly enhanced the phosphorus effectiveness by enhancing the carbon and nitrogen of the surface soil and optimizing the microenvironment of the soil in the root zone, which provided a key basis for conservation tillage in the black soil, and was of great significance for guaranteeing the food security and ecological sustainability of the region.

# Does particle size of digestate-derived biochar affect phosphorus losses and fertilizer value? Evidence from a lysimeter study in a temperate soil.

**Oliver Lindunda Daka[1*], Lars Juhl Munkholm[1], and Ingeborg Frøsig Pedersen[1]**

[1] *Department of Agroecology, Aarhus University, Blichers All´e 20, 8830 Tjele, Denmark*

*oliverldaka@agro.au.dk

**ABSTRACT**

Phosphorus (P) is essential for plant growth and ecosystem productivity, yet its mismanagement in agriculture contributes to eutrophication and regional nutrient imbalances. Surpluses of manure-derived P in livestock-dense areas and deficits in arable regions underscore the need for strategies that efficiently recover and redistribute excess P. Biochar particle size has been shown to affect its short-term P fertilizer value, with smaller particles providing a higher initial P fertilizer value under controlled conditions. However, the long-term effect of biochar particle size on its P fertilizer value remains unknown. Furthermore, small particles may be susceptible to leaching, creating a potential trade-off between short-term fertilizer value and P leaching. Yet studies under temperate field conditions are scarce, highlighting the need to assess agronomic benefits and environmental risks of biochar application.

We conducted a two-year lysimeter experiment using twelve cylindrical polyester lysimeters (1.5 m depth, 1 m diameter) arranged in a randomized complete block design. They contained a sandy loam soil representing a dominant soil type in P-deficient regions of Denmark. Digestate biochar produced at 600°C was applied at 90 kg P $ha^{-1}$ either as powder (<125 µm) or pellets (>4 mm) at 3-5 cm depth. References treatments included mineral P fertilizer (90 kg P $ha^{-1}$ as TSP) and an unamended control. Maize biomass yield and P uptake were determined at harvest, and cumulative P losses in leachate were measured. After harvest in both years, soil samples from 0-10, 10-25, 25-50, and 50-100 cm depths were analyzed for soil pH, water- extractable P (WEP), and Olsen- P.

Biochar pellets reduced cumulative dissolved reactive P and total P losses compared to biochar powder in the first year after biochar application, while preliminary second year results showed similarly low P leaching across all treatments. In the first year, contents of WEP and Olsen-P in the 0-10 cm soil layer increased after application of powdered biochar and mineral P, compared to the control, whereas mineral P fertilizer resulted in higher contents of soil labile P in the second year. No treatment affected P-pools below 10 cm depth. A comparison of rhizosphere and bulk soil within each treatment during early growth showed significantly higher WEP in the rhizosphere under biochar pellets, with no differences in other treatments. Soil pH, maize biomass yield, and P uptake remained similar across treatments throughout the study.

Our findings suggest that pelletized digestate-derived biochar can mitigate P leaching compared to powdered biochar in the first year after application. Powdered biochar increased labile P in the upper soil layer during the first year, but neither biochar type posed a leaching risk in the second year. Therefore, pelletized biochar does not appear to constitute an environmental risk in terms of P loss down the soil profile in a sandy loam under temperate conditions.

# Cultivar-Dependent Cluster Root Strategies Underpin Phosphorus Use Efficiency in Macadamia Grown Under Low Phosphorus Conditions

**Yu Pin Li[1*], Li Yang[1+], Wei Wang[1], Jiayu Bi[1], Patrick Finnegan[1, 2] & Yi Zheng[1, 3, *]**

## ABSTRACT

Phosphorus (P) limitation is a major constraint in highly weathered subtropical soils, necessitating crop- and cultivar-dependent strategies for sustainable P use. Macadamia (*Macadamia* spp.), a Proteaceae tree crop adapted to P-impoverished soils, exhibits high P-use efficiency through formation of specialized cluster roots (1) and is widely cultivated in southern China, where Yunnan Province is the world's largest macadamia-growing area (2). However, cultivar-level variation in cluster-root development and P-use strategies remains poorly understood. We evaluated four widely-cultivated macadamia cultivars (HAES741, HAES788, Own Choice (O.C.), and hybrid H2) under normal-P (NP) and low-P (LP) supplies in hydroponic and soil-based pot experiments. Plant nutrient status, cluster-root traits, and rhizosphere processes were analyzed. Under LP, dry matter partitioning among roots, stems, and leaves was similar among cultivars, with no root–shoot trade-offs. However, P-use efficiency differed significantly. Leaf P concentration was significantly higher in HAES741, O.C., and H2 than in HAES788, with HAES741 and O.C. having the highest values, indicating preferential P allocation to photosynthetic tissues. Cultivars O.C. and H2 produced a greater number of cluster roots (~30 clusters plant$^{-1}$), than HAES741 (~10 clusters plant$^{-1}$) under identical LP conditions. Despite lower cluster root abundance, HAES741 exhibited high cluster-root acid-phosphatase exudation activity, reflecting a low-cost, high-efficiency strategy. It also had a shorter young phase of cluster-root development, but prolonged senescence, a stage associated with enhanced organic acid secretion. Oxalate, citrate, and malate were most abundant in exudates from HAES741 and O.C. The LP supply also stimulated cultivar-dependent differences in rhizosphere microbial community structure without changing the dominant phyla. Overall, macadamia P-use efficiency is governed by coordinated regulation of cluster-root number, developmental timing, and functional specialization, providing a mechanistic basis for reducing P fertilizer inputs and improving the sustainability of macadamia production in P-limited agroecosystems.

# Organic P Mineralization in Agricultural Soils: Process Dynamics and Microbial Drivers

**Jinzhen Zhan[1], Yue Qiu[1], Wei Ji[1], Sibei Chen[1] , Klaus A. Jarosch[2], Wenxuan Shi[3], Owen Fenton[3], Hao Chen[1]**

[1] *School of Agriculture and Biotechnology, Sun Yat-sen University, Shenzhen, Guangdong, China*

[3]*Environment Research Centre, Teagasc, Johnstown Castle, Wexford, Co., Wexford, Ireland*

**ABSTRACT**

Globally, soil organic P (Po) accounts for 30–65% of the total P in agricultural soils and thus acts as a significantly potential available P source. However, Po must be mineralized before becoming plant available. Currently, the relative contribution of Po mineralization to soil total P supply and the associated mechanisms controlling the mineralization process remain highly uncertain. Soil P (e.g., Po and inorganic P) status as well as biotic and abiotic properties may affect Pi transformation and Po mineralization. The objective of this study was to understand the relationships between soil Po mineralization rates and soil P pools and microbial-relevant metrics. For this, three farmland soils with comparable P status were collected from north China (Songyuan, Beijing and Dingxi). By using isotopic ($^{33}$P) dilution technique, the biotic and abiotic P fluxes was quantitatively assessed. Further, the communities of core functional genes driving Po mineralization (i.e., *phoC*, *phoD*) and their regulatory mechanisms were investigated. Results showed that the variation in the Po mineralization rate presented a dissociation from the variation in total Po content. This finding indicated the significance of decomposing ability of soil microbes in addition to substrate quantity, which was verified by the difference in alkaline phosphatase activity. Regarding the community of phoD-harboring microorganisms across the three soils, core taxa such as *Aureimonas, Pleomorphomonas, Psychrobacter, Thalassospira, Bradyrhizobium, Aquabacterium* may play significant roles in promoting enzymatic activity and in turn Po mineralization. This work provides a theoretical foundation for enhancing P use efficiency and promoting sustainable agricultural development.

# Incorporating Chinese milk vetch and rice straw promoted inorganic phosphorus mobilization through assembling phosphate-solubilizing bacteria in rhizosphere

**Qiang Zhu[1*], Jianan Cao[1], Xinghua Chen[1] and Mingjian Geng[1]**

[1] *Microelement Research Center of Huazhong Agricultural University, Key Laboratory of Arable Land Conservation (Middle and Lower Reaches of Yangtze River), Ministry of Agriculture and Rural Affairs, Wuhan, China*

*E-mail Address: zhuqiang@mail.hzau.edu.cn

**ABSTRACT**

Previous study showed that incorporating Chinese milk vetch (CMV) and rice straw combined with 50% of recommended P fertilizer (MSP50) increased rice straw and grain yields compared with the conventional P fertilizer application treatment (P100). However, the responses of rhizobacterial community and inorganic P mobilization strategies to the incorporation practice with partial mineral P fertilizers remain unclear. Hence, a pot study based on the field trial was conducted to investigate the effects of CMV and rice straw incorporation on low-molecular-weight organic acids (LMWOA) concentrations, soil P fractions, and the rhizobacterial community. Results showed there were no significant differences in both shoot and root P accumulations between P100 and MSP50 treatments. At rice booting stage, MSP100 treatment significantly increased $Ca_2$-P and Fe-P by 14.8% and 28.7%, respectively, while reducing Al-P and O-P by 14.4% and 6.2%, respectively, compared with P100 treatment. The $Ca_2$-P fraction was positively correlated with oxalic and malic acids contents in rhizosphere. In MSP0 and MSP50 treatments, where P was deficient or highly utilized, phosphate-solubilizing bacteria (PSB) were recruited to improve P mobilization through LMWOA secretion. Based on the correlation between bacterial genera and P fractions, *Bacillus*, *Flavisolibacter*, *Massilia*, *Intrasporangium*, and *Gemmatimonas* were identified as PSB in the present study. The MSP100 treatment resulted in a significantly higher Shannon index but a lower Simpson index than other treatments, indicating the higher bacterial community diversity but lower abundance of the dominant species, which was also supported by the significantly higher MBP content. Consequently, incorporation of CMV and rice straw combined with half of the recommended mineral P fertilizer reduced the diversity of soil bacteria but increased the abundance of PSB, thus reducing the energy consumption of bacteria and enhancing soil inorganic P mobilization.

**ABSTRACT**

Phosphorus (P) is essential for global food production, yet it faces a dual crisis of increasing resource scarcity and escalating environmental pollution driven by wastewater P discharge. Recovering P from wastewater systems therefore represents a critical strategy to simultaneously address resource security and environmental sustainability. However, systematic assessments of this potential remain limited, particularly with respect to recovery pathways, regional heterogeneity, and integrated environmental and economic benefits. This gap is especially pronounced in China, where both P scarcity and wastewater P pollution are severe. Using high resolution data from more than 600 cities, this study quantified P waste flows and evaluated their recovery potential across China. We estimate that the national P recovery rate reached 21.9% in 2022, with pronounced spatial disparities. Under best available technology scenarios, P recovery from wastewater could be tripled to 189,600 tonnes, offsetting up to 6.6% of annual cropland P fertilizer demand. This recovery would simultaneously reduce waterborne P pollution by 30% and generate economic benefits of approximately 356 million USD. Our results provide a robust quantitative foundation showing that wastewater P recovery is a cost-effective alternative for achieving a synergistic triple win across food security, environmental protection, and economic gains.

# Land use controls soil phosphorus pools but not sorption mechanisms: insights from piecewise structural equation modelling

**G. Colinet**[1*]

[1] *Water Soil Plant exchanges Department, TERRA, University ofLiege, Belgium*

*Gilles.Colinet@uliege.be

## ABSTRACT

Phosphorus (P) sorption in soils is a key process regulating both plant P availability and the risk of soil P saturation and transfer to aquatic ecosystems. While the physicochemical controls of P sorption are well established, the extent to which land use modifies sorption mechanisms versus soil P pools remains insufficiently quantified within an integrated framework.

In this study, we analysed 80 soil samples equally distributed among four land-use types (forest, grassland, cropland, and kitchen gardens) to disentangle the direct and indirect effects of land use and soil properties on P sorption, availability, and saturation. Phosphorus sorption parameters were derived from isotherm experiments, including Langmuir maximum sorption capacity (Qmax) and sorption affinity (b). These parameters were related to soil P pools, oxalate-extractable Fe and Al, pH, soil organic carbon (SOC), texture and cationic exchange capacity (CEC) using a piecewise structural equation modelling (SEM) approach in R.

Land use exerted a strong control on soil P pools and SOC, explaining 32%, 41%, and 66% of the variance in total P, oxalate-extractable P, and SOC, respectively. In contrast, sorption mechanisms were largely independent of land use. Sorption capacity (Qmax) was primarily controlled by Fe and Al oxides and SOC, whereas sorption affinity (b) was strongly enhanced by Fe oxides but significantly reduced by SOC, highlighting contrasting organo-mineral effects on P retention. Both sorption parameters exerted a negative control on plant-available P, with sorption affinity emerging as the dominant driver. Soil P saturation (DSP) was mainly governed by oxalate-extractable P, counterbalanced by the pool of reactive Fe and Al oxides, with a secondary influence of soil pH.

Overall, this integrative analysis demonstrates that land use primarily influences soil P dynamics through long-term accumulation of P and organic carbon rather than through changes in fundamental sorption mechanisms. By disentangling direct and indirect controls, the piecewise SEM framework provides new insights into the hierarchy of processes governing soil P availability and saturation, and helps clarify trade-offs between soil fertility management and environmental risk.

# Long-term biochar application influences phosphorus and associated iron and sulfur transformations in the rhizosphere

**Jiahui Yuan[1*], Yu Wang[1], and Shenqiang Wang[1]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China*

*yuanjiahui@issas.ac.cn

**ABSTRACT**

The effects of long-term biochar application on soil phosphorus (P) flux across the root-soil interface and its availability in the rhizosphere of rice (*Oryza sativa* L) remain unclear. We used diffusive gradients in thin films (DGT), laser ablation-inductively coupled plasma mass spectrometry, and planar optode sensor techniques to characterize, *in-situ*, the 2D heterogeneity and dynamics of rhizosphere soil P, iron (Fe), sulfur (S) and trace element fluxes, dissolved oxygen and pH in paddy soil, after 10 years of biochar application. Compared to the control (no biochar applied), biochar applied at 4.5, 22.5 and 45.0 Mg $ha^{-1}$ $yr^{-1}$ decreased rhizospheric P fluxes by 11.6%, 63.4% and 79.0%, respectively. This decrease under biochar treatments was attributed to changed redox status of Fe and S caused by the lower dissolved oxygen in rhizosphere soil and increased soil pH induced precipitating of soluble inorganic P into insoluble P forms, such as calcium-bound and residual P that are unavailable for crop uptake. Higher application rate of biochar resulted in lower As and Pb fluxes in rice rhizosphere and their availabilities for crop uptake. The *in-situ* observation results in rice rhizosphere at μm-scale after 10 years of biochar addition directly showed the complex effects of long-term biochar and rhizosphere heterogeneity on P transformation process.

# Molecular-level understanding of transformation mechanisms of P in the calcareous agricultural soils

*[1] State Key Laboratory of Efficient Utilization of Arid Land in China (Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences), Beijing, 100081*, China

*[2] College of Agronomy and Biotechnology, China Agricultural University, Beijing, 100193, China*

**ABSTRACT**

With the increasing pressure on phosphorus (P) resources and global water eutrophication, the development of sustainable land management is pushed forward by detailed knowledge on the nature and fate of phosphorus (P) in agricultural soils. Therefore, understanding the transformation of P in the agricultural soils is of vital importance for effective management of P nutrient. Calcareous soils, in the Northern area of China, are important agricultural lands for crop production, but accumulated large amount of P as legacy P in the soils. Multiple reasons, including P fertilization regime, tillage practices, crop straw returning etc., could contribute the accumulation of legacy P in soils. However, the transformation mechanism of P in the agricultural calcareous soils remains largely unknown. Here, we showed the different impacts of long-term P fertilization regime and tillage practices on the transformation of P in calcareous soils using solution 31P nuclear magnetic resonance; P K-edge X-ray absorption near-edge, XANES and micro X-ray fluorescence and XANES spectroscopic techniques. We found long-term P fertilization regimes and tillage practices significant affected the availability and speciation of P in the calcareous soils. These results facilitate more effective management of P in agricultural calcareous soils

# Earthworms enhance soil phosphorus cycling but plant responses differ among earthworm ecological categories

**Wenli Ding[1*], Ziyue Wang[1], Zhihui Chang[1]**

[1] *School of Grassland Science, Beijing Forestry University, Beijing, China*

*Dingwenlii@bjfu.edu.cn

**ABSTRACT**

Earthworms are integral to soil processes and influence plant growth and phosphorus (P) nutrition. We investigated the role of earthworms in the P cycle by synthesizing data from 181 studies, of which 22 % were field observations and 78 % were from pot or mesocosm experiments. Earthworms increase the concentration of soil Olsen P and microbial P, phosphatase activity, and plant biomass. Deep-dwelling epi-anecic and anecic earthworms are more effective than other ecological groups at increasing the soil available P, although surface-dwelling earthworms (epigeic and endogeic) contribute more effectively to plant P uptake. The increase of plant biomass by earthworms decreases with increasing organic matter content, but Olsen P concentration and plant P uptake show the opposite trend. Moreover, the impact of endogeic earthworms on P is sensitive to soil organic matter content. The positive effects of earthworms on P cycling are more pronounced under acidic and alkaline conditions than under neutral conditions (6.5–7.5). Finally, the increased available P concentration due to earthworms directly stimulates microbial P uptake, while all three main ecological categories of earthworms indirectly stimulate root growth and increase plant P uptake. Overall, earthworms can effectively promote P cycling in ecosystems, with a more significant effect in nutrient-poor soils.

## ABSTRACT

Determining microbial biomass phosphorus (MBP) in soils is essential for understanding soil P cycling in agricultural systems where fertility management is progressively shifting from mineral fertilization toward more integrated and sustainable strategies. The latter approaches rely on recycled fertilizers, enhanced crop diversity, and preservation of soil biological functioning. Microbial biomass can represent a substantial and dynamic pool of readily available P even to plants following microbial turnover, making its accurate quantification critical for P management in the soil-plant sysyem. The classical fumigation–extraction (F–E) method is widely used to estimate MBP; however, it relies on chloroform fumigation, which poses health and environmental risks. In addition, several methodological limitations have been highlighted. In particular, P released after microbial cell lysis may be rapidly adsorbed onto organo-mineral colloid surfaces or precipitated in soils by polyvalent cations, leading to an underestimation of MBP. Although the application of P spikes after fumigation is commonly used to correct for these effects, this approach may still be inaccurate, as it does not account for soil–P interactions occurring during the fumigation period.

To address these limitations, three alternative approaches to the classical fumigation–extraction (F–E) procedure were evaluated using three soils differing in key physical and chemical properties that influence P dynamics (i.e., clay, carbonate, and Fe-oxide contents). Two approaches involved liquid fumigation combined with the use of P sinks, specifically an anion exchange resin and a filter paper impregnated with iron oxides, the latter being tested for the first time for this purpose. The third approach employed the recently proposed microbial lysis induced by high-pressure $CO_2$ fumigation, eliminating the need for chloroform and reducing procedural risks.

Results showed that MBP varied significantly among soils confirming the strong influence of soil properties on P adsorption and precipitation processes. The inclusion of P sinks consistently resulted in higher MBP estimates, highlighting a key limitation of the classical F–E procedure, which generally underestimates MBP. Among all tested approaches, the use of chloroform fumigation coupled with iron oxide–impregnated paper strips proved to be the most effective, yielding on average a 52% increase in MBP compared with the classical F–E approach, while also exhibiting the lowest variability and highest reproducibility.

This low-cost, safe, and innovative approach, after validation with $^{31}P$, could represent a significant advancement for accurately quantifying MBP and could substantially improve our understanding of P dynamics in agroecosystems, supporting the transition toward more diversified and sustainable soil management practices.

## ABSTRACT

Modern agricultural systems face a pervasive phosphorus (P) paradox, wherein P availability is often limited despite adequate fertilization. Sulphur (S), a naturally occurring element, possesses the inherent capacity to mobilize P from recalcitrant soil pools, thereby offering a promising strategy to alleviate P limitation. To leverage this phenomenon, S-enriched biochar (SEB) was prepared to synchronize P mobilization with carbon (C) stabilization, providing a novel approach to enhance P availability and promote soil fertility. A controlled incubation experiment was conducted to assess SEB's efficacy in modulating P dynamics and C stabilization in soil. The experimental design included four biochar treatments [pristine biochar (PB), two SEB types (SEB1 and SEB2, with low and high S contents, respectively), and an unamended control (CK)]. These treatments were evaluated under two P fertilizer rates [75% (P75) and 100% (P100) of the recommended dose] over 120 days. The results demonstrated that SEB significantly enhanced P availability and cycling, as evidenced by increases in labile, moderately labile, and non-labile P fractions. Notably, SEB application resulted in substantial increases in resin-P (84.4% at P100 and 67.2% at P75) and $NaHCO_3$-Pi (31.6%-34.5%) concentrations, accompanied by a marked rise in $NaHCO_3$-Po, indicating enhanced microbial P cycling. Moderately labile P pools, such as NaOH-Pi, peaked at day 60, with increases of up to 9.9% (P100) and 20.8% (P75), and were accompanied by continuous increases in NaOH-Po and Dil. HCl Pi. Furthermore, SEB also elevated the non-labile P fraction (residual P), indicating improved P stabilization. Additionally, SEB stimulated C-, P-, and S-acquisition enzyme activities, suggesting enhanced microbial nutrient cycling. In summary, these findings demonstrate that SEB provides a low-input, multifunctional strategy to improve P cycling, enhance SOC, and strengthen C-stabilization in agroecosystems, with significant potential for sustainable agricultural practices.

# Phosphorus Maximum Sorption Capacity in Soils from Paraná State in Southern Brazil

**Marcos Yassuhiro Inoue[1*], Esmeralda Aparecida Soares Garcia[1], Antonio Rafael Sánchez-Rodríguez[2], Oriel Tiago Kölln[1]**

[1]*Department ofAgronomy, State University ofNorthern Paraná, UENP Brazil*

[2]*Department ofAgronomy, University ofCórdoba, Córdoba, Spain*

antonio.sanchez@uco.es

**ABSTRACT**

Soils located in the state of Paraná, in southern Brazil, are largely weathered and characterized by the presence of iron and aluminum oxides and hydroxides, which confer a high capacity for phosphorus (P) sorption. The maximum P sorption capacity (MPSC) corresponds to the maximum amount of P that a soil can retain and can be used as a complementary parameter to understand P dynamics in soils. The objective of this study was to estimate the MPSC of 26 representative soils from the state of Paraná and to evaluate its relationship with physicochemical and geographic attributes, especially clay content, total organic carbon (TOC), remaining P, and altitude. The MPSC was determined by fitting the Langmuir isotherm. TOC was estimated by wet combustion using a dichromate solution followed by titration with ammonium ferrous sulfate. Remaining P was determined from the P concentration in solution after equilibrating the soil with a standard solution containing 60 mg $L^{-1}$ of P. Clay content was determined by the hydrometer method after mechanical dispersion and stabilization of the samples, using 1 mol $L^{-1}$ NaOH as the chemical dispersant. The sampled soils showed MPSC values ranging from 30 mg $kg^{-1}$ to 2930 mg $kg^{-1}$, with most presenting values above 500 mg $kg^{-1}$. A positive correlation was observed between MPSC and clay content ($\rho = 0.41$, $p = 0.041$), indicating a greater P retention capacity in soils with higher clay contents. Remaining P showed a negative correlation with MPSC ($\rho = -0.98$, $p = 2.8 \times 10^{-7}$), confirming its validity as an indirect and practical indicator of P retention capacity. TOC showed a positive correlation with MPSC ($\rho = 0.92$, $p = 1.5 \times 10^{-11}$), indicating that soils with higher organic matter content have a greater capacity to retain P. Altitude was also positively correlated with MPSC ($\rho = 0.73$, $p = 2.7 \times 10^{-11}$), demonstrating the indirect influence of pedogenetic factors, as well as greater or lesser preservation of organic matter under higher- altitude conditions. Overall, the results showed that clay content, as an indicator of P retention capacity, shows lower sensitivity to the mineralogy of the clay fraction when compared with remaining P. TOC and altitude do not directly control MPSC in the same way as the mineral fraction. Their relationship is modulated by pedogenetic processes and by climatic and textural soil conditions, which influence the preservation of soil organic matter and the mineralogy of the clay fraction. These results contribute to the understanding of P dynamics in weathered soils and to a more efficient management of soil and fertilization.

**ABSTRACT**

*Background and aims* Intercropping has been demonstrated to enhance crop productivity and phosphorus (P) uptake, in which root-microbe interactions played crucial roles. Our previous results showed that this beneficial effect of intercropping depends largely on a match between root traits and rhizosphere processes. However, little is known about the role of soil microbial communities in underground processes.

*Methods* Using a long-term field experiment with three P-fertilizer application rates and five cropping systems of maize, we integrated crop productivity, root physiological traits, root morphological traits and microbial amplicon sequencing data.

*Results* Our findings revealed that intercropping significantly enhanced maize crop productivity and P uptake, accompanied by increased plasticity of morphological and physiological root traits compared with monoculture. Additionally, intercropping with different companion crops significantly altered the soil microbial community structure of maize, while P-fertilizer application rates had minimal effect. Network analysis showed that intercropping promoted more complex and stable microbial networks characterized with increased cooperative relationships, relative to monoculture. The relative abundance of keystones enriched in intercropping systems were positively correlated with crop productivity and P uptake, explaining 41.11% of the variation in maize grain yield. Structural equation modeling (SEM) further indicated that keystones enhanced grain yields of maize by inducing carboxylate secretion and fostering more acquisitive root morphological traits.

*Conclusion* Our study elucidates how intercropping optimizes root-microbe synergies to improve P efficiency, highlighting the potential for targeted manipulation of keystone microbial taxa to enhance P acquisition and crop performance in sustainable agricultural systems.

**ABSTRACT**

Seabirds have a vital ecological role as linkage service between marine and terrestrial ecosystems. The amounts of excreted P inputs by seabirds to soils is ~100 Gg P yr and similar in magnitude to other fluxes in global P cycles (Otero et al. 20218). The studies on resulting 'ornithogenic soils', terrestrial environments significantly altered by the accumulation of large amounts of materials in bird colonies (e.g., guano, feathers, eggshells) mainly focus on the cold or wet regions of our planet. However, even in the driest place on earth, the hyper-arid core of the Atacama desert we find breeding seabirds. This unique situation allows here, due to the absence of co-founding vegetation P inputs, to precisely quantity such 'marine derived' seabird total and soluble P soil inputs to terrestrial ecosystems. Enlightenment on the actual baseline contribution and importance of seabirds (and birds in general) to soil P provision, is critical for future design into approaches to sustainable optimizing of nutrient management and ecosystem functionality, especially in the wider context of the worrying global decline in bird numbers and its diversity.

# Integrating regional critical boundaries and nitrogen-phosphorus limitation for global water quality

## ABSTRACT

Intensive crop production in recent decades has greatly increased nitrogen (N) and phosphorus (P) delivery to surface waters, causing severe water quality degradation and widespread eutrophication. Although regional safe boundaries for N delivery to surface waters have been proposed to support sustainable food production, comparable boundaries for P remain absent. Spatial variations in molar N:P ratios in nutrient delivery from cropland reveal region-specific nutrient imbalances, underscoring the need for differentiated nutrient management across regions. Using a spatially explicit modeling framework, we show that aggregating regional boundaries yields global boundaries of 7.3 and 1.0 million tons per year for N and P delivery to surface waters, respectively. In 2020, actual delivery exceeded these limits by 53% for N and 375% for P. Despite the greater magnitude of P exceedance, prioritizing N management proves to be a more effective strategy for mitigating eutrophication in most world regions, given the widespread occurrence of N limitation in aquatic ecosystems (N:P < 16). Integrating boundary exceedance with nutrient limitation analysis indicates that targeted nutrient reduction efforts could reduce global N and P delivery by 73% and 61%, respectively, providing a feasible pathway to restore water quality and protect aquatic ecosystems.

# Exploring characterization methods and thresholds of carbon-phosphorus ratio for promoting crop growth and microbial phosphorus activation

## ABSTRACT

To investigate the impact of microorganisms on enhancing crop phosphorus nutrition after increasing the soil carbon-to-phosphorus ratio by adding carbon sources in calcareous soils, and to clarify the key thresholds and optimal characterization methods of soil carbon-to-phosphorus ratio in farmland, this study designed a two-factor randomized block experiment. Carbon was added at levels of 0, 30, 60, 120, 180, 240, 360, and 480 mg/kg in single applications, with soil available phosphorus levels at 9 mg/kg, 22 mg/kg, and 50 mg/kg. By establishing relationships between indicators such as SOC/Olsen-P, DOC/Olsen-P, and DOC/Pw, and microbial phosphorus-solubilizing ability, crop biomass, and phosphorus uptake, the study analyzed the impact of carbon-to-phosphorus ratio regulation on microorganisms for efficient utilization of accumulated phosphorus. The following conclusions were drawn:

1. Under different levels of available phosphorus in soil, with the increase of carbon addition, the biomass, phosphorus uptake, and soil microbial biomass phosphorus of plants all increase, while the available phosphorus and alkaline phosphatase activity in soil show a trend of first increasing and then decreasing.

2. SOC/Olsen-P is the best indicator of the relationship between the carbon-phosphorus ratio in calcareous soil and crop biomass and phosphorus uptake. According to the linear plus plateau model, the regulation threshold of the carbon-phosphorus ratio in calcareous soil is 745~867.

In summary, this study found that regulating the soil carbon-phosphorus ratio can enhance microbial activity and promote crop growth and phosphorus absorption. It clarified the threshold value of carbon-phosphorus ratio and its characterization indicators for promoting crop phosphorus absorption, established a method for altering the soil carbon-phosphorus ratio to regulate indigenous microorganisms and promote phosphorus activation and turnover, and provided a theoretical References for efficient utilization of soil phosphorus.

**ABSTRACT**

Substitution of mineral fertilizers with milk vetch (*Astragalus sinicus* L.) organic fertilization strongly influences the dynamics and availability of phosphorus (P) in soil. How milk vetch organic fertilization affects the specific roles of P cycling functional genes in soil and, in turn, the mechanisms of altered P turnover remain unclear. Soil samples were taken from a 10-year field experiment that included mineral fertilizer and partial substitution of mineral fertilizer with milk vetch, together with an unfertilized control. The P-cycling functional genes in soil determined by metagenomics were related to phosphatase enzyme activities and P fractions with various availability. Milk vetch substitution decreased soil total P and $NaHCO_3$-OP (8 and 65%) but maintain similar available P and high phosphatase activities compared with mineral fertilizer, indicating a net solubilization/mineralization of soil P occurring in response to milk vetch substitution. The Proteobacteria, followed by Chloroflexi, Acidobacteria, Actinobacteria, Nitrospirae, Verrucomicrobia, and Gemmatimonadetes were the most abundant bacteria phyla involved in soil P-cycling. Shifts in P-cycling functional gene community were more related to soil total N and the ratio of SOC to total P. The relative abundance of P-cycling functional genes, increased the production of PQQ-GDH (*gcd*, *pqqE*), fumaric acid (*fumC*), acetic acid (*aldh*), acid phosphatase (*phoN*), alkaline phosphatase (*phoD*), the catabolism of organophosphonates (phnJ, phnN, and phnW) and the dissimilation of glycerol-3-phosphate (*glpB*, *glpF*, and *glpR*) by 4%–80%. Phosphatase activities increased with milk vetch substitution, because of raised abundance of related genes and gene-harboring communities (especially Chloroflexi). The *phoN* gene was the key predictor of organic P mineralization and thus available P. Overall, milk vetch substitution increased the P-acquiring enzyme activities and boosted the involvement of the functional genes in P cycling, which in turn stimulated P bioavailability. These results highlight the connections between milk vetch substitution and P cycling functional genes, which also have implications for offsetting the future demand for P mineral fertilizer by milk vetch substitution in agricultural systems.

**ABSTRACT**

Biochar is increasingly promoted as a climate-smart amendment, yet its long-term effects on nutrient retention and greenhouse gas emissions in flooded rice systems remain poorly resolved. Here we combine a 13-year field trial with graded straw biochar applications (0-22.5 t $ha^{-1}$ $season^{-1}$) and a 60-day anaerobic incubation of year-13 soils, to investigate how mineral and microbial processes regulate soil organic carbon (SOC), phosphorus (P), and methane ($CH_4$) dynamics. Long-term biochar progressively depleted Fe oxides and enriched Ca phases, promoting the formation of Ca bridged OC-mineral-P complexes that co-stabilize OC and P. Under prolonged anoxia, soils amended with high rates of biochar exhibited 2.5-3.2 fold slower Fe(III) reduction and delayed sulfate reduction, resulting in 53-80% lower $CH_4$ emissions and 60-71% P release relative to the no-biochar control. Nanoscale imaging and microbial profiling corroborated this mineral transition, showing a shift toward redox-resilient organo-mineral complexes and microbial communities associated with suppressed methanogenesis and enhanced nutrient retention. These findings provide the long-term field-based evidence that biochar can simultaneously sustain crop productivity, enhance C and P retention, and mitigate $CH_4$ emissions in flooded rice agroecosystems. Our findings highlight biochar's potential as a scalable nature-based strategy for integrating nutrient management with climate mitigation in global rice production.

**ABSTRACT**

The Philippines faces a phosphorus (P) paradox, characterized by persistently low yields among rural farmers due to P deficiency in soils, contrasted with P surpluses in urban and intensively farmed regions. Aiming for a more circular P use, this study evaluated three iron (Fe)-based adsorbents, i.e., synthetic layered double hydroxide (LDH), ferrihydrite, and schwertmannite, for P removal from synthetic solutions and real wastewater. Full isotherms for the three adsorbents were first established using synthetic P solutions. A subsequent comparative experiment evaluated adsorption at matched concentrations (5, 8 and 16 mg P $L^{-1}$) in both synthetic solutions and wastewater collected from sewage treatment plant, a dairy milking facility and a dairy processing plant. Langmuir isotherm indicated that synthetic LDH exhibited the highest adsorption capacity at 19.31 mg P $g^{-1}$, nearly double ferrihydrite (10.33 mg P $g^{-1}$), while schwertmannite was lowest (2.95 mg P $g^{-1}$). Freundlich models provided the best fit, suggesting multilayer adsorption. P uptake by adsorbents peaked in synthetic P solutions at 16 mg P $L^{-1}$ (~7 mg P $g^{-1}$ for LDH and ferrihydrite) but declined markedly in wastewater (~4-5 mg P $g^{-1}$ ). Synthetic LDH and ferrihydrite achieved near-complete P removal in synthetic solutions; however, their efficiencies declined by more than 90% in wastewater matrices. In contrast, schwertmannite exhibited superior performance under real wastewater conditions, attaining 60% removal at the lowest tested concentration. These findings highlight that removal efficiency was influenced by both sorbent properties and matrix chemistry. Overall, Fe-based adsorbents demonstrate strong potential for P recovery, offering a dual strategy to mitigate wastewater P excess and address soil P deficiencies in crop production systems.

**ABSTRACT**

Recycling lake sediments as phosphorus (P) fertilisers offers a promising pathway to close nutrient cycles, reduce reliance on synthetic P inputs, and potentially mitigate P losses to freshwater systems. Within a broader context, lake sediments arise as a by-product of lake restoration initiatives across Europe, such as the FERRO project (Fostering European Lake Restoration). This project, alongside other restoration approaches, involves the removal of substantial quantities of nutrient-rich sediments as part oflake recovery strategies. These sediments have been extensively monitored and are known to contain high concentrations of P. Their reuse in agricultural systems as P fertilisers therefore represents an opportunity to valorise a restoration by-product, enhance nutrient recycling, and support both sustainable agriculture and long-term lake restoration outcomes. Here, we present results from studies evaluating the use of lake sediment as an alternative P fertiliser under both controlled (I) and field conditions (II). I) A 45-day pot experiment with pea (*Pisum sativum* L.) was conducted using lake sediment and mineral fertiliser as P sources, alongside an unfertilised control. Plant biomass, nutrient uptake, and rhizosphere soil properties, such as nutrient availability, cation exchange capacity (CEC), and enzyme activities, were assessed. (II) A 78-day field experiment with pea was established at an agricultural site near the lake where sediment dredging had occurred, comparing the same treatments. In the pot experiment, P source influenced both plant and soil responses with sediment-amended treatment producing biomass comparable to mineral fertiliser, while enhancing nutrient uptake, CEC, and rhizosphere functionality. In the field experiment, no statistical differences in biomass were detected among P sources, although both P treatments tended to produce higher biomass compared with the unfertilised control. Furthermore, sediment-amended plots in the field showed indications of improved below-ground responses and a reduced potential risk of P leaching compared with mineral fertiliser treatments, based on water-extractable P, which was higher in the mineral-fertilised treatment. Overall, these findings indicate that dredged lake sediment can function as an effective P source under controlled conditions and may deliver environmental benefits under field conditions. Recycling lake sediment as a fertiliser supports circular nutrient management and represents a promising strategy within European lake restoration initiatives; we speculate that these effects may be even more pronounced in agricultural systems with lower background soil P availability, as the soil used in our trials had a high P status.

## ABSTRACT

Enhanced rock weathering involves crushing rocks, such as basalt, and applying them to cropland to accelerate the natural weathering of basaltic minerals, including plagioclase (e.g., $CaAl_2Si_2O_8$) and pyroxene, thereby removing $CO_2$: $CaAl_2Si_2O_8 + 2CO_2 + 3H_2O \rightarrow Al_2Si_2O_5(OH)_4 + 2Ca^{2+} + 2HCO_3^-$. Despite numerous recent studies, direct evidence of basaltic mineral weathering in soils is lacking. Here, we applied quantitative X-ray powder diffraction (XRPD) to detect changes in basaltic minerals in cropland.

A field experiment was conducted in a buckwheat field with brown lowland soils (pH 6.0) in Fukushima, Japan, from July 27 to October 12, 2022. Two treatments were set: without basalt powder (control) and with basalt powder applied at 150 t $ha^{-1}$. Soil samples were collected from the surface before planting, and from both the rootzone and the non-rootzone after harvest. The mineral composition of air-dried, 2 mm-sieved soils was quantified by XRPD [1]. Soil water samples at 10 cm were collected on September 2 and 23 to determine pH and inorganic carbon, and bicarbonate ($HCO_3^-$) concentration was calculated.

Major basaltic minerals in the basalt were plagioclase (i.e., labradorite [31.1 wt.%] and bytownite [36.2 wt.%]) and pyroxene (10.8 wt.%). Basalt application significantly ($p < 0.05$) increased these minerals in soils. After cultivation, bytownite and pyroxene in the buckwheat rootzone decreased significantly, from 4.7 to 1.9 wt.% and from 1.1 to 0.38 wt.%, respectively. In contrast, no significant decrease was observed in the non-rootzone, likely due to lower $CO_2$ partial pressure, organic acid release, and elemental uptake. The percentages of decrease to input in the rootzone were 58.8% for bytownite, 65.1% for pyroxene, and 25.6% for labradorite, reflecting higher dissolution rates of bytownite and pyroxene. Alongside these decreases, kaolin [$Al_2Si_2O_5(OH)_4$], a weathering product of plagioclase, increased significantly, and its increase correlated significantly ($r = 0.84$) with the decrease in plagioclase. As no carbonate minerals increased and $HCO_3^-$ showed an increasing trend ($p < 0.10$) relative to the control, we considered that basaltic mineral weathering primarily consumed $CO_2$ to produce $HCO_3^-$ rather than forming pedogenic carbonates under Japan's high-precipitation and acidic soil conditions. In conclusion, we successfully detected, for the first time, actual weathering of basaltic minerals applied to cropland, enabling quantitative verification of mineral weathering under field conditions.

# Pedogenic Carbonates and Calcimetry Near Detection Limits: Field-scale weathering dynamics in wollastonite-amended clayey/acidic soils

**Francisco S.M. Araujo[1*], Yi Wai Chiang[1], and Rafael M. Santos[1*]**

[1] *Department of Civil, Environmental, and Water Resources Engineering, University of Guelph, Guelph, Canada*

*santosr@uoguelph.ca

**ABSTRACT**

Enhanced Rock Weathering (ERW) is increasingly evaluated through alkalinity generation and bicarbonate export, yet in field systems dominated by rapid carbonate cycling, solid-phase pedogenic carbonates may offer a conservative and measurable proxy for carbon dioxide removal (CDR). In this study, we applied wollastonite, a highly reactive calcium silicate mineral, to cropland soils in the Port Colborne area of Southwestern Ontario, classified as Humic Luvic Gleysols (Jeddo series), developed in reddish-hued lacustrine clay with poor to imperfect drainage, clay loam textures, and moderately acidic pH (~6.2–6.5) (Kingston and Presant, 1989). These soils are typically considered marginal for carbonate formation due to high bulk density and seasonal water saturation, yet pedogenic carbonates are consistently observed following wollastonite amendment (Araujo and Santos, 2025).

For the first time, we conducted monthly measurements of soil pH and calcimetry over a full growing season, enabling resolution of short-term carbonate precipitation and re-dissolution dynamics. Despite carbonate concentrations near the detection limits of calcimetry, we observed statistically significant pH increases (~+1.0 unit) and measurable carbonate fluxes ($\Sigma\Delta CCE/\Delta t$), confirming that wollastonite can induce carbonate formation even under conditions not typically considered favorable for precipitation. These results build on prior validation of calcimetry for ERW monitoring (Silva et al., 2024), and demonstrate its sensitivity in marginal soil contexts. We hypothesize that localized microenvironments near silicate particles may exhibit elevated pH, enabling carbonate formation not predicted by bulk soil chemistry, a mechanism supported by prior column studies (Khalidy et al., 2023).

Rainfall was found to modulate carbonate formation, with cumulative precipitation over the preceding 7–10 days enhancing fluxes up to a saturation threshold (~30 mm), while dissolution fluxes remained largely independent of rainfall. This study also represents our first direct observation of carbonate cycling in the field, and provides a more dynamic view of ERW behavior than previous trials (Khalidy et al., 2025). By comparing calcimetry-derived fluxes with kinetic dissolution models and prior field studies, we help close the gap between theoretical weathering rates and those observed under real agronomic conditions. These findings support the integration of solid-phase carbon tracking into MRV frameworks and broaden the applicability of ERW monitoring approaches in temperate agroecosystems.

# Reframing Carbon Accounting in Enhanced Rock Weathering: Counterfactuals, stoichiometry, and MRV implications

**Karam Abu El Haija[1*], Yi Wai Chiang[1], and Rafael M. Santos[1*]**

[1] *Department of Civil, Environmental, and Water Resources Engineering, University of Guelph, Guelph, Canada*

*santosr@uoguelph.ca

## ABSTRACT

Enhanced Rock Weathering (ERW) is increasingly positioned as a scalable carbon dioxide removal (CDR) strategy, yet its credibility depends on reconciling idealized stoichiometric assumptions with field-scale realities. This perspective introduces a geochemically grounded accounting framework that integrates counterfactual scenarios and proposes a conservative baseline of one mole of $CO_2$ removed per mole of alkaline earth metal (AEM) weathered. While ERW is often modeled with a 2:1 molar ratio of $CO_2$ removal per mole of Ca or Mg (Beerling et al., 2020; 2025), this ideal assumes complete weathering, uninterrupted alkalinity transport, and permanent ocean storage. Field evidence and geochemical modeling show that these assumptions are frequently unmet due to acidic soil conditions, carbonate precipitation, and degassing during hydrological transit (Renforth and Henderson, 2017; Holden et al., 2024).

By considering counterfactuals such as carbonate liming and natural carbonate weathering, the net climate benefit of ERW is reframed. Silicate weathering often displaces processes that would otherwise release $CO_2$, such as acid-driven carbonate dissolution (Hamilton et al., 2007; Kaushal et al., 2013; Müller et al., 2020; Khalidy et al., 2022), thereby preserving native or added carbonates. This preservation, termed Natural Carbonate Protection (NCP), complements direct CDR and contributes to the total climate benefit. A stoichiometric model is presented to partition climate benefits into CDR and NCP, showing that the sum remains two moles of $CO_2$ per mole of AEM, but that only one mole should be credited as CDR under typical field conditions.

This reframing has implications for Monitoring, Reporting, and Verification (MRV). A 1:1 baseline simplifies MRV by focusing on direct indicators of weathering, such as cation flux, rather than requiring full tracking of bicarbonate fate. Projects may scale toward higher ratios only with robust evidence of carbonic acid-driven weathering, negligible counterfactual alkalinity, and demonstrated permanence. This tiered approach supports scalable, credible ERW deployment while maintaining scientific integrity and market confidence.

# Subsurface and surface transport of crushed basalt

**Taku Nishimura[1*],Takuhei Yamasaki[1], and Yuji Yamashita[1]**

[1] *Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan*

*atakun@g.ecc.u-tokyo.ac.jp

**ABSTRACT**

Carbon Dioxide Removal (CDR), which removes $CO_2$ from the atmosphere, has been considered as a mitigation measure for global warming. One CDR method is the enhanced weathering of easily weathered rocks in soil. When crushed basalt is mixed with soil, the reaction of basalt with $CO_2$ in the air phase produces the bicarbonate. Either by entering groundwater as percolating water or by forming carbonates due to drying, $CO_2$ is fixed in the vadose zone. Finely crushed basalt is better for this purpose because it has a higher specific surface area. However, it is well known that fine mineral particles tend to move with flowing water. There was almost no information on the migration of incorporated fine basalt particles in soil. In this study, we conducted a preliminary experiments to examine the transport of crushed basalt particles through and above the soil.

Column percolation experiment and simulated rainfall experiment with a soil box were conducted. In the column experiment, two types of basalt mixing were carried out: one mixed basalt into the entire 25 cm layer, and the other mixed it into only the top 10 cm layer. Pure water was applied at 15 mm per day for 30 days. During the percolation, drainage from the column was periodically sampled, and cation and anion concentrations were analyzed. After the 30-day percolation, the soil column was sectioned into 1-5 cm layers, and the basalt content in each layer was measured. For the rainfall experiment, soil was packed into a 20 cm x 50 cm box with a 4 cm soil thickness. A 60 mm $h^{-1}$ simulated rainfall was applied for 60 min. During the rainfall, discharged sediments were sampled periodically, and after the rainfall, basalt contents of the surface soil were measured. Quantification of basalt in soil and sediment samples was conducted using X-ray powder diffraction (XRPD) by a method reported by Kurokawa et al. (2024). Andisol and Kunigami mahji soil (Hapludalt) were used. Basalt was crushed to a particle size < 0.1 mm. Basalt was applied at 10% or 20% by mass to the entire soil.

Results of column experiments with two different mixing depths suggested that the applied crushed basalt decreased due to reaction with $CO_2$ and other acids in soil, but the basalt itself did not move through the soil. Weathering of the basalt estimated from discharged cations and inorganic carbon was smaller than that estimated from XRPD analysis. Rainfall experiments showed that sediment discharge increased with increasing applied basalt. This is consistent with the understanding that areas with a higher fine-sand content are more susceptible to water erosion. Due to the sediment discharge from the box with a short slope length, the basalt content of the soil at the upstream decreased. This result suggests that topography should be considered when spreading basalt in situ and when assessing the amount of weathering of incorporated basalt.

# Reframing Soil Carbon Stabilization: The Reactive Mineral Sink (RMS) Model and Its Synergy with Enhanced Mineral Weathering

**Songlin Wu**[1, 2,*], **Tong Liu**[1, 2], **Baodong Chen**[1, 2]

[1] *State Key Laboratory of Regional and Urban Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, 100085 China*

*E-mail Address of Presenting Author: *slwu@rcees.ac.cn*

**ABSTRACT**

Reactive primary and secondary minerals play a pivotal yet underrecognized role in the transformation and stabilization of organic matter (OM) in soils. To address this gap, we introduce the Reactive Mineral Sink (RMS) model[1], which conceptualizes the key mechanisms through which reactive minerals govern the bioprocessing, transformation, transport, and long-term stabilization of OM. The RMS model encompasses three interconnected pathways. Biologically, reactive minerals modulate enzymatic and microbial processing of OM by binding extracellular enzymes and shaping microbial community structure and function. Chemically, they facilitate OM stabilization through adsorption and coprecipitation while simultaneously catalyzing OM transformation via surface-mediated reactions, including redox processes and mineral-induced catalysis. Physically, reactive minerals influence soil architecture - modifying aggregation, porosity, and hydrological flow paths - which in turn regulates OM transport, accessibility, and persistence.

The RMS framework provides an important and emerging insights for enhanced mineral weathering (EMW) as a soil carbon sequestration strategy. EMW accelerates the dissolution of silicate minerals, generating new reactive mineral surfaces and secondary weathering products that expand the mineral-associated organic carbon pool. By supplying fresh reactive phases and altering soil geochemistry, EMW reinforces all three RMS pathways: it stimulates microbial and enzymatic activity through nutrient release, increases chemical sorption and coprecipitation capacities, and promotes structural changes that stabilize carbon physically.

Together, the RMS model provides a comprehensive lens for understanding how reactive minerals regulate OM dynamics and soil carbon sequestration. It also highlights opportunities to restore soil biogeochemical function and enhance ecological resilience. We advocate for management strategies grounded in the RMS framework—including EMW-based approaches—to maximize organic carbon retention in soils, rejuvenate soil health, and contribute meaningfully to $CO_2$ mitigation.

## ABSTRACT

Enhanced rock weathering (ERW) has been proposed as an effective $CO_2$ sequestration strategy in agricultural systems through the application of crushed silicate rock powders. However, its effects on soil physical properties and $CO_2$ dynamics remain poorly understood, particularly under field conditions, where soil structure and moisture dynamics play critical roles in regulating gas exchange. Based on two years of field monitoring in the same farmland where crushed basalt powders were applied, the continuous impact of basalt application on soil physical properties and $CO_2$ dynamics was investigated. Field monitoring was conducted at an agricultural field with gray lowland soil at Hokkaido University, Japan (43.07° N, 141.34° E) during the 2023 (soybean, Glycine max) and 2024 (feed maize, Zea mays) growing seasons. Continuous measurements of soil $CO_2$, $O_2$, moisture, EC, temperature, and water potential were taken at depths of 10, 25, and 40 cm under four treatment regimes: Basalt–No Crop (BNC), Basalt–Crop (BC), No Basalt–Crop (NBC), and No Basalt–No Crop (NBNC; only in 2024). HYDRUS-HP1, which couples the Hydrus-1D model with the PHREEQC geochemical code, was tested for simulating soil water, temperature, and $CO_2$ behavior under silicate rock powder applications.

Measurements of soil physical properties showed an increase in dry bulk density, resulting in reduced total porosity in the BC and BNC plots. This change was attributed to pore clogging by the applied rock powder. In addition, the measured water retention curves exhibited enhanced water retention in the basalt-treated plots. In 2023, soil $CO_2$ concentrations at 10 cm depth were significantly higher in the BC plots compared to the NBC plots. The estimated net $CO_2$ production rate at 10 cm depth was also greater in the BC plot than in the NBC plot. In 2024, although the difference in $CO_2$ production rate between the basalt-treated and untreated plots was smaller than that observed in 2023, the cumulative $CO_2$ production rate remained higher in the basalt-treated plots. An increase in soil pH was observed in the basalt-treated plots, likely due to mineral weathering. Therefore, further investigation is needed to clarify how changes in soil pH influence the rate of organic matter decomposition (i.e., $CO_2$ production rate). Numerical simulations that incorporated basalt weathering successfully reproduced the observed soil moisture, temperature, and $CO_2$ dynamics with high accuracy. In the future, sensitivity analyses of environmental factors such as air temperature, rainfall patterns, and soil organic matter content on soil $CO_2$ dynamics and carbon sequestration will be conducted.

**ABSTRACT**

Powdered silicate rocks added to acid soils may remove atmospheric carbon dioxide by forming bicarbonates ($HCO_3^-$) eventually stored in oceans. A 10-ha farm-scale study with reduced-tillage in Maryland, USA, with Ultisols (initial $pH_w$ 5.7-6.0) formed from shale or limestone was begun October 2023 when we applied metabasalt powder at 17 and 34 Mg/ha (1x and 2x the rate modeled to raise soil pH equivalent to the recommended limestone), 3.4 Mg/ha limestone, and an unamended control. Wheat was planted in late October 2023, followed by soybeans planted in July 2024, a wheat cover crop in October 2024, and maize in June 2025. We periodically sampled soils from 0-10, 10-20, and 20-30 cm depths, and macropore water at 60 and 90 cm (by suction lysimeters). We measured pH (in water, 0.01*M* $CaCl_2$, and 1*M* KCl ), electrical conductivity (EC), dissolved $HCO_3^-$, and magnesium. We sampled winter wheat leaves in May, wheat grain in July, and soybean foliage in August 2024.

We conducted an aerobic lab incubation of limestone, olivine, and metabasalt powders mixed with high soil organic matter (SOM) topsoil (0-10 cm) or low SOM subsoil (20-30 cm) from four soils (initial $pH_{water}$ 4.6 to 5.6), ranging from loamy sand to silty clay loam kept at 20 ºC and 50-60% water-filled pore space. After 0, 30, 90, and 240 days, soils were mixed 2:1 soil:water, and the EC, $pH_{water}$,$pH_{CaCl2}$, $pH_{KCl}$ , and dissolved $HCO_3^-$, in the suspension were measured.

In the field study, by early April 2024, the pH of 0-10 cm soils treated with limestone was significantly higher than in the control and 17 Mg/ha metabasalt. The 34 Mg/ha metabasalt soil pH was intermediate. After 18 months, only limestone treatment had significantly higher pH than the control. No treatment effects were detected below 10 cm. Soil $pH_{CaCl2}$ and $pH_{KCl}$ were less variable than $pH_{water}$. Soil EC fluctuated with time and soil depth, but was elevated in limestone plots. There were no differences in the porewater $HCO_3^-$ among rock treatments. No treatment effects were observed on elemental concentrations in any plant samples.

During the incubation study, EC increased from < 100 mS/cm to > 500 mS/cm in the topsoils, but only from 50 to 100 mS/cm in the subsoils, suggesting SOM mineralization dominated over rock powder weathering. Mean $pH_{CaCl2}$ of unamended topsoils declined from 4.5 to 4.0, while rising to 4.6, 5.4, and 6.8 in the topsoils amended with metabasalt, olivine, and limestone, respectively. In the subsoils, $pH_{CaCl2}$ reached levels of 6.2, 6.5, and 7.3, respectively, suggesting less buffering with lower SOM. After 90 days of incubation, $HCO_3^-$ averaged 2.2, 7.3, 10.5, and 10.6 mg/L for the soils amended with no rock, metabasalt, olivine, and limestone, respectively. Thus, both silicate rocks dramatically increased $HCO_3^-$ in the static incubation, but no increase was detected in the field leaching water sampled from metabasalt plots.

# Column experiment and numerical simulation for quantification of carbon fixation by enhanced rock weathering

**Takuhei Yamasaki*, Yuji Yamashita, and Taku Nishimura**

*The Graduate school of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan*

*Yamasakit-chisui@g.ecc.u-tokyo.ac.jp

**ABSTRACT**

Enhanced rock weathering (ERW) is a promising carbon dioxide removal technology by silicate mineral dissolution with $CO_2$. Though numerous laboratory and field trials have been conducted to assess the effectiveness of ERW, accurate quantification of carbon fixation remains challenging. The common approach estimates carbon sequestration from the concentrations of cation released by basaltic mineral dissolution (mainly Ca and Mg). However, this method must account for mineral weathering caused by other acids present in soil, such as nitrates, sulfates, and organic acids. Alternatively, bicarbonate leaching will provide a direct indicator of carbon fixation by ERW, but its application in field condition is difficult because bicarbonate is not conservative after sampling.

To compare these quantification methods, we conducted controlled column experiments and numerical simulations. The acid red soil from Okinawa Prefecture, Japan was used. The soil pH (1:5 H2O) was 5.6. The basalt powder was composed mainly Ca-plagioclase (60%) and median diameter was 66 μm. The soil and basalt were mixed with 10:1 mass ratio and packed into a cylindrical column at 25 cm in height. Pure water was supplied at 15 mm/day for one month (total 450 mm), and effluents at the bottom were sampled. pH, EC, major cations (Na, K, Ca, Mg), anions (Cl, nitrate and sulfate) and total inorganic carbon in the effluents were analyzed. After the leaching experiment, the dissolution of Ca-plagioclase was evaluated by the X-ray powder diffraction. Experimental results were reproduced using a coupled HYDRUS-1D and PHREEQC (HP1) reactive transport model. Plagioclase dissolution was expressed as the first-order reaction proportional to mineral surface area.

Bicarbonate concentrations in the effluents were approximately 100 times higher than those expected from equilibrium with the soil $CO_2$ concentration in the column (0.1%), showing great enhancement of $CO_2$ leaching by ERW. However, most of anions in the effluents were chloride and sulfate, suggesting that weak carbonic acid was not dominant proton source for silicate dissolution in this acidic soil environment. XRD analysis showed that 57% of the added Ca-plagioclase had dissolved, whereas Na-plagioclase which originally contained in the soil remained unchanged, consistent with the dissolution kinetics of plagioclase minerals (Ca>>Na).

**ABSTRACT**

Soil science and geology, once intertwined, have long evolved in isolation and remain largely disconnected in Japan to this day. Although the Fukushima nuclear accident drew geochemists' attention to soil mineralogy—particularly the specific adsorption mechanisms of radiocesium on 2:1 clay minerals—most soil scientists have rarely crossed disciplinary boundaries to engage with geology. Enhanced rock weathering (ERW) offers a unique opportunity to bridge this gap, fostering collaboration between these historically separated fields.

In 2022, the new project "Advanced enhanced rock weathering technology development (A-ERW)" funded by New Energy and Industrial Technology Development Organization (NEDO), Japan, was launched. The project encompasses multi-site field experiments to investigate the effect of basalt powder amendment on soil fertility, plant nutrition, and carbon budget. We applied same basalt to the top soil at a mixing ratio of 10 wt% across eight sites: three rice fields, two soybean fields, one sugarcane field, one buckwheat field and one sugar beet field, all subjected to continuous cultivation trials for two to three years.

Soil pH increased consistently by 0.5-1.0 unit after amendment and remained higher than control plots throughout the experiments. Significant weathering of minerals in basalt powder, i.e., Ca-rich feldspars (bytownite and labradorite) and pyroxenes (diopside), was confirmed using quantitative X-ray diffraction method in several research sites. Net negative carbon emission relative to control plots was observed in soybean fields, based on $CO_2$ flux monitoring (chamber method) and soil sensors. Increased availability of basalt-derived nutrients (e.g., Si and Mg) and corresponding improvements in crop performance, including increase in yield or better nutrient balances, were evident especially for *Poaceae* crops such as rice and sugarcane, whereas no significant adverse effect was observed in other crops examined.

Thus, a single basalt amendment can modify soil mineralogy and provide multiple benefits for soil rejuvenation, including acid neutralization, greenhouse gas mitigation, and improving nutrient status. Since the Green Revolution, modern agriculture relies heavily on chemical fertilizers containing nitrogen, phosphorus, and potassium. Supply of rock-derived micro- and macro-nutrients has long been dismissed in the fertilization strategies. Exploring the nexus between geomaterial weathering, carbon cycling, and nutrient dynamics represents a new challenge for soil science, paving the way for a broader One Health framework that includes geology.

**ABSTRACT**

Among carbon dioxide removal (CDR) technologies, the enhanced rock weathering (ERW) using finely ground basalt to farmlands has emerged as a promising nature-based solution that can both improve soil health and reduce $CO_2$ emissions. Despite its application across diverse farmland systems, the efficiency of ERW under flooded conditions remains poorly understood. Rice paddy system is one of the major sources of anthropogenic methane ($CH_4$); therefore, any increase in $CH_4$ emission following basalt application could offset the $CO_2$-based CDR potential of ERW. Thus, this study aimed to quantify the impacts of ERW on carbon dioxide ($CO_2$), $CH_4$, and nitrous oxide ($N_2O$) emissions from paddy soils. A field experiment was conducted on Fluvisols in Kyoto in Japan in 2025 comparing a control plot and a basalt-amended plot (200 ton $ha^{-1}$) in triplicate. GHG fluxes were collected biweekly using the closed-chamber method. The results indicated that basalt amendment reduced $CO_2$ and $CH_4$ flux by about 20% and 10%, respectively, decreasing cumulative emissions of $CO_2$ and $CH_4$ by totally 0.58 t C $ha^{-1}$ during the five months of growing season, while $N_2O$ fluxes remained near detection limits. Nevertheless, the reductions of basalt-amended and control plots had no statistical significance. Although greenhouse gas fluxes significantly correlated with soil temperature, moisture, and Eh, these variables showed limited difference between treatments. In contrast, basalt amendment consistently increased soil pH by an average of 0.2 units relative to the control, with the difference becoming more pronounced during drainage periods. Although basalt amendment increased soil pH and reduced seasonal $CO_2$ and $CH_4$ emissions, the available field measurements were insufficient to identify the underlying mechanism. Thus, the biogeochemical pathways responsible for these changes cannot yet be resolved from the present dataset. This study provides the first field evidence of ERW potential in GHG mitigation in rice paddy systems. Future studies should incorporate measurements which can directly reflect biogeochemical dynamics. Furthermore, comparative analyses across climatic zones will be essential to determine whether the biogeochemical mechanism proposed in this study is consistent across paddy systems under different climatic conditions.

**ABSTRACT**

Enhanced Rock Weathering (ERW), using mafic rock powder (e.g., basalt) on agricultural land, is a carbon dioxide removal (CDR) strategy that offers the co-benefits of increasing soil pH and supplying essential elements like magnesium (Mg) and calcium (Ca). Additionally, plant promote mineral weathering in the rhizosphere, but there is few research on enhancement effect in rhizosphere on silicate mineral weathering in ERW application. This study investigated the reciprocal interactions between basalt powder application and soybean (*Glycine max* (L.) Merr.) growth in both pot and field experiments. In the pot experiment, soybean was cultivated in 3 kg of soil (gray lowland soil) for 118 days. Treatments included basalt treatments at 5, 10, and 20 wt.% (BA5, 10, 20), lime treatments (Lime5, 10, 20) matching the pH increase of BA treatments, and no application (Control). Planted and unplanted treatments were established for Control and BA treatments. At maturity (R8), shoot dry weight and element concentrations were measured. Soil was thoroughly mixed and sampled before planting and after harvest, and analyzed for soil pH and exchangeable cations (Ex-cations). The mineral weathering was quantified as ΔCa (or ΔMg), calculated as the sum of total Ex-Ca (or Ex-Mg) and total plant uptake at R8, minus the initial total Ex-Ca (or Ex-Mg). The field experiment included basalt plots (75, 150, 300 t $ha^{-1}$, equivalent to BA5, 10, 20), one lime plot (1.5 t $ha^{-1}$), and Control plot, all with planted and unplanted plots. Soil and plant samples were collected throughout the growing season and analyzed for the same parameters, with soil mineral composition assessed using X-ray Powder Diffraction (XRPD). Both experiments showed that basalt application increased soil pH and Ex-Mg, while lime application increased soil pH and Ex-Ca. Regarding soybean growth, significantly higher shoot dry weight was observed only in BA10 and BA20 compared to Control in the pot experiment, but no significant difference in the field experiment. The growth promotion in the pot experiment was correlated with Ex-Mg but not soil pH, and the limited soil volume led to lower post-harvest Ex-Mg levels compared to the field, both of which imply that the Mg supply from basalt was beneficial under these relatively low available Mg conditions. Indicators of mineral weathering showed a significant positive root enhancement effect: In the pot experiment, ΔMg was higher in planted treatments than in unplanted treatments. In the field experiment, the content of pyroxene (a major basalt mineral) in the soil was significantly lower in planted plots compared to unplanted plots in BA20. This root-enhanced weathering indicates a positive feedback loop that can accelerate CDR and nutrient supply in ERW application.

## ABSTRACT

Enhanced rock weathering (ERW) is a promising strategy for atmospheric $CO_2$ sequestration, but its impacts on soil organic carbon (SOC) fractionation and stabilization remain poorly understood. This study investigated how wollastonite application influences SOC dynamics in a three-month soybean pot experiment. In surface soils, the apparent SOC decline following wollastonite addition was primarily a dilution effect, not true carbon loss. Nevertheless, wollastonite significantly restructured SOC fractions and microbial activity, weakening organo-mineral associations (mineral-associated organic carbon reduced by 5%-10%), reducing microbial $CO_2$ assimilation (RubisCO carbon-fixing genes cbbL and cbbM decreased by 49%-90%), weakening macroaggregate protection (water-stable aggregate stability index reduced by 4%-6%), and enhancing SOC mineralization (easily oxidized organic carbon decreased by 18%-24%). In contrast, deeper soils exhibited increased SOC stabilization and accumulation (mineral-associated organic carbon increased by 5%-10%). Across the 0-30 cm profile, wollastonite application increased both organic and inorganic carbon pools, producing a net gain of 3.7-4.1 $Mg \cdot ha^{-1}$ in total carbon stocks. Soybean presence had little effect on net SOC storage but altered fractionation, stimulating dissolved organic carbon accumulation and easily oxidized organic carbon mineralization, while contributing less to particulate organic carbon formation. Collectively, these findings reveal that ERW did not uniformly enhance SOC storage but rather redistributed SOC fractions, reducing stability near the surface while promoting stabilization at depth. This study provides experimental evidence that ERW outcomes are strongly depth-dependent and regulated by soil–plant–mineral interactions, underscoring the importance of SOC fraction dynamics in assessing its long-term climate-mitigation potential.

**ABSTRACT**

Enhanced rock weathering (ERW) is a promising, scalable pathway for carbon dioxide removal (CDR), but its net soil-system benefits and governing mechanisms remain debated. This study synthesized empirical studies from January 2014 to June 2025, assembling a database spanning rock properties ($SiO_2$ content, dosage, particle size), soil factors (initial pH, clay content), and experimental conditions (field/pot, planted/unplanted, duration). Overall effects were quantified using weighted random-effects models with bootstrap confidence intervals. Boosted regression trees (BRT) were used to identify dominant drivers. Results indicate that ERW produced a measurable net carbon sink at the ecosystem scale, with an average CDR of 3.5 t $CO_2$ $ha^{-1}$ $yr^{-1}$ and an increase in total soil carbon (TC) of 2.1%. Within carbon pools, dissolved inorganic carbon (DIC) increased most (+273.5%), followed by soil inorganic carbon (SIC; +187.9%). Soil organic carbon (SOC) and microbial biomass carbon (MBC) increased by 3.6% and 23.3%, respectively, while dissolved organic carbon (DOC) and soil $CO_2$ flux showed no overall change. Methane emissions declined by 30.5%, which further enhanced ERW's net climate benefit. Design and context modulated outcomes. Each additional 1 t $ha^{-1}$ of rock raised CDR by approximately 20 kg $CO_2$ $ha^{-1}$ $yr^{-1}$; fine powder (<2 mm) achieved about 6 times the CDR of coarse powder (>2 mm). Higher initial soil pH strengthened CDR (+183 kg $CO_2$ $ha^{-1}yr^{-1}$ per 0.1 pH unit); whereas acidic and low-clay soils favored SOC accumulation. SOC often declined in the short term but increased over longer durations; while SIC gains diminished over time. Methodologically, pot studies overestimated SIC gains by approximately sevenfold relative to field studies and underestimated SOC stabilization. BRT results attributed CDR and TC mainly to soil factors (pH, clay content), whereas SOC and SIC were governed primarily by rock properties ($SiO_2$, particle size, dosage). In summary, ERW delivers net soil-system carbon sequestration, jointly regulated by soil, rock, and design. Practically, a "fine powder-low-to-medium dosage-matched soil background" strategy is recommended. Integrating methane (and where relevant, nitrous oxide) into $CO_2$-equivalent accounting, together with long-term field monitoring and cost-risk assessments, is essential forcredible, scalable deployment.

# Enhanced weathering using blast furnace slag(BFS) for carbon sequestration in soil

**Seong-hyeon Nam[1], Seok Soon Jeong[1], Jung-hwan Yoon[1], Jae-E. Yang[1] and Hyuck-Soo Kim[1*]**

*[1] Kangwon National University, (Department of Biological Environment, Kangwon National University, Chuncheon 24341, Korea)*

* Kimhs25@kangwon.ac.kr

**ABSTRACT**

As climate change intensifies globally, the importance of Carbon Dioxide Removal (CDR) technologies has become increasingly critical. The Intergovernmental Panel on Climate Change (IPCC) suggested ten priority CDR technologies, including Enhanced Weathering (EW). EW technology accelerates natural weathering processes by grinding and applying silicate minerals such as basalt and olivine or industrial byproducts rich in calcium (Ca) or magnesium (Mg) to soils, thereby sequestering atmospheric $CO_2$ in the form of stable inorganic carbon. However, South Korea faces constraints in implementing EW technology due to limited domestic reserves of silicate minerals such as basalt and olivine. Consequently, this study utilized blast furnace slag (BFS), an steel industry byproduct characterized by high Ca content and alkaline properties (pH: 8.9), as an EW feedstock material. Following assessment of the CDR potential (CDRpot) of BFS, field trials were conducted on agricultural soils at Kangwon National University's experimental farm to evaluate carbon sequestration capacity, change in soil properties changes, and impacts on maize (*Zea mays*) productivity. Results demonstrated that soil exchangeable Ca, available phosphorus (Av.$P_2O_5$), available silicon, and cation exchange capacity (CEC) increased relative to controls in proportion to BFS application rates, with higher values observed in fine-particle treatments compared to original-particle applications. Maize grain yields generally increased compared to controls; however, fine-particle treatments exhibited reduced yields in certain plots due to poor drainage conditions. CDRpot values for coarse-particle treatments at 2 and 10 t $ha^{-1}$ were 0.08 and 3.17 $CO_2$-t $ha^{-1}$, respectively, while fine-particle treatments at equivalent rates yielded 1.45 and 4.39 $CO_2$-t $ha^{-1}$, respectively. These results indicate that increased surface area accelerates weathering reactions. As this represents a single-year field trial, long-term reapplication studies are necessary to accumulate additional data on sustained carbon sequestration efficacy and soil health dynamics. Furthermore, $CO_2$ emissions from grinding processes for fine-particle production must be incorporated into CDRpot calculations to ensure accurate life cycle assessments.

**ABSTRACT**

The continuous rise in global atmospheric carbon dioxide ($CO_2$) concentrations has led to a significant increase in carbon output through the priming effect of soil microbial respiration, thereby limiting soil carbon sink capacity. Enhanced rock weathering represents a promising strategy for $CO_2$ removal, which can promote the conversion of $CO_2$ released by the priming effect into $HCO_3^-$, ultimately forming inorganic carbon to stabilize the soil carbon pool. This study investigates how the combined application of basalt and Bacillus subtilis, mediated by the soil priming effect, influences the turnover of the soil carbon pool. Over a 28-day incubation period, we added Bacillus subtilis, basalt, and $^{13}C$-labeled glucose solution to the soil, and systematically analyzed soil respiration, glucose mineralization, priming effect, carbon pool content, as well as changes in soil physicochemical properties and carbon particle morphology. The results showed that Bacillus subtilis accelerated soil respiration, while basalt weathering suppressed cumulative $CO_2$ release, with the inhibitory effect strengthening over time. Additionally, basalt significantly reduced cumulative glucose mineralization and altered the direction of the priming effect. The combined application of basalt and Bacillus subtilis notably increased soil organic carbon and inorganic carbon content, with organic carbon rising by up to 24.07%. The net soil carbon fixation reached 595.86 $\mu g \cdot C \cdot g^{-1}$, enhancing the stability of the soil carbon pool. The soil priming effect, mediated by microorganisms, intensified basalt weathering, accelerated proton neutralization in the soil, increased bicarbonate alkalinity, raised soil pH, effectively ameliorated acidic conditions, and released soluble $Ca^{2+}$ and $Mg^{2+}$ ions. These findings indicate that microbially enhanced basalt weathering, driven by the soil priming effect, significantly improves soil carbon sink potential and mitigates soil acidification through mechanisms such as inhibiting substrate mineralization, accelerating inorganic carbon fixation, and increasing mineral-associated organic carbon content.

## ABSTRACT

[**Background]** Enhanced Rock Weathering (ERW) is a climate mitigation strategy that accelerates natural rock weathering processes to sequester atmospheric carbon dioxide. In agricultural fields, the application of crushed basalt to soil is expected to release base cations ($Ca^{2+}$, $Mg^{2+}$) through weathering processes. These cations can react with carbonate ions in the soil solution, resulting in the formation of relatively stable carbonate minerals. Bicarbonate ions generated during these reactions may be leached and contribute to carbon sequestration in the ocean. In addition, elements released during basalt weathering can serve as nutrients for crops, providing co-benefits such as enhanced growth, increased yields, and improved crop quality. To implement ERW technology in the field, it is necessary to evaluate the persistence of its effects following basalt application. This study aimed to elucidate the effects of basalt application on maize (*Zea mays* L.) growth and soil carbon sequestration, with a particular focus on elemental dynamics.

**[Methods]** Field experiments were conducted in 2024 using maize (Zea mays L., cv. P9027) at an experimental field of Hokkaido University (43.07° N, 141.34° E; gray lowland soil). To evaluate the residual (second year) effects of ERW, the study utilized plots that had received a one-time application of crushed basalt (particle size: <100 μm) in 2023, followed by a soybean crop. Five treatments were arranged in a randomized design with three replications: a control (no application), three basalt application rates (5, 10, and 20 wt.% incorporated into the top 15 cm; hereafter BA5, BA10, and BA20), and a lime application (0.15 wt.%). While basalt was applied only in 2023, lime was reapplied in 2024 to match the soil pH of BA10. Soil and plant samples were collected at the vegetative (V9), reproductive (R1), and harvest (R6) stages. For plant analyses, dry weight, elemental concentrations, and grain yield were determined. Soil analyses included pH, exchangeable cations, available silicon (Si), inorganic carbon concentrations, and mineralogical composition determined by X-ray powder diffraction (XRPD). Additionally, the total carbon budget was calculated based on integrated plant and soil data.

**[Result]** Soil pH increased similarly in both basalt and lime treatments across all growth stages. However, basalt application tended to enhance maize dry weight and grain yield compared to the control, with BA20 showing a significant increase in leaf dry weight at R1. In basalt treatments, soil exchangeable magnesium (Mg) at V9 and R1, and plant Mg concentrations at R6, significantly increased. Furthermore, soil exchangeable Mg was significantly and positively correlated with shoot dry weight at R1 and R6. Soil available Si also significantly increased with basalt application. While plant Si concentrations showed an increasing trend in basalt treatments, they were significantly lower in the lime treatment than in the control, BA5, and BA10. Soil exchangeable calcium (Ca) concentrations were significantly higher in the lime treatment at V9 and R1, and plant Ca concentrations also tended to be higher. Although basalt contains Ca, soil exchangeable Ca remained unchanged, likely due to high initial soil Ca levels. These results suggest that basalt-induced growth promotion may not be solely attributable to pH changes but also to the supply of essential elements such as Mg and Si released through weathering. The influence of basalt application remained evident in the field two years after the initial treatment. The potential for soil carbon sequestration via ERW is currently under investigation.

# Soil Re-engineering – A New Approach to Improve Crop Productivity on Constrained Sandy Soils in Water-Limited Environments in Western Australia

**Gaus Azam[1*], Kanch Wickramarachchi[1], Glenn McDonald[3], Chad Reynolds[2], Md Shahinur Rahman[1], Steve Davies[2], Wayne Parker[2]**

## ABSTRACT

Western Australia (WA) produces high-quality grain crops under rainfed systems on some of the world's oldest, infertile sandy soils. Nearly two-thirds of WA's cropping land is constrained by soil compaction, acidity, poor fertility, and low water-holding capacity. While deep tillage with lime and clay can alleviate these issues, the full productivity potential from their complete removal remains unclear.

We used a "*soil profile re-engineering*" approach — involving removal and replacement of soil horizons with uniform mixing plus lime, clay, and inorganic and organic nutrient incorporation — to simulate the maximum benefits of deep soil amelioration (Azam, 2025). We then tested farm-scale experiments using conventional and novel machinery to assess the feasibility of adoption by the farmers. Our research addressed two key questions: (i) can the immediate improvements in soil health and productivity be sustained long-term, and (ii) can this approach be scaled for growers' adoption? To evaluate this, we conducted two long-term trials (Bolgart, a deep sand; Meenar, a sandy duplex) over five seasons and four grower-scale trials (Grass Valley, Mt Horner, Wagin and North Stirling) in 2025 season across WA.

In the long-term profile re-engineering trial at Bolgart site, some re-engineering treatments at least doubled grain yield and water-use efficiency (WUE) of five crop types compared to the untreated control, while the most effective treatment achieved the estimated water-limited yield potential (Yp) on both sites. Overall, yields increased by 66% following the removal of acidity and compaction. Deep incorporation of clay and organic matter enhanced yield and WUE on deep sand but not sandy duplex soils, whereas deep inorganic nutrient placement was more beneficial on sandy duplex soils. These improvements persisted for five seasons and are likely to last longer. Yield and WUE gains were associated with deeper, more continuous root growth, improving capture of water and nutrients otherwise unused in untreated subsoils.

Farm-scale re-engineering experiments using traditional and emerging machinery confirmed immediate mitigation of acidity and compaction and significant improvements in water-holding capacity. Grain yield and WUE increased by 4 t $ha^{-1}$ and 12 kg $mm^{-1}$, respectively, in the first season in the farm-scale trials compared to the controls.

Overall, our findings show that soil re-engineering can transform sandy soil into more resilient production systems, enabling consistent achievement of Yp at farm scale. Future research should explore the interaction of soil re-engineering to different depths with seasonal variability, crop rotations, and alternative soil management strategies to maximise its agronomic and economic benefits.

# Combined Application of Straw and Biochar: A Synergistic Strategy to Enhance Fertilizer Efficiency, Boost Yield, and Reduce Greenhouse Gas Emissions in Northeast China

**Aizheng Yang[1*], Hongyu Li[1], Yan Sha[1], Qiuju Wang[2] and Mo Li[1]**

[1] *School of Water Conservancy and Civil Engineering, Northeast Agricultural University, Harbin, Heilongjiang 150030*

[2] *Heilongjiang Province Black Soil Protection and Utilization Research Institute, Heilongjiang Academy of Agricultural Sciences, Harbin, Heilongjiang 15003*

* aizheng.yang@neau.edu.cn

**ABSTRACT**

Incorporating straw or biochar into soil is widely acknowledged for improving soil structure and nutrient content. However, applying large amounts without proper management may lead to negative effects, including increased greenhouse gas (GHG) emissions, imbalances in the soil carbon-to-nitrogen (C/N) ratio and inhibition of crop growth. Thus, careful management is essential to optimize benefits and minimize risks. A field experiment conducted in black soil region of Northeast China (2022 to 2023) to explore the effects of straw and biochar return methods along with varying N fertilizer on GHG emissions and soybean yield. This study investigated two straw and biochar return methods (36 t ha-1 full straw return, S; and conversion of 18 t ha-1 straw to biochar mixed with residual straw return, SB) along with three N fertilizer levels (72 kg N $ha^{-1}$, N1; 57.6 kg N $ha^{-1}$, N2; and 43.2 kg N $ha^{-1}$, N3). Additionally, the control treatment (CN1) applied conventional nitrogen fertilizer without straw or biochar. Results showed that the SBN combination produced a higher soybean yield with lower GHG emissions compared with the SN combination. This improvement was attributable to biochar-induced regulation of soil hydrothermal conditions, which enhanced soil moisture content by 7.68% and raised soil temperature by 0.78–2.14°C at key growth stages (seedling and maturity). Moreover, biochar significantly increased C and N sequestration, boosting soil total nitrogen by 8.35% and soil organic carbon by 38.97%. Specifically, the most effective treatment was the SBN2, which increased soybean yield by 16.88% and reduced greenhouse gas emission intensity (GHGI) by 42.37%. Structural equation modeling and regression analysis revealed that soil hydrothermal conditions and C and N sequestration were key factors driving both yield improvement and emission reductions. The results indicated that combining straw and biochar return with optimized N fertilizer input was effective in reducing GHG emissions and increasing grain yield. This approach offers a sustainable method for soybean production with lower nitrogen fertilizer inputs, providing valuable insights for agricultural practices in the black soil region of Northeast China.

## ABSTRACT

**Research Background and Scientific Basis**

Albic soil is a key soil type for grain production and is widely distributed across several countries. It is also a typical problematic soil in eastern China, covering approximately 5.27 million hectares, among which Heilongjiang Province accounts for about 3.31 million hectares—mainly located in the Sanjiang Plain, where it serves as the dominant arable soil type. However, Albic soil suffers from multiple severe constraints, including nutrient deficiency, strong acidity, compact physical structure, and especially low microbial activity, which severely restrict crop growth and result in low and unstable yields. These problems not only hinder local agricultural productivity but also threaten the sustainable development of cultivated land resources. Therefore, improving the productivity of Albic soil is of strategic importance for ensuring global food security.

Traditional fertilizer-dependent management systems have failed to reverse soil degradation effectively; excessive fertilization has instead intensified acidification and nutrient imbalance. Hence, restoring the fertility of Albic soil urgently requires an integrated regulatory strategy capable of improving its physical structure, chemical properties, and biological functions simultaneously. Organic waste recycling—particularly the application of crop straw, livestock manure, and biomass ash—offers a promising pathway to rebuild soil organic carbon pools and nutrient cycling capacity. Nevertheless, under cold environmental conditions, microbial activity is suppressed and straw decomposition is slow, limiting the effectiveness of such measures.

To address these limitations, this study focuses on integrating organic waste amendments with functional microbial inoculants to construct a synergistic soil fertility enhancement system tailored for Albic soil. By combining field trials with controlled-environment experiments, the study systematically elucidates the roles of organic residues and microbial communities in aggregate formation, enzyme activity regulation, nutrient transformation, and community assembly. The overarching goal is to establish a mechanistic framework for transforming Albic soil ecosystems from a state of "low fertility–high resistance" to "high activity–high stability–high nutrient efficiency."

**Experimental Framework and Methodology**

**1.Soil Type and Cropping System**

Field experiments were conducted in a typical Albic soil region under a soybean–maize rotation system. Complementary pot and microcosm experiments were designed under controlled conditions to explore microbial and biochemical mechanisms.

**2.Treatment Design**

Treatments included:(1) untreated control; (2) straw return; (3) straw return + composite microbial inoculant; (4) organic substitution for chemical fertilizer; (5) biochar inoculated with *Piriformospora indica*; (6) biomass ash combined with arbuscular mycorrhizal fungi (AMF) inoculation.

**3.Measured Parameters**

Soil physicochemical properties (pH, organic matter, total nitrogen, total phosphorus, available phosphorus), enzyme activities (urease, alkaline phosphatase, cellulase, β-glucosidase, laccase), and aggregate size distribution were determined. Microbial community structures were analyzed via 16S rRNA and ITS high-throughput sequencing, coupled with FUNGuild and FAPROTAX functional annotations. Co-occurrence network analysis, structural equation modeling (SEM), and redundancy analysis (RDA) were applied to reveal causal relationships between biological processes and soil fertility improvement.

**4. Metabolomics and X-ray Tomography**

Non-targeted metabolomics was employed to characterize root–microbe carbon flow, while X-ray CT scanning visualized changes in aggregate microstructure. Glomalin-related soil protein (GRSP) was quantified to assess the contribution of AMF to aggregate stability.

**Main Findings and Mechanistic Insights**

**1.Synergistic Effects of AMF and *Trichoderma longibrachiatum* under Straw Incorporation**

The synergistic role of AMF and *T. longibrachiatum* in promoting straw decomposition and nutrient release in Albic soil was systematically elucidated. Results indicated that *T. longibrachiatum* enhanced host root responsiveness to AMF, increasing mycorrhizal colonization rates and strengthening AMF-mediated regulation of *Trichoderma*'s ecological functions, shifting its role toward organic matter degradation. The co-inoculation significantly improved key decomposing enzyme activities and soil pH, ameliorating soil acidity and optimizing nutrient release and transformation conditions.

This accelerated straw decomposition and nutrient availability, thereby enhancing nutrient uptake efficiency and biomass accumulation in crops. Furthermore, AMF–*Trichoderma* interaction reshaped rhizosphere fungal community structures, enriched straw-decomposing taxa, and increased the abundance of *Sphingomonas* and other aerobic heterotrophs, thus altering the functional composition of the microbial community. The co-inoculation also markedly improved the soil quality index (SQI) of Albic soil.

Overall, the synergistic inoculation of AMF and *T. longibrachiatum* represents a promising biotechnological innovation capable of enhancing straw return efficiency and soil fertility, offering significant potential for ameliorating degraded Albic soil and optimizing straw resource utilization.

**2. Complementary Effects of Biochar and *Piriformospora indica* and Rhizosphere Metabolic Reconfiguration**

The combined regulation of crop–microbe interactions in Albic soil by biochar and P. *indica* was investigated through a metabolomic network approach. Results demonstrated that co-application significantly increased bacterial α-diversity and reshaped dominant genera such as *Bacillus* and *Lysobacter*. The synergistic treatment promoted root secretion of key metabolites including *isoleucine* and *isocitrate*.

These metabolites attracted *Lysobacter*, establishing a positive feedback loop between microbial populations and rhizosphere metabolites, which in turn modulated root exudation, stimulated root morphological development, and enhanced biomass accumulation (RPA, RSA, RV). Increases in *Bacillus* and *Lysobacter* abundances were strongly correlated with plant biomass, with isocitrate identified as a key metabolic driver in the biochar–*P. indica* synergy. Although confirmed under pot conditions, further field-scale validation is required to assess its agronomic applicability in Albic soil.

**3. Long-Term Effects of Organic Fertilizer Substitution**

Compared with conventional fertilization, partial replacement of chemical fertilizers with organic amendments significantly increased soil pH and nutrient levels. Under high substitution ratios, soil pH rose by approximately 4.33%, while organic matter (OM), total phosphorus (TP), available phosphorus (AP), and hydrolyzable nitrogen (HN) increased by 20–30%.

Bacterial diversity and abundance rose by more than 20%, whereas fungal diversity decreased correspondingly. The dominant phyla—Proteobacteria and Basidiomycota—increased by 36.11% and 286.79%, respectively. Soil pH and organic matter content were identified as key determinants of rhizosphere microbial community composition in soybean-grown Albic soil. Organic substitution also strengthened bacterial interactions, rendering the microbial network more complex and stable. These findings highlight the diverse responses of rhizosphere microbial communities to organic inputs and provide a scientific foundation for optimizing fertilization strategies and improving soil health in Albic soil regions.

**Integrated Analysis and Theoretical Implications**

Based on multi-year, multi-scale investigations, this study proposes a conceptual model of a microbe–organic matter synergistic regulation system for Albic soil restoration. The mechanism operates through three hierarchical layers:

**1. Biophysical Reconstruction Layer:** Organic wastes (straw, biochar, manure) provide structural and chemical support, alleviating compaction, enhancing porosity, and regulating acidity.

**2. Biochemical Activation Layer:** Functional microbes catalyze organic matter degradation, release nutrients, and form microbial residues that stabilize soil carbon.

**3. Bioecological Feedback Layer:** Improved structure and nutrient conditions further enhance microbial diversity and ecological resilience.

This tripartite feedback system transforms recalcitrant organic wastes into "active resources," achieving synergy between waste minimization, soil restoration, and productivity enhancement.

**Conclusions and Future Perspectives**

This research demonstrates that integrating organic waste recycling with targeted microbial symbiosis technologies can fundamentally reshape the fertility trajectory of Albic soil. The combined strategy restores nutrient cycling and structural functionality while establishing a self-sustaining biological network capable of maintaining high productivity with reduced fertilizer input.

The proposed microbe–organic co-amendment model holds profound implications for sustainable agriculture worldwide:(1) It provides a renewable agricultural pathway for organic waste valorization aligned with carbon neutrality goals;(2) It deepens understanding of soil–microbe–organic matter interactions, introducing precise regulation indices centered on enzyme networks, glomalin-related soil protein (GRSP), and co-occurrence networks;(3) It offers theoretical support for region-specific soil restoration technologies with cross-ecosystem applicability.

Future research integrating isotope tracing and transcriptomics will further elucidate microbial carbon flow and key functional gene regulation within this synergistic system. In conclusion, this study provides systematic evidence that when organic residues and beneficial microbes are scientifically coupled, a cyclic, efficient, and resilient soil fertility enhancement pathway can be established. The recovery of Albic soil thus represents not merely nutrient replenishment, but an ecological reconstruction process of rebuilding a living soil matrix.

# Subsoil Mixed Profile Reconstruction Technology

**Qingying Meng**[1*]

[1] *Heilongjiang Academy ofAgricultural Sciences,Harbin,China*

*mqy269@126.com

**ABSTRACT**

According to the World References Base for Soil Resources (WRB), more than ten soil groups are characterized by the presence of an albic horizon or albic materials, which are commonly distinguished by their low organic matter content. In China, Albic soils are widely distributed, with a predominant concentration in Northeast China, particularly in Heilongjiang and Jilin provinces. Among these regions, Heilongjiang Province alone contains approximately 3.31 million hectares of albic soil, accounting for about 10% of the total cultivated land area.Traditionally, the improvement of Albic soils has relied on chemical, physical, biological, and mechanical approaches. However, these methods often suffer from either limited persistence of improvement effects or excessively high implementation costs. In response to the unique soil profile structure of albic soil, a novel soil improvement mechanism has been proposed. This approach maintains the position of the black soil (topsoil) layer while mechanically mixing the two underlying subsoil layers at an appropriate ratio, thereby reconstructing the soil profile. Based on this principle, a specialized soil-improving machine, namely the subsoil mixing machine, has been developed.Mechanical improvement of albic soil through subsoil mixing significantly reduces soil hardness within the albic horizon, alters the vertical distribution of soil moisture, and effectively mitigates surface waterlogging under extreme rainfall conditions by enhancing deep soil water storage capacity. As a result, crop yields increase by approximately 10 –15%, with the improvement effects persisting for 3 –5 years. Furthermore, under subsoil mixing conditions, the additional application of organic amendments markedly increases nutrient availability in the reconstructed albic layer and promotes soil microbial abundance.Overall, subsoil mixed profile reconstruction technology represents a fundamentally effective and sustainable strategy for the improvement of albic soil.

# Ecological Prevention and Control of Early-Stage Gully Erosion in Black Soils: Concepts, Mechanisms, and Integrated Technologies

**Enheng Wang[1*], Chunmei Wang[2] and Changjia Li[3]**

[1] *Soil and Water Conservation, Northeast Forestry University, Harbin, China*

[2] *Remote Sensing and Geographic Information System, Northwest University, Xi'an, China*

[3] *Geographical Science, Beijing Normal University, Beijing, China*

**ABSTRACT**

The Northeast China black soil region is one of the most important grain-producing areas in China and a globally significant concentration of high-fertility soils. However, long-term intensive cultivation, inappropriate land-use practices, and the increasing frequency of extreme rainfall events have exacerbated soil erosion, among which gully erosion has become a major driver of black soil degradation and farmland loss. Current management practices tend to prioritize the treatment of large, well-developed gullies, while the far more numerous and widely distributed early-stage gullies receive limited attention. This imbalance has resulted in a typical pattern of "emphasizing treatment over prevention." Statistics indicate that approximately 60% of gully erosion occurs on farmland, and grain losses caused by gully erosion account for nearly one-tenth of the annual marketed grain yield, highlighting the urgency of controlling gully development at its source.

Focusing on the early stage of gully evolution, this study systematically examines key challenges associated with ephemeral gullies, including unclear conceptual definitions, insufficient understanding of development mechanisms, and the lack of predictive and targeted control technologies. Drawing inspiration from the holistic philosophy of traditional Chinese medicine—characterized by "preventing disease before its onset, preventing deterioration after occurrence, and preventing recurrence after recovery"—this study proposes an ecological prevention and control framework for early-stage gully erosion in black soils. By treating hillslopes, flow convergence zones, and gully bottoms as an integrated system, a comprehensive technology package is developed, encompassing potential gully identification, prediction of critical erosion thresholds, optimized configuration of cover crops on slopes, construction of green waterways at gully bottoms, and regulation of gully incision processes.

Results from representative demonstration areas show that cover crops effectively reduce runoff and sediment transport on slopes and contributing areas, while green waterways significantly enhance erosion resistance and suppress gully downcutting by increasing critical hydraulic thresholds. Compared with conventional engineering-based gully treatments, the proposed ecological control system demonstrates clear advantages in terms of cost efficiency, farmland protection, and black soil conservation, with strong potential for large-scale application. This study emphasizes the need to shift black soil management from post-event remediation to process-based prevention, and from localized treatment to systematic governance, providing scientific support and policy-relevant insights for ensuring long-term black soil sustainability, food security, and soil health.

# Tillage and straw return alleviate soil compaction in Northeast China: From pore structure to root development and crop productivity

**ABSTRACT**

Soil compaction threatens agricultural productivity by disrupting pore structure and impeding root growth. While tillage and straw management are key mitigation strategies, their synergistic effects on soil aggregate microstructure, compression characteristics, and crop productivity remain incompletely elucidated. A two-year field experiment in Northeast China compared no-tillage with straw return (NTS) and removal (NT), plow tillage with straw return (PTS) and removal (PT), and subsoiling tillage with straw return (STS) and removal (ST). Synchrotron-based X-ray micro-computed tomography quantified aggregate pore characteristics, and uniaxial confined compression tests assessed soil compression properties, alongside root traits and yield measurements. Results showed that plow tillage and subsoiling tillage reduced bulk density and penetration resistance compared to no-tillage. STS enhanced subsoil organic carbon (30.7–124.9%). These two tillage practices increased aggregate total porosity (68.7–153.4%) and connectivity porosity (84.1–204.5%), and enhanced the proportions of macropores (75–100 μm) and megapores (>100 μm). Straw return to the subsoil further amplified these pore improvements. Plow tillage and subsoiling tillage decreased pre-compression stress ($\sigma_p$) while increasing compressibility (Cc) and recovery coefficient (Rc), benefits significantly enhanced by straw return under STS. These practices also increased root length, surface area, and volume while decreasing average diameter, resulting in STS achieving the highest maize yield (10.1 Mg ha$^{-1}$) in the second year. Partial least squares path model revealed tillage practice negatively affected $\sigma_p$ and positively affected Rc, while porosity positively influenced Cc. Redundancy analysis confirmed strong links between soil parameters and plant parameters. Overall, subsoiling tillage with straw return (STS) alleviated soil compaction through optimizing pore structure, organic carbon, and compression characteristics, promoted root development, and thereby enhanced yield. This practice provides a scientifically feasible strategy for sustainable agricultural development in Northeast China.

# Bacterial richness enhances the thermostability of soil organic matter: long-term perspective

**Meng Wu**[1*]

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China*

**ABSTRACT**

The persistence of soil organic matter (SOM) is influenced by its molecular features and stable status. However, the temporal dynamics of these features remain unclear. Here, we employed FT-ICR mass spectrometry to investigate the molecular diversity (number of molecules) and molecular thermodynamic-stability (the theoretically Gibbs free energy for the half reaction of carbon oxidation) of SOM in soils from long-term (> 30 years) paddy and upland experimental fields. Thermogravimetric analysis showed that enhanced SOM thermostability (the thermal decomposition resistance of total SOM) aligns with the temporal variation of molecular thermodynamic-stability in these soils. We observed that increased SOM molecular thermodynamic-stability occurs alongside decreased molecular diversity over decades, and this temporal trade-off (negative relationship) is modulated by increased bacterial richness. Microbial communities with richness gradients were established using a dilution-to-extinction approach and were further inoculated into a sterilized soil for 90 days, and the subsequent measurements of SOM molecular diversity and thermodynamic-stability reproduced the aforementioned temporal trade-off relationship. Overall, our findings demonstrate that higher bacterial richness facilitates the selective transformation of SOM into a chemically more stable molecular pool and enhances SOM thermostability over decades, suggesting that agronomic fertilization strategies promoting bacterial richness are more likely to contribute to improved SOM persistence in agricultural food systems.

**ABSTRACT**

Microalgae are promising platforms for biological carbon capture and utilization/storage (CCU/CCS), yet their large-scale deployment is constrained by inefficient $CO_2$ hydration and mass transfer, resulting in limited $CO_2$ delivery to the RuBisCO carboxylation site under industrial flue-gas conditions. In an internal-LED flexible air-lift photobioreactor operated at 20% $CO_2$, exogenous carbonate anhydrase (CA) markedly enhanced carbon-concentrating mechanisms in Chlorella sp., leading to increased chlorophyll, lipid, and protein accumulation, elevated key carbon-flux intermediates such as malate and succinate, enhanced RuBisCO and acetyl-CoA activities, reduced oxidative stress, and strengthened extracellular electron transfer. To enable scalable and cost-effective deployment, Mesorhizobium loti carbonic anhydrase (MlCA) was produced via high-throughput promoter screening in Escherichia coli, achieving a specific activity of 34.6 WAU $mg^{-1}$ and rapidly catalyzing $CO_2$ mineralization to calcite ($CaCO_3$) under mild conditions, supporting integrated CCU/CCS strategies. Transitioning from enzyme supplementation to autonomous systems, mutualistic *Chlorella* sp.–M. loti co-cultures stabilized pH, coupled carbon and nitrogen metabolism, and increased total $CO_2$ fixation by 34.1% at 20% $CO_2$, with nitrogen transfer reaching 18% on day 2 as quantified by $^{15}N$ isotope labeling. Further enhancement was achieved using a facultative autotroph, Cytobacillus KQ-2, which genomically encodes both Calvin-Benson-Bassham and reductive TCA carbon fixation pathways and formed a highly synergistic consortium with *Chlorella*, increasing total $CO_2$ fixation by 52.11% over 10 days at 20% $CO_2$; metabolomic and electrochemical analyses revealed intensified metabolic cross-feeding, reinforced antioxidant networks, reduced reactive oxygen species, and enhanced interspecies electron transfer. Collectively, CA-enabled microalgal systems spanning low-cost enzyme production, reactor-level intensification, and engineered microbial consortia provide a mechanistically grounded and scalable pathway for high-$CO_2$ flue-gas treatment and next-generation biological CCU/CCS.

**ABSTRACT**

Degradation of soil functions by human activities in urban areas poses significant challenges to ecological health and urban sustainability. Effective rehabilitation of these soils requires reliable indicators that reflect changes in soil quality and functioning over time. This study explores the use of thermal indicators of soil organic matter (SOM), derived from thermal Rock-Eval® analyses (a pyrolysis and oxidation-based method), as a promising tool for monitoring ecological rehabilitation actions in anthropized soils. By assessing the thermal carbon stability and content of SOM, Rock-Eval® indicators offer insight into the SOM quality and properties (labile and recalcitrant forms of soil carbons) after rehabilitation actions and allow monitoring of soil re-functionalization. In this work, a gradient of rehabilitation effort was designed and implemented in an urban site in France (Pierre-Bénite) to evaluate the influence of varying soil amendments, treatments, and plantations on soil function recovery (e.g., soil decompaction, bio-techno materials, etc.). Thermal indicators of SOM were estimated at three different stages: the initial phase of rehabilitation, short-term (2.5 years), and long-term (7.5 to 8.5 years).

Regarding the thermal properties of SOM (hydrogenation, oxygenation, lability, and stability of organic matter), the most significant rehabilitation effort (techno-soil with high organic matter amendment) is largely dominated by HI/OI values. Intermediate rehabilitation efforts (techno-soils with low organic matter amendment) show a typical signature of subsoils. In contrast, the low-cost rehabilitation effort (no organic matter amendment) is also characterized by a SOM of subsoils, which evolves rather towards a typical signature of topsoils over time. After 8.5 years, a clear difference between the techno-soils is observed, linked to the decomposition of the more labile components (I-index) and an increase in the thermal stability of the SOM (R-index). The low-cost rehabilitation effort modality is dominated by a more stable organic matter over time. A relative increase in soil organic carbon (SOC) content over time is also observed for all modalities, especially for the most significant rehabilitation effort, which is dominated by much higher SOC values.

Finally, results from field and laboratory assessments demonstrate a correlation between the progression of soil rehabilitation and shifts in SOM thermal properties, indicating substantially enhanced agricultural and forestry productivities of SOM. Nevertheless, the magnitude of this improvement seems to be inversely proportional to the intensity of rehabilitation effort, suggesting that low-cost actions can be competitive in the long term. This research highlights the potential of thermal carbon stability indicators (e.g., I, R indices, SOC, HI/OI) as cost-effective, sensitive, and integrative tools for assessing soil health and guiding urban ecological restoration strategies.

**ABSTRACT**

Potassium (K) is essential for plant growth, yet only a small fraction in soil is available to plants. Traditional extraction methods, such as ammonium acetate ($NH_4OAc$), provide measurements of exchangeable K but overlook its diffusion and spatial dynamics. This study developed and validated a diffusive gradients in thin films (DGT) technique using a cation exchange membrane (CXM-200) to assess K availability and movement, using polyhalite ($K_2Ca_2Mg(SO_4)_4 \cdot 2H_2O$) fertiliser in soil. The CXM-DGT had a good detection limit (9.93 µg/device), high binding capacity (1687 µg at 0.01 M ionic strength), and stable performance across pH 3.5–8.5 and ionic strengths up to 0.01 M $NaNO_3$. Its results were comparable to Amberlite IRP-69 DGT for K measurement but with advantages of easier use and reusability. The presence of competing cations ($Ca^{2+}$, $Mg^{2+}$) slightly affected performance, and shorter deployment times (~6 h) were recommended to minimise interference in cation-rich soils. Coupling CXM-DGT with X-ray fluorescence microscopy (XFM) enabled high-resolution mapping of K distribution. After incubation for one week, Alfisol soils exhibited peak available K concentrations (49.6 ± 16.8 mg/L) at the fertiliser band, decreasing beyond 20 mm. In contrast, the clay-rich Oxlsol showed lower K concentrations (21.4 ± 15.4 mg/L). Lateral K distribution patterns from CXM-DGT closely matched exchangeable K measured via $NH_4OAc$ extraction, both showing steep declines away from the fertiliser zone. The stronger K binding in the Oxlsol highlights the role of clay content and mineral surfaces in controlling K mobility and availability. Overall, the CXM-DGT technique provides a robust and high-resolution method for quantifying K diffusion and spatial lability in soils. When integrated with XFM, nutrient gradients around fertiliser bands can be visualised. These results highlight how soil texture and mineralogy regulate K redistribution. The combined CXM-DGT and XFM approach can be used to provide valuable insights into developing more efficient and sustainable K fertilisation practices.

**ABSTRACT**

Phosphorus (P) limitation in agriculture demands efficient mobilization of soil-fixed P. While phosphate-solubilizing bacteria (PSB) offer a sustainable solution, current methods struggle to isolate truly functional strains[1]. We developed a hierarchical single-cell approach to directly target in situ active PSB[2]. Initially, single-cell Raman spectroscopy with $D_2O$ probed PSB activity under fixed-P conditions, but its low throughput (1-60 cells/min) limited comprehensive analysis. To address these challenges, our research introduces an innovative single-cell analysis framework, designed to progress from direct targeting to high-throughput functional mining of the active community. We developed a high-throughput method that uses fluorescent D-amino acid (FDAA) labeling under fixed-P stress to sort metabolically active PSB through fluorescence-activated cell sorting, enabling direct downstream applications of sorted cells for cultivation and sequencing. This strategy revealed unprecedented diversity, identifying 11 previously unreported genera and substantial unclassified taxa. Targeted cultivation yielded 71 isolates across 19 genera, with six genera and 11 potential new species first reported as PSB. Notably, 61% of isolates originated from rare (<0.1% abundance) taxa. Soil validation showed key isolates released fourfold more bioavailable P and maintained colonization for over three weeks, outperforming commercial strains. This function-driven platform directly links microbial identity to in situ activity and cultivability, providing a scalable strategy for mining hidden microbial resources to advance sustainable agriculture.

## ABSTRACT

The soil microbiome regulates vital soil functions, including nutrient cycling, soil structure formation, and the suppression of plant diseases. However, metabolic monitoring and mining for in-situ functional microbes have been challenging, due to the inability to rapidly untangle the single-cell "6W" questions: What metabolic functions are being performed (doing What), Who it is (Who), Why they perform these functions (Why), generating Wealth (pure cultures), When, and Where. To systematically investigate these questions and elucidate their spatiotemporal patterns at both local and global scale, we developed the Metaramanomics Platform, which consists of FlowRACS, RAMS, and DCP (Digital Clone Picker). The platform enables label-free, rapid, high-throughput, low-cost profiling, sorting and cultivation of soil microbiota based on in situ metabolic phenome in a “screen first, culture second” fashion. Based on this platform, over 20 institutions worldwide jointly launched the Soil iMAPS (https://www.iMAPS.info), to establish a global network of facilities for metabolic sensing, strain mining, and ecological restoration of soil microbiomes. This will accelerate the translation of soil microbiota into deployable solutions for tackling global warming, food security, water shortage and degradation of farmlands. This presentation will report the latest progress from the Soil iMAPS Initiative.

**ABSTRACT**

Heavy metals in soils represent a major category of pollutants, regardless of their origin—be it from anthropogenic activities or the natural leaching of bedrock. The hypothesis of a natural source for elevated metal concentrations opens avenues for soil research that extend beyond pollution assessment and agriculture, positioning it as a tool for geochemical prospecting. A critical challenge is identifying specific metal forms, for which sequential extraction techniques provide valuable differentiation and insight into metal mobility and origin.

This study applied a ligand-based extraction method targeting mobile metal fractions, underpinning the ATHAR-M hydrocarbon prospecting technique. This approach detects trace inorganic markers mobilized from depth via hydrocarbon microseepage, generating geochemical anomalies in surface soils. Mobile, weakly bound heavy metals serve as primary indicators.

We analyzed 345 soil samples from eight arid-region fields dominated by aridisoils. Mobile metal ions were extracted using a ligand solution selective for weakly bound ionic forms and quantified by high-precision ICP-OES. Optimal extraction conditions and key indicator elements (V, Ni, Cu, As, Ti) were established.

Results revealed significant spatial variability in metal concentrations. Vanadium concentrations exceeded 30 ppm with multiple outliers above 5 ppm, contrasting with median background levels below 2 ppm. Five fields exhibited right-skewed vanadium distributions; one field showed a standard deviation of 4.7 ppm (n=45). Nickel displayed similar heterogeneity, with maximum concentrations above 1 ppm and baselines near 0.15 ppm. Other elements followed comparable distribution patterns, varying by field.

These pronounced inter-field differences suggest metal enrichment arises from both bedrock weathering and natural hydrocarbon microseepage. Our findings demonstrate that combining selective chemical extraction with ICP-OES provides a sensitive and precise method for detecting subtle geochemical anomalies relevant to hydrocarbon prospecting.

# Raman-based flow cytometry for single-cell microbial phenotyping

**ABSTRACT**

Raman microspectroscopy offers a direct and efficient approach to identify and classify target microorganisms based on their phenotypic characteristics (e.g., metabolic activities and functional roles) within complex microbial communities. In this talk, I will demonstrate how this technology can be integrated with a fluidic system to enable automated, high-throughput Raman-based flow cytometry. The platform incorporates five core enabling technologies: Raman microspectroscopy, microfluidics, optical tweezers, stable isotope probing (SIP), and software automation. A model bacterial strain, *Escherichia coli*, was used for platform development and validation, after which the system was applied to a natural complex sample — the mouse colon microbiome. Using this approach, mucin-degrading bacteria were selectively sorted, and downstream metagenomic analysis confirmed that function-driven Raman flow cytometry directly links target cell phenotypes to their genotypes. Furthermore, artificial intelligence was integrated into the platform as an adaptive sorting criterion for nitrite-oxidizing bacteria in marine sediment samples, in which Raman signatures varied depending on physiological states. Collectively, Raman-based flow cytometry establishes a powerful new avenue for intuitively bridging microbial phenotypes and genotypes at the single-cell level.
