Global population is projected to increase to about 10 billion by 2050, with a corresponding 100% increase in global food demand. Meanwhile, sustainable farming – which requires an annual use of fertilizers and agrochemicals to the tune of 200 million metric tons – is central to meeting this demand. Consequent upon this, is the detrimental effects on soil health, human health, aquatic lives and food chain, following an uncontrolled use of these resources. The aim of this research is the first split evaluation of plant available nutrients in soil treated with novel fertilizers combination (AN – ammonium nitrate; OMP – organo-mineral pellets and FYM – farmyard manure) in three splits. Ion selective electrodes (ISEs) have been identified as a suitable technology - due to their simplicity, affordability and portability – to achieving this. Presented herein, are characterization of key response characteristics of ISEs (slope, limit of detection, signal stability) to determine nitrate and ammonium ions (two key nitrogen-containing species uptake by plants) in a range of soil samples obtained from School of Agri-Food Technology and Manufacturing, Riseholm Campus, University of Lincoln, Lincoln, U.K. Eight soil samples were analysed in quadruplicates and results validated with Ion Chromatography. Membranes calibration was done, under uncontrolled general laboratory temperature, using various volumes of ammonium nitrate solution in concentrations ranging between 1 M and $10^{-3}$ M. Calibration results obtained showed that the slope, limit of detection and membranes responses obeyed the principles of both Nernstian and Nikolskii-Eisenman theory within the range tested (NH4+: y = 58.972x + 709.29, R^2 = 0.9946; NO3-: -55.705x + 255.79, R^2 = 0.9324). Meanwhile, ISEs recorded higher nitrate concentrations in 100% of the sample plots than I.C, with concentrations ranging from 47.01 mg/Kg to 14.38 mg/Kg and 4.97 mg/Kg to 3.77 mg/Kg respectively. Although, the concentration of nitrate in the fertilizers added per Kg of soil in the first split was low, however, this concentration is closer to ISEs analysis results but far higher than the I.C results. Similarly, ammonium analysis by ISEs recoded higher concentrations in 100% of the sample plots than analysis by I.C, with concentrations ranging from 13.79 mg/Kg to 5.58 mg/Kg and 5.97 mg/Kg to 1.79 mg/Kg respectively. There are disparities between the two methods, which can be attributed to the high sensitivity of ISEs in responding to low nutrient concentration in soil, rather than systemic bias from matrix effect or background interferences. In conclusion, although this is a first year Ph.D. research, however, polymer membrane-based ISE technology has shown promising potentials as an analytical method of choice for the evaluation of soil "available" nutrients, using the right amounts of selective ionophores.

# Designing drought-resilient plant microbiomes using single-cell Raman spectroscopy

## ABSTRACT

Plant-associated microbiomes are increasingly recognized as key determinants of crop performance under environmental stress, particularly drought. However, a fundamental limitation in plant microbiome research is the inability to directly link microbial identity with *in situ* metabolic activity and stress tolerance. Sequencing-based approaches infer functional potential from gene content but cannot resolve phenotypic heterogeneity, dormancy, or activity differences among closely related taxa. Single-cell Raman microspectroscopy provides a label-free, non-destructive technique that captures biochemical fingerprints of individual microbial cells based on molecular vibrations of proteins, lipids, nucleic acids, and carbohydrates. When combined with stable isotope probing, particularly heavy-water ($D_2O$) labeling, Raman spectroscopy enables direct quantification of microbial metabolic activity through the formation of C–D bonds in newly synthesized biomass, offering a universal, substrate-independent measure of cellular activity. Recent advances in Raman-activated cell sorting further allow the targeted isolation and downstream genomic characterization of functional microbial populations, establishing Raman spectroscopy as a powerful "next-generation physiology" tool for resolving plant–microbe interactions at single-cell resolution.

Applying $D_2O$-labelled single-cell Raman spectroscopy to the wheat rhizosphere under graded drought stress, we observed a significant enrichment of metabolically active drought-tolerant bacteria (DTB) as drought severity increased. Raman C–D ratio distributions revealed strong functional skewness, with a small fraction of highly active cells contributing disproportionately to community-level metabolic activity. Targeted Raman-based sorting and sequencing identified 21 active DTB taxa enriched in genes related to osmotic stress regulation, phytohormone synthesis, biofilm formation, and carbon, nitrogen, phosphorus, and sulfur cycling. DTB activity was tightly coupled to drought-induced plant phytochemicals, including jasmonic acid, pipecolic acid, phenylpropanoids, and gibberellins, indicating metabolite-driven microbial selection. Importantly, a synthetic community constructed from four Raman-identified DTB strains significantly improved wheat growth and drought resistance, directly linking Raman-defined microbial phenotypes to plant fitness outcomes.

Our work demonstrates that single-cell Raman spectroscopy overcomes key limitations of traditional microbiome analyses by directly resolving microbial activity, stress tolerance, and ecological function within plant-associated communities. Integrating Raman-based phenotyping with microbiome ecology provides a robust framework for identifying functionally important microbes and enables trait-informed strategies for microbiome-assisted crop resilience in a changing climate.

**ABSTRACT**

Understanding root architecture is essential for improving pasture persistence and productivity under changing climates; however, measuring roots directly is challenging and often requires root washing that disturbs the spatial distribution of roots. We used X-ray micro-computed tomography (micro-CT) scanning as a non-destructive imaging technique to characterise and quantify root architecture of pasture plants within a controlled soil column (25 cm height, 65 mm inner diameter) system.

Three pasture species, a grass (*Lolium perenne* cv. Base AR37), a legume (*Trifolium repens* cv. Legacy) and a herb (*Cichorium intybus* cv. Puna II), were grown individually from seeds in a sand medium and were scanned multiple times using micro-CT. High-resolution (65 micrometre voxels) 3D image data sets were collected, segmented and processed to identify the presence and distribution of roots along the vertical axis at 3 cm intervals of the soil column.

Micro-CT scanning successfully detected root systems in all soil columns, which revealed inter-species differences in root distributions. At the surface (0-3 cm), the herb had the greatest presence of roots (0.54 $cm^3$), followed by grass (0.32 $cm^3$), and then the legume (0.11 $cm^3$). At greater depths (6-9 cm), the herb and grass were similar and had greater root volume than the legume. Near the bottom of the soil column (> 15cm), the herb had greater root volume than both the grass and legume, indicating a deeper and more extensive root system. These findings highlighted the potential of micro-CT to decipher species-specific rooting strategies in a pasture system with acquired three-dimensional datasets.

This study demonstrated the value of the X-ray micro-CT scans as an advanced instrumental technique for non-destructive root phenotyping and quantitative analysis without affecting the growth of the scanned species. This approach provides a robust methodological framework for future studies that plan on repeatedly investigating root architecture in pasture species.

**ABSTRACT**

Aluminum (Al) toxicity in acidic soils poses a major constraint to both plant productivity and microbial functionality, yet the adaptive evolution and practical applications of plant growth–promoting rhizobacteria (PGPR) under chronic Al stress remain poorly understood. Here, we combined experimental evolution, single-cell Raman–D2O spectroscopy, and multi-omics analyses to dissect the Al tolerance of three PGPR strains and their associated plant benefits. Over a 32-day evolution, as observed in single-cell metabolic activity, Al-tolerant subpopulations progressively became dominant with the proportion of tolerant cells increasing to 58.9–96.2%. Whole-genome and transcriptomic analyses revealed coordinated mutations and lineage-specific transcriptional reprogramming that remodel metabolism, strengthen cellular structures, and activate distinct stress-response functions to confer Al tolerance across evolved strains. Additionally, the evolved isolates and their synthetic communities (SynComs) increased rhizosphere pH, reduced Al bioavailability, and enhanced rice growth under both hydroponic and soil conditions. Notably, SynCom inoculation reduced shoot Al content by up to 58.9% in acidic soil. Furthermore, the rhizobacterial community was enriched with beneficial plant-associated taxa following SynCom inoculation. Together, these findings establish a scalable framework for evolving and assembling Al-tolerant PGPR to mitigate Al toxicity and enhance crop resilience in acid soils.

**ABSTRACT**

This study presents the new application of dual-analyte single particle inductively coupled plasma quadrupole mass spectrometry (spICP–QMS) to the discrimination and quantification of two typical soil nanoparticles (kaolinite and goethite nanoparticles, abbr. KNPs and GNPs) in three samples (SA, SB, and SC) with three detection events (Al unpaired event, Fe unpaired event, and paired event). SA was mainly composed of KNPs with a concentration of 28443 ± 817 particle $mL^{-1}$ and a mean particle size of 140.7 ± 0.2 nm. SB was mainly composed of GNPs with a concentration of 39283 ± 702 particle $mL^{-1}$ and a mean particle size of 141.8 ± 2.9. In SC, the concentrations of KNPs and GNPs were 224541 ± 1401 and 70604 ± 1623 particle $mL^{-1}$, respectively, and the mean particle sizes of KNPs and GNPs were 140.7 ± 0.2 and 60.2 ± 0.3 nm, respectively. The accuracy of dual-analyte spICP–QMS was determined by spiking experiments, comparing these results with the measurements of other techniques, analyzing the samples in different SA and SB proportions and in different SC concentrations. Our results demonstrated that the dual-analyte spICP–QMS is a promising approach to distinguishing different kinds of natural NPs in soils.

**ABSTRACT**

Aluminium (Al)-tolerant beneficial bacteria confer resistance to Al toxicity to crops in widely distributed acidic soils. However, the mechanism by which microbial consortia maintain Al tolerance under acid and Al toxicity stress remains unknown. Here, we demonstrate that a soil bacterial consortium composed of *Rhodococcus erythropolis* and *Pseudomonas aeruginosa* exhibit greater Al tolerance than either bacterium alone. P. aeruginosa releases the quorum sensing molecule 2-heptyl-1H-quinolin-4-one (HHQ), which is efficiently degraded by *R. erythropolis*. This degradation reduces population density limitations and further enhances the metabolic activity of *P. aeruginosa* under Al stress. Moreover, *R. erythropolis* converts HHQ into tryptophan, promoting the synthesis of peptidoglycan, a key component for cell wall stability, thereby improving the Al tolerance of *R. erythropolis*. This study reveals ametabolic cross-feeding mechanism that maintains microbial Al tolerance, offering insights for designing synthetic microbial consortia to sustain food security and sustainable agriculture in acidic soil regions.

# From lab to field: An open-source, low-cost toolkit for soil $CO_2$ respiration research

**Thuc T. Nguyen[1*], Nurit Agam[1] and Elad Levintal[1]**

[1] *The Jacob Blaustein Institutes for Desert Research, Ben-Gurion University of the Negev, 84990, Israel*

*nguyan@post.bgu.ac.il

**ABSTRACT**

Soil $CO_2$ respiration is a fundamental component of the terrestrial carbon cycle and a key determinant of ecosystem carbon budgets and climate feedbacks. Accurate quantification of soil–atmosphere $CO_2$ exchange requires measurements that resolve temporal and spatial variability, whereas interpretation of subsurface dynamics and carbon source attribution requires depth-resolved monitoring complemented by incubation experiments. However, existing commercial approaches—such as flux chambers, eddy-covariance towers, and instrumentation for soil profile monitoring and laboratory incubations—are often costly, labor-intensive, and logistically demanding, limiting their applicability for long-term, high-replication studies, particularly in remote or resource-limited environments. Here, we present a toolkit of three complementary, low-cost, open-source systems that together enable surface flux measurements, depth-profile monitoring of subsurface processes, and laboratory incubations for mechanistic soil respiration research. The first component is a portable incubation chamber system designed to support controlled, replicated laboratory soil respiration experiments (Nguyen et al., 2025a). The second component is a gradient-based sensor system that enables subsurface monitoring of soil $CO_2$, temperature, and relative humidity, together with atmospheric microclimate measurements (temperature, pressure, and relative humidity) (Nguyen et al., 2025b). A complete processing workflow is provided to derive soil $CO_2$ fluxes from depth-resolved concentration profiles using Fickian diffusion, and the system has demonstrated strong agreement with LI-COR References chambers. The third component is an automated flux chamber based on a closed dynamic approach, which has been tested under in situ conditions and shows good agreement with both LI-COR and Eosense systems across a wide range of fluxes. All three systems are fully open source, with openly available hardware designs, source code, and technical documentation, enabling users with limited prior experience to build, deploy, and adapt the systems for their own soil respiration studies.

# Nitrogen-fixing seed endophytes synergize with soil functional microbiota to enhance rice nitrogen supply

**Jia-Yan Xu[1], Chuan-Chao Dai[1], and Kai Sun[1*]**

*[1] College of Life Sciences, Nanjing Normal University, Nanjing 210023, China*

*kaisun@njnu.edu.cn

**ABSTRACT**

Rice (*Oryza sativa* L.) relies heavily on substantial nitrogen (N) inputs to ensure yield. Notably, *indica* rice subspecies generally exhibit higher N-use efficiency (NUE) compared to *japonica* subspecies. Plant microbiomes significantly influence rice N supply. Seed endophytes constitute a major source of the core plant microbiomes, particularly those functional ones, such as N-fixing microorganisms. However, the role and mechanism of functional seed endophytes in modulating rice N supply remain to be elucidated. Here, we investigated the N-fixing capacity of seed endophytes from multiple *indica* and *japonica* varieties. Results showed a significantly higher abundance of N-fixing genes in *indica* seeds than those in *japonica* seeds. Concurrently, distinct differences were observed in the N-fixing bacterial communities, with *indica* seeds enriched in bacteria such as *Paenibacillus* and *Bradyrhizobium*. Integrating high-throughput sequencing with pure-culture techniques, we selected the most abundant *Paenibacillus* from *indica* for in-depth study. *Paenibacillus* sp. JS-27, isolated from the conventional *indica* male parent 93-11, was ultimately chosen. Inoculating the *japonica* variety "Nangeng5055" with JS-27 significantly enhanced plant biomass and total N accumulation compared to non-inoculated plants. Further, scanning electron microscopy of inoculated seeds showed that JS-27 colonized the seed surface early and migrated to the roots of emerging seedlings upon germination, with some cells dispersing into the rhizosphere soil. To investigate whether JS-27, after soil migration, could also influence rice N supply by modulating the soil microbiome, we conducted inoculations under both natural and sterile soil conditions. The promotion of N uptake and plant growth by JS-27 was more pronounced in natural soil. Moreover, soils from the inoculated group showed significant enrichment of ammonia-oxidizing bacteria. Application of the nitrification inhibitors allylthiourea (ATU) and nitrapyrin (NRP) showed that JS-27-promoted rice growth was compromised by both inhibitors, concomitant with the reduced expression of *amoA*, and diminished JS-27-drived increase of rhizosphere nitrate/ammonium ratio. Experiments using an NRT1.1B knockout mutant (*nrt1.1b*, Zhonghua 11 (ZH11) background), which impairs nitrate transport, showed that in natural soil, the growth-promoting effect of JS-27 on *nrt1.1b* was significantly decreased compared to wild-type ZH11. Additionally, analysis of rhizosphere soils from multiple *indica* and *japonica* varieties across major rice-growing provinces in China revealed a potential correlation between the abundances of N-fixing and ammonia-oxidizing bacteria. These results demonstrate that *Paenibacillus* sp. JS-27 drives soil ammonia oxidation, which cooperatively enhances rice N supply and growth. To enhance stable colonization and efficacy, we embedded *Paenibacillus* sp. JS-27 onto seed surfaces using sodium alginate and pectin. This microbial seed coating treatment significantly increased total N content and yield compared to non-inoculated treatments. The present work provides insight into how the seed N-fixing microbes promote rice N supply and offers a promising strategy for optimizing crop growth by harnessing the functional seed microbiota for sustainable agriculture.

**ABSTRACT**

*In situ* and non-destructive root phenotyping remains a challenge due to the difficulty of continuous monitoring, of recognizing roots within a complex soil matrix and generating a robust, automated analysis workflow. Here, we present a novel fluorescence minirhizotron (FMR) system that simultaneously obtains root images of green fluorescent protein (GFP) fluorescence and regular visible-light root images, taken at the same time and position, allowing for a direct comparison between the two. The root fluorescence images originate from a constitutively GFP-expressing transgenic 16c line of *Nicotiana benthamiana* with wild-type serving as the non-GFP fluorescent control. A pilot system was initially tested based on root imaging with rhizoslides and, later, in a real-world scenario using the FMR system in soil, thereby demonstrating the system's robustness and applicability across a wide range of scenarios. A total of 1,080 and 2,108 images with the pilot system and the FMR, respectively, were collected, each comprising equal numbers of visible-light and corresponding GFP images. From these images, 100 pilot-system and 204 FMR images were manually annotated for total root length (TRL) using Rootfly software. In addition, we present an automated solution for GFP intensity measurements, comparing four thresholding methods. We also incorporate automated TRL analysis for imaging types, using a well-established convolutional neural network model which achieves $R^2$ values of 0.93-0.99 for the automatic TRL estimations. These automated methods were used to successfully differentiate between GFP-expressing and non-expressing plants, which cannot be achieved based on regular bright-field imagery.

**Keywords:** Root, minirhizotron (MR), green fluorescence protein (GFP), total root length (TRL), Convolutional neural networks (CNNs).

# Green Surfactant Remediation of Petroleum Hydrocarbon-Contaminated Soil and Bacterial Community Response

**Changhao Wu[1], Gubai Luo[1], Qingqing Qin[1], and Yan Zhu[1*]**

[1] *Technical Center, Center Environmental Protection Technology Co., Ltd., Beijing, China*

*zhuyan@centerint.com

**ABSTRACT**

Soil contamination by total petroleum hydrocarbons (TPH) has become a prominent global environmental issue, which severely threatens soil ecosystem functions, groundwater security and human health. Surfactant-enhanced soil washing is widely applied in TPH-contaminated soil remediation, yet the ecological impacts of green surfactants on soil bacterial communities, especially the dynamic changes of microbial co-occurrence networks and the succession of keystone taxa during washing and post-remediation recovery, remain largely unclear. In this study, a laboratory column experiment was conducted using rhamnolipid and rhamnolipid-alkyl polyglucoside (APG) green surfactant systems at low and high concentrations, with four sampling stages including original control (CB), post-washing (L), 30-day incubation (T30) and 60-day incubation (T60). We systematically analyzed TPH removal efficiency, soil physicochemical properties, bacterial community structure, co-occurrence network topological characteristics and multi-method identified keystone taxa. The results of non-metric multidimensional scaling (NMDS) showed that sampling stage rather than surfactant type and concentration was the dominant driving factor of bacterial community structural divergence. The co-occurrence network analysis revealed that surfactant washing significantly enhanced microbial interspecies connectivity but reduced community stability, and the network structure gradually recovered to the native state with the extension of incubation time. Keystone taxa analysis indicated that the abundance of core functional taxa decreased sharply after washing and recovered rapidly during recovery, which was highly coupled with network stability and TPH degradation efficiency. Among all treatments, the low-concentration rhamnolipid-APG mixture (M1) achieved the highest TPH removal efficiency (77.2% at 60 days), with mild disturbance to soil bacterial communities and rapid recovery of network structure and keystone taxa. This study confirms that the low-concentration rhamnolipid-APG mixture is an optimal green surfactant system for TPH-contaminated soil remediation, and provides important theoretical support and technical References for efficient and eco-friendly in-situ remediation of TPH-contaminated sites with built infrastructure.

# Contrasting soil functional responses to climate change in restored and spontaneously colonized mine tailings

**Ceacero-Moreno, Matías[1*], Álvarez-Rogel, José[1], Martínez-Sánchez, J. José[1] and González-Alcaraz, M. Nazaret[1]**

*[1] Department of Agricultural Engineering of the E.T.S.I.A., Technical University of Cartagena member of European University of Technology EUT+, 30203 Cartagena, Spain.*
*matias.ceacero@upct.es

**ABSTRACT**

Metalliferous mine tailings pose major environmental hazards and hinder biotic colonization due to their harsh conditions (high levels of metals/metalloids and salts, scarcity of organic matter and nutrients). Traditional restoration based on topsoil capping and revegetation is costly and can yield ecosystems with limited long-term sustainability, especially in semiarid regions. As a nature-based alternative, phytomanagement, particularly phytostabilization, relies on the ability of certain plants to establish directly on mine wastes, reducing pollutant mobility and enhancing soil functions. This approach can be strengthened by studying native vegetation that spontaneously colonizes tailings and underlying soils, offering a natural model of passive restoration. Because restoration seeks to minimize human and environmental risks over the long-term, understanding how tailing soils respond to climate change is essential.

This study experimentally evaluated the effects of climate change on the functionality of soils from mine tailings differing in their management history over the last 40 years: one technically restored through topsoil capping and pine afforestation, and another spontaneously colonized by native vegetation. Soils were collected from both type of tailings in the La Unión-Sierra de Cartagena mining district (SE Spain, semiarid region), one of Europe's major 20th-century mining areas, which currently hosts 89 tailings, most of them unrestored. Soils were sampled under two types of vegetation cover (shrubs and pines) and incubated for four months in climate-controlled chambers (two months simulating spring and two summer) under three IPCC-based scenarios: current climate (450 ppm $CO_2$, current temperature), moderate warming (700 ppm $CO_2$, +3 °C), and strong warming (1000 ppm $CO_2$, +5 °C). A range of soil physicochemical and biological indicators were analyzed, including enzyme activities (C, N, P cycles), microbial biomass C and N, microbial community composition, and C and N mineralization.

Results showed that soil responses varied across climate scenarios and were modulated by both tailing management history and type of vegetation cover. Microbial biomass and enzyme activities were particularly sensitive to climatic stress, with stronger shifts in restored tailing soils. Spontaneously colonized tailing soils displayed more stable patterns, suggesting higher resilience to climate change. Across both tailings, bacterial richness decreased under moderate and strong warming, whereas functional diversity increased in colonized soils, indicating potential microbial adaptation. These findings highlight the need to integrate climate change projections into mine tailings management, promoting nature-based restoration strategies that enhance soil resilience and long-term ecosystem stability in semiarid environments.

**ABSTRACT**

While inputs from natural sources constitute a significant burden of trace elements, for most elements the contribution from anthropogenic sources is much greater than from natural sources, raising environmental and health concerns [1]. Heavy metals from anthropogenic sources also tend to be more mobile and therefore more bioavailable compared to pedogenic or lithogenic sources [2]. The contribution of anthropogenic sources can be more reliably determined by the amount of heavy metals in the non-residual fraction rather than their total amount. In surface soils (0-10 cm), the contribution of anthropogenic sources to Cu, Zn, Pb and Ni in the non-residual fraction, i.e. the readily and potentially bioavailable and mobile fraction, was 51%, 70%, 24% and 49%, respectively [3].

Contamination of soils and arable land with trace elements such as Cu, Zn and Pb can occur due to the transfer of these elements into the fertilizer during the production of phosphorus fertilizers from phosphate rock [4; 5], the metal content in phosphate fertilizers may increase with the depletion of high quality phosphate rock in the world [6], and the potential of phosphorus fertilizer to increase the amount of heavy metals in soils is considered as an environmental concern [7]. When 1 ton of phosphorus fertilizers such as superphosphate and TSP are applied to the soil, Cu (20-138 g $ha^{-1}$), Zn (55-235 g $ha^{-1}$), Pb (3.13-17.4 g $ha^{-1}$), Ni (19.2-44.2 g $ha^{-1}$) are added to the soil [8]. Total Cu (0.2-1170 mg $kg^{-1}$), Zn (15.81-1450 mg $kg^{-1}$), Pb (3-225 mg $kg^{-1}$) and Ni (0.5-151 mg $kg^{-1}$) in phosphorus fertilizers; total Cu (3-93.5 mg $kg^{-1}$), Zn (96.3-424 mg $kg^{-1}$), Pb (3.3-240 mg $kg^{-1}$) and Ni (<0.25-35 mg $kg^{-1}$) in micronutrient fertilizer; total Cu (12-50 mg $kg^{-1}$), Zn (1.3-25 mg $kg^{-1}$), Pb (60 mg $kg^{-1}$) in pesticides were determined [7; 8; 9; 10; 11; 12; 13; 14; 15].

In a previous study; the determination of high amounts of total Cu, Zn and Pb in agricultural soils compared to the References soil was the result of long-term application of high amounts of fertilizers and pesticides-fungicides. Phosphorus and potassium fertilizers were identified as the main source of anthropogenic effect in the soil since Cu, Zn, Pb, P and K were in the same principal component and group according to principal component and cluster analysis [16].

In our study, soil samples were taken from depth of 0-20 cm of apple orchards and leaf samples were also taken from the trees. In order to evaluate the behavior, mobility, bioavailability and phytotoxicity of Pb and Ni elements in the soil, total and available Pb and Ni as well as seven geochemical fractions of Pb and Ni (water soluble and exchangeable, bound to carbonates, bound to Mn oxides, bound to amorphous Fe/Al oxides, bound to crystalline Fe oxides, bound to organic and sulfides, residual fractions) were determined using sequential extraction and compared with control samples. Additionally, the relationship of Pb and Ni with available P, Cu and Zn in the soil, their relative distribution among fractions evaluated. To assess the degree of soil contamination, pollution indices such as Enrichment Factor (EF), Contamination Factor ($C_f$), Bioaccumulation Factor (BAF) were determined.

## ABSTRACT

Iron (Fe)-driven biogeochemical processes are central to the production of reactive oxygen species, particularly hydroxyl radicals (•OH), under redox-fluctuating conditions in soil. Although Fe and manganese (Mn) frequently coexist in soils, their coupled effects on •OH generation remain poorly understood. This study revealed previously unrecognized synergistic interactions between Fe and Mn that significantly enhanced •OH production during soil oxygenation, as demonstrated through both soil microcosm incubation and mineral model experiments. In the soils enriched with Fe and Mn, substantial •OH accumulation (19.8-325 μM) was observed, with Fe(II) and Mn(II)/Mn(III) identified as primary electron donors. Scavenging experiments showed that the combined contribution of Fe and Mn to •OH generation exceeded 100%, confirming their synergistic interaction. This synergism was further demonstrated in mineral systems containing both reduced Fe oxides and Mn oxides, where •OH accumulation surpassed theoretical additive values by 61.8%, and electron utilization efficiency measured via ABTS+• increased nearly threefold. Wet chemical analysis, electron microscopy, and in situ Fourier transform infrared spectroscopy collectively elucidated that Fe(II)-driven regeneration of Mn(II)/Mn(III) facilitated the production of $O_2^{\bullet-}$, the precursor species of •OH, while atomic-scale Fe and Mn proximity induced the formation of Fe-O-O-Mn peroxide complexes—both mechanisms synergistically enhancing •OH accumulation. The •OH generated via Fe-Mn synergism further mediated the oxidative transformation of soil organic carbon, copper sulfide, and organically bound copper. These findings unveil a novel natural pathway for •OH production under redox oscillations, and underscore the critical yet overlooked role of Fe-Mn coupling in soil biogeochemical cycles.

# Bioremediation Mechanism of Polycyclic Aromatic Hydrocarbon Contaminated Soil Based on Signal Molecular Regulation Strategy under Low Temperature Stress

**Ning Hou[1*], Qiuying Song[1], Dapeng Li[1]**

[1] *College of Resources and Environment, Northeast Agricultural University, Harbin 150000, China*

*houning@neau.edu.cn

**ABSTRACT**

As persistent organic pollutants, the degradation and mineralization efficiency of Polycyclic Aromatic Hydrocarbons (PAHs) further decrease in low-temperature environments, leading to significant accumulation of PAHs in soil. However, their toxicity mechanisms remain unclear, and the biodegradation mechanisms and remediation strategies for these pollutants under low-temperature stress are not well defined. This study aims to analyze the natural degradation efficiency and pathways of PAHs under low-temperature conditions, assess their toxic mechanisms on plants and soil microorganisms, detect the types of signaling molecules produced during the bioremediation process of contaminated soil, and elucidate the mechanism of interkingdom transduction of these signaling molecules and their mediated bioremediation mechanism for contaminated soil under low-temperature stress.

The study found that the ecological toxicity of PAHs to soil under low-temperature stress primarily involves oxidative stress, inhibiting plant growth and microbial metabolic activity. The combined application of synthetic microbial communities and plants demonstrated significant pollutant removal effects, effectively removing 83% of PAHs from the soil under low-temperature stress. This remediation process alleviated the oxidative stress caused by PAH contamination, lifted the inhibition of PAHs and the low-temperature environment on plant and microbial metabolic activities, ultimately achieving simultaneous PAH removal and restoration of the soil ecosystem. Further research revealed cross-feeding and communication among the functional degrading bacterial consortia. This interaction promoted PAH degradation and biofilm formation, further enhancing energy production and stress responses in the functional bacteria. As PAHs degraded, mediated by the LasI/LasR quorum sensing system, the T6SS system, and serine metalloproteases, the interaction among functional microorganisms shifted from cooperation to competition. This shift could provide more niche space for indigenous microorganisms involved in nutrient cycling, effectively restoring the ecological multifunctionality of the PAH-contaminated environment. The aforementioned research provides innovative strategies for PAH degradation and ecological restoration from the perspective of microbial interkingdom signaling.

**ABSTRACT**

Coal mining leaves a deep and lasting geochemical footprint on soil systems, yet a global synthesis of pollutant concentrations has been lacking. The meta-analysis by Alekseenko et al. (2025) establishes the first global References concentrations for chemical elements in coal mine soils, derived from a systematic review of 95 studies encompassing 13,925 soil samples across 55 coal fields in 32 countries. The resulting dataset provides mean concentrations for 41 elements, total organic carbon (TOC), and total rare-earth elements (∑REE).

Our findings reveal that coal mine soils are significantly enriched in specific pollutants compared to global pristine soils. The highest enrichment factors are for As, Bi, Hg, Sb, and Se, i.e., elements classified as coalphile, indicating their strong affinity for coal during geologic formation. This demonstrates that the geochemical signature of mined coal is a primary driver of soil contamination. Furthermore, TOC was 1.24 times higher than the global average, a misleading indicator of fertility likely driven by coal dust rather than humus formation. The calculated global References levels serve as a critical benchmark for risk assessment and policy. For instance, the global mean arsenic content (15.9 mg/kg) in coal mine soils exceeds the industrial soil screening levels of Canada, Russia, and the USA, highlighting a widespread ecological risk.

As the world's leading coal producer, China is represented through over 8000 soil samples from the coal basins and coalfields of Bayanhuxu-Eren, Beijing, Huainan, Junggar, Lianxing-Qujiang, Ordos, and South Yellow Sea. The calculated mean concentrations for key pollutants like arsenic do not exceed the global average. However, certain sites exhibit extreme anomalies, such as mercury and cadmium hotspots linked to other industrial and agricultural activities. When benchmarked against the Chinese Environmental Quality Standard for Soils, the average national-scale data for coal mine soils shows safe levels.

The global References values are essential for: (1) distinguishing site-specific pollution patterns from global trends, (2) predicting pollutant burdens in prospective mining areas, and (3) informing soil remediation guidelines and land-use planning in post-mining landscapes. This continental-scale deciphering of the soil-pollutant nexus provides a tool for soil scientists and environmental managers addressing the legacy of coal extraction.

## ABSTRACT

Methylmercury (MeHg), due to its bioaccumulation and neurotoxicity, is a global concern affecting soil and human health. Soil MeHg is usually produced via methylation of inorganic mercury (Hg) by microorganisms possessing *hgcAB* gene pairs. Microbial methylation of inorganic mercury is strongly mediated by soil organic matter (SOM) through affecting Hg species, the community structures of Hg methylators as well as their interactions with non-methylators. SOM regulates soil Hg species mainly through reduction or complexation pathways, depending on the properties of SOM such as electron donating capacity and sulfur species (Xing et al., 2025). Hg complexed by SOM is available for microbial uptake and methylation. Recent studies found that, in addition to their binding constants, the configuration of SOM-Hg complexes plays an important role in affecting microbial Hg methylation (Liang et al., 2023). Meanwhile, Hg methylation efficiency differs among Hg methylators owing to their differences in cell surface properties. The dominant Hg methylators in soil are usually shaped by SOM via functioning as carbon and energy sources (Pu et al., 2025). An intriguing point is that SOM metabolism by non-methylators can likely fuel Hg methylation by methylators. For instance, ester sulfate within SOM may be catabolized to produce sulfate, which in turn can promote the growth of the Hg methylators thus increasing the production of MeHg (Pierce et al., 2022). However, the detailed mechanisms governing the interactions between Hg methylators and non-methylators remain unclear. Taken together, we will try to summarize current understandings of microbial Hg methylation mediated by SOM and propose some knowledge gaps for better controlling soil MeHg production and its risk.

**ABSTRACT**

Chlorinated organic pollutants (COPs) are common pollutants in flooded environments. To examine the residual status and effects of COPs on flooded soil, we first applied a meta-analysis of COPs around the world, including 25 kinds of COPs from 977 sites. Results indicated that COPs were globally detected. The environmental risk of COPs on wetlands soil was higher than in other flooded environments.

We further surveyed 7 coastal wetlands soil in Zhejiang, East China. Gamma-HCH and o,p'-DDT posed the greatest risk. Samples with higher COP pollution had higher microbial diversity, more complex microbial networks, more deterministic community assembly processes and lower microbiome stability. Further analysis using quantitative real-time PCR suggested COP degradation interacted with natural redox processes. Non-obligate organochlorine-degrading bacteria (ODB) might play a significant role in the degradation process of COPs

Thus, we try to isolate ODB from these wetland soil samples. 4 strains were isolated and first demonstrated for γ-HCH degradation. They were identified as *Petrimonas sulfuriphila* PET, *Robertmurraya* sp. CYTO, *Hungatella* sp. CloS1 and *Enterococcus avium* PseS3, respectively. The residual γ-HCH concentrations were 58.8% (PET), 45.6% (CYTO), 60.2% (CloS1), and 69.3% (PseS3) of its initial value, respectively. They are generalists and non-obligate ODB. Genomic analysis indicated that each strain harbours genes annotated to the pathway of halogenated organic matter degradation (e.g. 2-haloacid dehalogenase) and cobalamin biosynthesis. The co-localization of these functional genes with horizontal gene transfer fragments was also identified. Cobalamin and 2-haloacid dehalogenase are involved in γ-HCH degradation. Horizontal gene transfer might facilitate the adaptation of the microbe. Together, these findings provide novel insights into improved bioremediation strategies for COP-polluted soil based on generalist ODB.

**ABSTRACT**

Antibiotic use in livestock production is increasingly scrutinized due to risks of soil contamination, selection of antimicrobial resistance, and trophic transfer. Yet, national-scale spatial patterns of soil deposition remain poorly characterized, limiting targeted mitigation. This study presents a first-approximation framework to estimate and map annual soil deposition of veterinary antibiotics across Brazilian municipalities. We compiled 2023 livestock inventories for 5,298 municipalities and combined them with literature-derived consumption coefficients and average live weights. A generic degradation/deposition factor was applied to translate use into potential soil loads. Cattle, swine, and poultry accounted for >97% of estimated deposition, yielding a national load of 4,769 t year$^{-1}$, with relative contributions of 85.6%, 12.2%, and 2.2%, respectively. Although poultry accounts for the largest number of animals, their comparatively low body mass results in only 2.2% of total antibiotic deposition, while swine contribute 12.2% and cattle 85.6%. Regional total antibiotic loads corresponded to 28, 23, 21, 16, and 13% in the Mid-West, North, Southeast, South, and Northeast regions. Because municipal-level livestock data, antibiotic-use coefficients, and deposition parameters vary in quality and completeness, the resulting maps must be interpreted with caution. Municipalities in highly intensive production regions such as Santa Catarina and Paraná may be underrepresented. These states have vertically integrated poultry and swine industries in which detailed farm-level information is commercially sensitive; as a result, production data are commonly reported only in grouped or averaged forms across wider administrative units rather than at municipality level. This reduces the spatial precision of official inventories and can obscure local hotspots. Consequently, some mismatches between expected and mapped deposition patterns likely reflect limitations in data resolution rather than true environmental differences. Despite these uncertainties, the framework provides an operational baseline for national-scale assessments and can support future integration with molecule-specific usage data, biome sensitivity layers, and uncertainty propagation analyses. This approach is replicable for other countries and can help build harmonized global evaluations of soil exposure to veterinary antibiotics.

## ABSTRACT

Chlorinated organic pollutants (COPs), encompassing legacy pesticides as well as emerging compounds, persist in soils worldwide, exerting subtle yet profound environmental risks at trace levels. A pivotal but underappreciated facet of their environmental fate is the interplay between their dominant degradation process—microbial reductive dehalogenation—and other redox pathways, such as methanogenesis, which can amplify ecological impacts in anaerobic settings. This study adopts a multi-scale strategy, spanning national soil surveys to targeted microbial consortia, to elucidate this coupling.

A comprehensive nationwide survey of 278 soil samples from seven habitats in China uncovered ubiquitous COPs contamination, with 100% detection rates for key groups like DDTs and HCHs. Residue levels averaged 103.03 ng $g^{-1}$, sustained by both historical legacies and ongoing inputs. Notably, anaerobic soils (e.g., paddies and wetlands) displayed elevated ecological risks (89.1% moderate risk) relative to aerobic counterparts (90.8% low risk), correlating with higher methane emission potentials and underscoring how COPs may exacerbate greenhouse gas fluxes.

Quantitative PCR (qPCR) profiling of organohalide-respiring bacteria (OHRB) across these soils revealed their prevalence, especially in waterlogged anaerobic environments ($10^6$–$10^8$ gene copies $g^{-1}$ dry soil). Microcosm assays with lindane (γ-HCH) as a proxy pollutant confirmed a synergistic dehalogenation-methanogenesis dynamic: degradation rates correlated strongly with dehalogenase (rdhA) gene abundance ($R=0.90$, $P<0.001$), while methane yields rose in tandem ($R=0.81$, $P<0.001$). This indicates that OHRB communities not only attenuate COPs but also potentially intensify methane production, posing dual challenges for pollution remediation and climate goals.

Mechanistic insights from synthetic co-cultures of the obligate dechlorinator *Dehalococcoides mccartyi* (Dhc) and methanogen *Methanosarcina barkeri* (Met) illustrated this syntrophy: the pair achieved >98% lindane removal within 10 days, yielding 14.56 mmol $CH_4$. Met's provision of cobalamin to Dhc and $H_2$ scavenging enhanced dehalogenation efficiency while modulating carbon cycling, highlighting how microbial partnerships can balance pollutant fate with biogeochemical outcomes.

In conclusion, this research underscores the critical need to consider the ecological risks of COPs, particularly in anaerobic soils where their persistence and interaction with methanogenesis can exacerbate environmental challenges. Our findings provide a foundation for developing targeted bioremediation strategies that not only enhance COP removal but also mitigate greenhouse gas emissions, contributing to the "One Health" paradigm.

**ABSTRACT**

Fomesafen (FSA), a widely applied diphenyl ether herbicide, frequently contaminates soils by agricultural application, yet its anaerobic fate in soils remains poorly resolved. This study systematically evaluated FSA biodegradation under five environmentally relevant anaerobic redox conditions—nitrate, $MnO_2$, Fe(III), sulfate, and bicarbonate (methanogenic)—using microcosms constructed from deep soil. Paired treatments with and without glucose (1 mM) assessed the extent of co-substrate stimulation. FSA remained stable in sterile controls, confirming negligible abiotic loss. In active microcosms, degradation was strongly redox-dependent. Fe(III)-reducing conditions supported complete FSA removal within 140 days, and glucose addition accelerated transformation dramatically, achieving full removal within 18 days, reducing the half-life from 36.9 to 2.5 days. Sulfate- and bicarbonate-reducing systems displayed moderate removal (49.9–53.8%), while $MnO_2$-supported degradation was limited (14.4%). Glucose significantly enhanced all three systems, increasing removal efficiencies to 55.9–90.3%. Nitrate-reducing microcosms exhibited negligible transformation (<5%), with only minor enhancement upon glucose addition. These findings demonstrate that Fe(III)-reducing conditions represent a dominant anaerobic pathway for FSA degradation in groundwater and that co-substrate stimulation can greatly improve biodegradation rates. The study provides critical insight into the natural attenuation potential and informs the development of targeted redox-based bioremediation strategies for FSA-contaminated soils.

**ABSTRACT**

As a representative newly emerging pollutant, perfluorooctanoic acid (PFOA) with high environmental persistence and resistance to degradation, poses serious risks to soil ecosystems and human health under ongoing climate change. The increasing concentration of $CO_2$ in the atmosphere is perturbing the global nitrogen cycle, altering soil properties and associated microorganism. However, the impact of elevated $CO_2$ ($eCO_2$) on the residues of PFOA and nitrogen cycle in contaminated soil is insufficiently understood. Here, a free air $CO_2$ enrichment (FACE) system was used to evaluate defluorination, nitrogen cycle and related microbial communities in response to $eCO_2$ (ambient $CO_2$ concentrations + 200 μmol $mol^{-1}$). Our results demonstrate that $eCO_2$ significantly decreased the residues of PFOA (by 15.2-28.1%). The relative abundance of organohalide-respiring bacteria (OHRB, e.g. *Dehalococcoides, Desulfitobacterium*, *Desulfovibrio*, and *Anaeromyxobacter*) were significantly increased by $eCO_2$, indicating the enhanced defluorination effects induced by $eCO_2$. Besides, exposure to $eCO_2$ led to reductions in the concentrations of $NH_4^+$-N and $NO_3^-$-N and in the abundances of nitrogen cycle-related genes (Bac-*amoA*, Arch-*amoA, nirS*, *nirK* and *nosZ*), which simultaneously alleviate the competitive inhibition on OHRB and restrict the substrate availability for nitrification and denitrification, thereby suppressing $N_2O$ emissions. Bac-*amoA* gene copies showed a strong and significant negative correlation with PFOA degradation rate ($p < 0.05$). SEM also showed PFOA degradation exhibited notable positive feedback on nitrogen cycle ($p < 0.001$). Overall, this research preliminarily revealed that PFOA removal was promoted and nitrogen cycle may be associated with reductive defluorination under $eCO_2$, providing new insights into the interactions between defluorination and elemental cycle under climate change.

**ABSTRACT**

Soil enzymatic activities and organic carbon (C) and nitrogen (N) pools are fundamental indicators of microbial functioning and nutrient cycling, providing an integrated assessment of soil health under both natural and disturbed conditions. Despite their global importance for C-storage and food production, tropical soils remain understudied with respect to their biochemical sensitivity to heavy metal contamination and the extent to which land-use and management practices modulate this response and impact on soil health. Soils from three contrasting land-use systems (native forest, conventional crop rotation, and crop rotation with diversified cover crops) were incubated for 45 days under Control, Cd (3 mg $kg^{-1}$), and Cr (150 mg $kg^{-1}$) treatments. Phosphatase, arylsulfatase, urease, and β-glucosidase activities were determined by colorimetric assays, while organic C and total N were measured by dry combustion. All indicators were integrated into a Biological Soil Quality Score to compare management-specific resilience. Enzymatic responses reflected land-use effects rather than metal addition. Short-term responses showed that soil management, rather than Cd or Cr addition, governed biochemical behavior: neither metal altered enzyme activities or C and N pools, suggesting low bioavailability and strong buffering typical of highly reactive tropical soils reach in Fe- and Al-hydroxides. Native forest exhibited the greatest phosphatase, arylsulfatase, and urease activities, reflecting intense P, S, and N mineralization in unfertilized, nutrient-limited (oligotrophic) conditions. Conversely, the most biodiversity system (regenerative agriculture) showed the highest β-glucosidase, reflecting stronger cycling of labile C; while conventional crop rotation had the lowest phosphatase and arylsulfatase activities, consistent with reduced enzymatic demand under fertilization. Despite higher enzyme activities and C contents, except for β-glucosidase, the native forest (0.15) showed the lowest Biological Soil Quality Score, whereas agricultural systems (conventional crop rotation - 0.84 and crop rotation with diversified cover crops - 0.86) scored much higher due to greater mineral nutrient inputs and markedly lower acidity from liming. Overall, the results demonstrate that enzyme profiles must be interpreted considering resource constraints and management history, as elevated activity can denote compensatory response rather than enhanced soil condition.

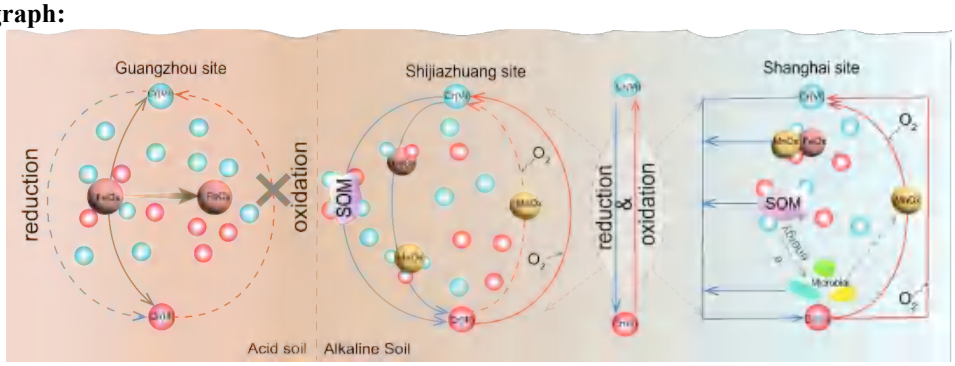
**ABSTRACT**



Rising sea levels and climate change are intensifying soil flooding and altering redox dynamics, profoundly influencing chromium (Cr) behavior in contaminated industrial soils. Here, we combined *in situ* techniques, including high-resolution diffusive gradients in thin-films (HR-DGT) and planar optodes (PO), with *ex situ* incubation to unravel the transformation and availability of Cr in different industrial soils under both short-term and long-term flooding. Results showed that soil physicochemical properties strongly governed oxic-anoxic microzone (<3 mm) formation and redox-driven Cr availability. In acidic soils characterized by low soil organic matter (SOM) and amorphous Fe oxides (Ox-Fe), limited Cr(VI) reduction led to high labile Cr(VI) concentrations even under prolonged flooding. Conversely, high SOM and Ox-Fe in alkaline soils promoted significant Cr(VI) reduction and stabilization. However, the potential for Cr(III) reoxidation was confirmed at oxic-anoxic microzones in MnOx-rich alkaline industrial soil, where microbial activity further intensified redox transformations. Specifically, higher 16S rDNA copy numbers and abundances of Cr-related bacteria genera (e.g., *Sphingomonas* and *Lysobacter*) were found in soils facilitating Cr transformation. This study provides a mechanistic framework for predicting Cr behavior in flood-prone industrial soils and highlights the need for site-specific management strategies under climate change impacts.

**Keywords:** HR-DGT, planar optodes, anoxic-oxic interfaces, soil properties, microbial activity

**Highlights:**

a) Coupled HR-DGT and planar optodes revealed in situ Cr redox heterogeneity.
b) Acidic soils with low SOM maintained high mobile Cr(VI) under flooding.
c) MnOx-rich alkaline soils triggered Cr(III) reoxidation at oxic-anoxic microzones.
d) Microbial communities intensify redox-driven Cr transformations and mobility.
e) Soil properties governed Cr availability under varying flooding durations.

**ABSTRACT**

The interplay between inorganic arsenic (As) and soil minerals is critical for predicting As geochemical processes. However, our understanding of the reactive mineral interfaces and the microscopic interaction mechanisms of As in soils remains limited. Here, by integrating multiple characterization techniques and focusing on microscopic interfacial speciation, we successfully elucidated the interactions between As and two representative minerals—ferrihydrite and silicate clay minerals. Batch adsorption experiments revealed an apparent contradiction between the adsorption affinity and capacity of As(III) and As(V) on ferrihydrite. We demonstrate that As(III) forms predominantly monodentate complexes at high loadings, whereas As(V) consistently forms bidentate complexes. Consequently, although As(III) exhibits weaker binding strength, it occupies more surface sites and therefore displays lower affinity but higher adsorption capacity (*Figure 1*) [1]. Component extraction and adsorption experiments showed that clay minerals exhibit substantial adsorption of As—contrary to common assumptions that net negative charged clay minerals should have been ignorable regarding the adsorption of As. We conclude that, despite electrostatic repulsion on basal surfaces, hydroxyl groups on edge surfaces can form hydrogen bonds and covalent bonds with oxyanions, indicating a non-negligible contribution of clays to As retention (*Figure 2*) [2]. Our study further identified the key reactive surfaces controlling As adsorption in soils and, elucidated how microscopic speciation governs macroscopic behavior. This bottom-up, mechanistic approach provides fundamental insights into the environmental behavior of As.

# Microbial Degradation of Soil Microplastics (MPs) Related to Greenhouse Gas Emissions

**Yuhan Yin, Zhihuai Chen, and Xiao-San Luo***

*Department of Agricultural Resources and Environment, Nanjing University of Information Science & Technology, Nanjing, China*

*E-mail Address: xsluo@nuist.edu.cn

**ABSTRACT**

Microplastics (MPs) pollution and greenhouse gas (GHG) emissions are two significant global environmental issues. While microorganisms are central to MPs degradation, their specific response to environmental stress in unique soil ecosystems (e.g., saline-alkali land) and the subsequent regulatory mechanisms over GHG emissions remain poorly understood. This work deciphers the link between microbial-mediated MPs degradation and soil GHG emissions, particularly under such stressed conditions. Results demonstrate that MPs function as an exogenous carbon substrate, enhancing GHG emissions. Their degradation reshaped the native microbial community structure and actively interfered with soil carbon and nitrogen cycling processes. These findings highlight microbial degradation of MPs as a critical driver in regulating GHG emissions from terrestrial environments.

**ABSTRACT**

Efficient bioremediation of chlorinated organic pollutants (COPs) under anaerobic soil is often constrained by concurrent methane production, posing a trade-off between pollutant removal and greenhouse gas mitigation. Here, we present a digital-driven framework that integrates pure/co-culture experiments, multi-omics comprehensive databases, and genome-scale metabolism-expression modeling to rationally design microbial consortia for COPs remediation.

We focused on orchestrating interactions among key microorganisms: obligate dechlorinating bacteria (Dhc), methanogens (Met), and facultative dechlorinators, including iron-reducing bacteria (Geo) and sulfate-reducing bacteria (Dsv). Dhc displayed limited yet stable dechlorination activity and showed dependence on essential metabolites supplied by its partner strains. The Dhc-Met consortium demonstrated high pollutant removal efficiency and carbon-reduction potential. Incorporation of Dsv or Geo with Dhc further enhanced synergistic interactions, enabling directed metabolite and electron flow toward dechlorination pathways. Notably, the Dhc-Met-Dsv community achieved high dechlorination rates with minimal methane accumulation via combined direct interspecies electron transfer (DIET) and complementary metabolic exchanges. Under lactate-fed conditions, the four-member consortium sustained efficient dechlorination and methane suppression through competitive carbon utilization and metabolic complementarity. Key metabolites (e.g., cobalamin, cysteamine), electron carriers, and environmental factors (carbon sources, sulfate, hydrogen partial pressure) were identified as critical regulators of community function.

This study provides a theoretical basis and new perspectives for developing precision bioremediation strategies for COP-contaminated soils. It also contributes to advancing sustainable environmental management under the “dual-carbon” goals.

## ABSTRACT

Residual herbicides persist widely in soybean-producing soils and may disrupt rhizosphere microbial communities underlying plant health. However, their combined impacts on soilborne disease dynamics remain poorly understood. In this study, pot experiments together with supporting microbiological tests were used to examine how different levels of combined herbicide residues influence microbial communities, core microbial taxa, microbial functions, and the development of soybean root rot. Combined herbicides at high residual level negatively affected soybean growth and significantly contributed to soybean root rot ($P < 0.05$). Microbial complexity and stability were significantly reduced by herbicides at moderate and high levels, conducive to pathogen invasion. The typical pathogens of *Fusarium* spp. exhibited as the keystone taxa in microbial networks or significantly ($P < 0.05$) enriched in treatments with herbicide residues. Additionally, we highlight the importance of core microbial taxa by tracking rhizosphere microbial changes across different time points. Herbicide stress increased root rot severity, with elevated DSI evident from the early seedling stage (5-7d) and persisting throughout the period. Notably, herbicide-induced changes in core taxa on days 5-7 significantly ($P < 0.05$) correlated with final disease severity. Herbicide stress reduced key disease-suppressive functions (biosynthesis of macrolides, enediyne and vancomycin group antibiotics, and siderophore group nonribosomal peptides), which mechanistically explained DSI variation. These functions were linked to the identified core taxon Streptomyces. These findings provide improved evidence regarding the effect of combined residual herbicides on soybean root rot, with direct facilitation at high level and potential contributions at low and moderate levels. Importantly, days 5-7 was a sensitive period when herbicide stress disrupted core microbial taxa and promoted disease development. Therefore, maintaining the abundance and stability of core taxa during this period is important, even under low-herbicide stress. This study highlights the often-overlooked effects of herbicides on soil and plant health, and the key role of early core taxa in shaping plant–pathogen interactions under herbicide stress. These findings offer useful insights for developing microbiome-based strategies to improve plant protection in sub-healthy agricultural soils.

## ABSTRACT

Metalliferous mine tailings are among the most challenging terrestrial environments due to their high concentrations of metal(loid)s, lack of organic matter and nutrients, poor soil structure and, in some cases, extreme pH and high salinity. Conventional restoration strategies usually rely on topsoil capping and revegetation, but their long-term sustainability in semiarid regions has been questioned. Alternatively, phytomanagement approaches based on the direct growth of plants on mine wastes are increasingly considered nature-based solutions capable of promoting functional soil-plant systems through the formation of fertility islands. However, little is known about how restored and spontaneously colonized tailings respond to global warming in terms of functionality and ecotoxicological risks, which is essential to evaluate the suitability of phytomanagement versus conventional restoration under current and future climate scenarios.

The SIMULATE project aims to assess how and to what extent conventionally restored (capping and revegetation) and spontaneously colonized metalliferous mine tailings from Mediterranean semiarid areas respond to warming, relative to natural surrounding soils. To achieve this, warming conditions are experimentally forced in the field by installing open-top chambers (OTCs) in shrubland patches. The greenhouse effect inside the OTCs increases air and surface soil temperatures, enhancing evapotranspiration and inducing soil dryness and plant stress. Physical, physicochemical and biological soil parameters related to ecosystem functionality are being monitored over a 2-year period, allowing successive seasonality to stimulate system responses to forced warming. Monitoring includes key biological indicators such as $CO_2$ emissions, organic matter decomposition, enzyme activities, microbial metabolic activity and phylogenetic composition, and invertebrate feeding activity and microarthropod community structure. Multigenerational ecotoxicity bioassays with soil invertebrates will be performed under controlled conditions that mimic the field warming treatments, enabling a comprehensive assessment of potential risks. SIMULATE will generate essential knowledge on the sensitivity of tailing soil-plant systems to climate warming and on the performance of nature-based phytomanagement strategies relative to conventional technical restoration. The results will support improved planning, management and restoration of metal-polluted environments in semiarid regions under present and future climate conditions. The poster presents the outline of the project.

*nazaret.gonzalez@upct.es

## ABSTRACT

Metalliferous mine tailings, which store waste from ore processing, are often regarded as barren, biologically impoverished substrates, yet many of them exhibit spontaneous plant colonization and the development of functional soil-vegetation systems. Over the last decade, our research in Mediterranean semiarid tailings, mainly from southeastern Spain, has investigated how management history (conventional capping and revegetation vs. abandonment without restoration and spontaneous colonization over years) shapes the functional and ecotoxicological performance of these systems under current and future climate conditions simulated through combining climate-controlled chambers and in situ warming experiments with open-top chambers. We adopt a holistic approach integrating soil physics and chemistry, multiple biological indicators of system functionality, microbial community attributes, plant functional traits and ecotoxicity tests to understand how the processes observed in spontaneously colonized tailings can inform and support nature-based phytomanagement strategies, and under which conditions these can be a realistic alternative to classical technical restoration.

Our studies show that fertility islands formed by native vegetation in abandoned tailings can attain levels of soil functionality comparable to those of nearby natural areas, despite high total metal(loid) concentrations. These vegetated patches modulate seasonal variability in soil moisture and temperature and act as hotspots of biological activity, enhancing microbial processes and soil-fauna dynamics. The structure and stratification of vegetation emerge as key determinants of medium- and long-term sustainability, but their functional roles in supporting processes such as C and N mineralization, mediated by the dominance of *k*- or *r*-strategy microbial communities, differ between management histories. Ecotoxicity assessments consistently show that biological functioning can be partially decoupled from total metal(loid) concentrations, highlighting the importance of bioavailability, microhabitat buffering and vegetation-driven amelioration. The presence of soil microarthropods is linked to the first stages of spontaneous plant colonization in abandoned tailings, acting as key agents in organic matter turnover and the recovery of ecosystem structure and function.

Overall, this research line provides an integrated, process-based framework to evaluate trade-offs between technical restoration and phytomanagement, and to support evidence-based management of metalliferous mine tailings in a warming, increasingly water-limited world. Together, these findings redefine how tailings are perceived, demonstrating that spontaneous ecological processes can generate functionally resilient soil-vegetation systems whose mechanisms are directly transferable to climate-smart phytomanagement interventions. The presentation will summarize these advances and highlight key knowledge gaps for future research.

# Photochemical characterization of paddy water: Formation of reactive intermediates for micropollutant degradation

**Yu Zeng[1*], Mingyang Zhang, and Guodong Fang[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*zengyu@issas.ac.cn

**ABSTRACT**

Although the photochemical behavior of surface water and its effects on pollutant transformation have been studied extensively in recent years, the photochemistry of paddy water remains largely unknown. In this study, we examined the photochemical processes involving paddy water samples collected at four different cultivation stages of rice. Triplet dissolved organic matter (3DOM*), singlet oxygen (1O2), and hydroxyl radicals (•OH) were found to be the dominant reactive intermediates (RIs), and their apparent quantum yields and steady-state concentrations were quantified. Compared with the typical surface water, quantum yields of 3DOM* and •OH were comparable, while quantum yields of 1O2 were about 2.4-6.7 times higher than those of surface water. Fluorescence emission-excitation matrix (EEM) spectra, Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS), and statistical analysis revealed that DOM properties and nitrite concentration were the main factor influencing RIs generation. The results suggest that DOM with lower molecular weight and humification extent generated more RIs, and nitrite contributed to 23.9%–100% of •OH generation. EEM and FTICR-MS data showed that DOM with more saturated and less aromatic formulas could produce more 3DOM* under the irradiation, while the polyphenolic components of DOM inhibited the formation of RIs. A kinetic model of RIS-induced pollutant transformation in overlying water of paddy field was constructed, and the contribution of RIs to the abiotic transformation of the typical insecticide imidacloprid was investigated. Firstly, the direct photolysis quantum yield of IMD is determined to be 1.05×10-4. The second-order reaction rate constants of IMD with 3DOM*, 1O2 and •OH are 3.77×108 L mol-1 s-1 (kIMD,3AQDS*), 3.78×106 L mol-1 s-1 (kIMD,1O2) and 2.52×109 (kIMD,•OH) L mol-1 s-1, respectively. The primary degradation rates of IMD in overlying water at seedling, tillering and joint stages were 0.024, 0.022 and 0.032 h-1, respectively. The steady-state concentration of RIs in water samples and the reaction rate of RIs with IMD determined the contribution of RISs to IMD degradation. Kinetic calculation determined that 3DOM* was the main active component (88-92%) that promoted the degradation of IMD. Further, a kinetic model was used to predict the photodegradation process of IMD in rice water under different environmental conditions according to the water photochemical parameters of rice and IMD photoreactivity of different RIs. DOM and NO2- concentrations determined the dominant position of 3DOM* and •OH, respectively. In addition, the degradation rate of IMD decreased gradually with the growth of rice. Product analysis showed that the primary denitrification intermediate was highly toxic, but further oxidation reduced its toxicity. The cleavage and ring-opening products are smaller in size than other intermediate molecules and are easily degraded in rice fields, but harmful to aquatic animals. The hydroxylation pathway related to 3DOM* and •OH is the detoxification process of IMD. This study provides new insight into the pathways of micropollutant abiotic transformation in paddy soil and water.

## ABSTRACT

Soil and water pollution pose a major environmental challenge in China. Emerging contaminants like agricultural plastic films, their additives, and microplastics (MPs) are of growing concern, yet critical gaps remain. These include inadequate monitoring, unclear pollution levels, poorly understood environmental processes and risks, and ineffective conventional controls—all compounded by their complex, multi-process-driven fate in the environment.

This research systematically assessed the environmental behavior and risks of plastic-associated pollutants across agricultural and wetland systems. For agricultural films, suspect screening and modelling revealed 89 additives, with 62 quantified. Their release, influenced by film properties and environmental conditions, introduces thousands of metric tons of additives like phenolic antioxidants and phthalates into Chinese soils annually, posing a moderate ecological risk and altering soil microbial functions.

Simultaneously, coastal wetlands were identified as key hubs for microplastics (MPs) and co-transported organic pollutants. Field and microcosm studies demonstrated that MP aging is co-driven by photo-oxidation (>55% contribution) and microbial degradation, altering their surface properties. This aging process critically enhances MPs' adsorption capacity for pollutants like γ-HCH while paradoxically inhibiting their microbial degradation. Furthermore, aged MPs perturb sediment microbiomes, amplifying processes such as methane production. The findings underscore that the interactions between additive release, MP aging, and co-contaminants create compounded, system-level risks that challenge conventional single-pollutant assessments

Collectively, our findings underscore the complex, system-level interactions between plastic pollution, contaminant dynamics, and environmental conditions. This integrated perspective is vital for developing refined monitoring strategies, accurate risk assessment frameworks, and targeted mitigation measures for plastic pollution under real-world, multi-stress scenarios.

# Microalgae enhance the ameliorative effects of organic materials on soil treated by thermal desorption

**Hua Li**

[1] *School of Environmental & Resource Sciences, Shanxi University, Taiyuan, China*

*E-mail: lihua@sxu.edu.cn

**ABSTRACT**

After thermal desorption treatment, the soil physical structure became worse, the organic carbon content became lower, and the nutrient was unbalanced. Therefore, improving the properties and nutrient cycling capacity of the treated soil is essential for its ecological restoration. In this study, a incubation experiment was conducted on soil treated by the ex-situ thermal desorption of a polycyclic aromatic hydrocarbon (PAH)-contaminated site. Common organic material amendments (e.g., sheep manure and organic fertilizer) and new biofertilizers (e.g., microalgae) were used to investigate the alterations in soil physicochemical properties, microbial community function and microbial community diversity under eight different treatments. The results showed that microalgae increased the ameliorative effects of organic materials on treated soil. In detail, microalgae decreased the mean particle size of soil and significantly increased the content of clay and silt, and changed its particle size distribution. They also significantly increased the contents of soil total organic carbon (TOC), cation exchange capacity (CEC), total nitrogen (TN), nitrate nitrogen ($NO_3^-$-N), available phosphorus (AP), and available potassium (AK), and reduced soil pH, but with no significant effects on electrical conductivity (EC). Furthermore, microalgae significantly altered the microbial community composition and enhanced soil multifunctionality, especially carbon, nitrogen, and phosphorus cycling. Redundancy analyses showed that TN, TK, and TOC were the primary factors explaining the changes in the composition of the main functional microbial community. The findings of this study provide a theoretical basis for soil fertility restoration and structural reconstruction on soil treated by thermal desorption.

## ABSTRACT

**[Objective]** Soil health assessment is essential for food security and sustainable agriculture, especially in Cadmium (Cd)-contaminated farmlands. While microbial diversity and activity, including soil virome, are essential for maintaining agroecosystem functions, robust frameworks for evaluating contaminated soil health are still lacking. This work aims to develop and optimize assessment methodologies under Cd remediation and elucidate the potential contribution of soil viruses to soil health enhancement. **[Method]** Soil samples were collected from an in-situ remediation experiment involving three amendment application rates (CK, Low, and High) under rice-soybean monoculture and rotation systems. Soil physical, chemical, and biological properties were measured, and viral communities were characterized by metagenome and metatranscriptome. **[Result]** Soil health was quantitatively evaluated across four dimensions: environmental quality improvement, Cd stress mitigation, microbial diversity maintenance, and ecosystem multifunctionality. Using Principal Component Analysis and correlation analysis, a 10-indicator Minimum Data Set (MDS) was derived from 20 candidates. Among the three scoring approaches, Comprehensive Assessment of Soil Health (CASH) method exhibited the best sensitivity in reflecting Cd-polluted soil health status at the plot scale. Compared to monoculture and untreated controls, rotation and amendment increased the Soil Health Index (SHI-CASH) by 19.6% and 6.9%, respectively. Significant correlations between grain Cd accumulation, crop yield, and SHI-CASH further validates the robustness of the MDS framework. Random Forest analysis identified soil viral parameters, such as Shannon diversity, transcriptional activity, and the relative abundances of *Herelleviridae* and *Autographiviridae* as key predictors of SHI-CASH, with their ecological contribution being more pronounced in dryland ($R^2$ = 44.5%) than in flooded paddy systems ($R^2$ = 12.8%). **[Conclusion]** These findings validate the MDS-CASH framework as a robust tool for evaluating contaminated soil health and reveals that soil viruses are potential overlooked drivers of farmland health recovery.

## ABSTRACT

Excessive heavy metals in soil pose a threat to food safety and human health. The research on remediation of heavy metal contaminated soil mostly focuses on acidic soils, while there are still problems such as low attention, mismatched treatment technologies, and outdated research and development technologies for Cd pollution in weakly alkaline soils. This study took weakly alkaline cadmium contaminated soil as the research object, selected materials with good passivation effects, and explored modification methods to improve the passivation ability of materials. And the passivation mechanism and stability of passivation materials on soil Cd were further explored. The research results showed that potassium permanganate/hematite modified biochar, manganese dioxide modified phosphate rock powder, and the combination application of biochar and phosphate rock powder significantly reduced the biological activity of Cd in weakly alkaline soils, promoted plant growth, but would reduce the diversity of soil microorganisms. This study also comprehensively evaluated the effects of passivation materials on soil environment, including soil nutrient availability, enzyme activity, abundance of resistance genes, and microbial communities. The passivation mechanisms of biochar and phosphate powder on soil Cd include precipitation, complexation, oxidation-reduction, ion exchange, and π-electron accumulation. The contribution rates of various mechanisms to Cd passivation need further research.

## ABSTRACT

In Central Kazakhstan, from 119 falling sites of the 1st stage of the Proton launch vehicle (LV launched from the Baikonur cosmodrome) formed since 2001, we selected sites occurred in the most widespread communities of the *Artemisia terrae-albae* formation, including derivative communities formed during pyrogenic succession with a predominance of annuals and/or cespitose grasses within the leveled surfaces of interfluves. Then we divided them into four age groups based on the years elapsed since the stage falling: 0-3(5), 5-10, 10-15 and 15-25 years. The group 1 corresponds to communities dominated by annuals, while the group 4 corresponds to communities recovering and conditionally recovered after the impact. Among these 73 falling sites, we selected (whenever possible) sites with similar age of pyrogenic succession (most of them burned in 2017) to reduce the contribution of pyrogenic dynamics to the state of vegetation, assuming that the combined impact of stage falling would still outweigh the pyrogenic impact. However, subsequent analyses revealed that the combined impact of the Proton LV stage falling, including the pollution with highly toxic heptyl is similar in the environmental impact to the one caused by fire.

During field study in the stage falling sites, we conducted 56 geobotanical descriptions at 100 $m^2$ plots and collected 51 topsoil samples (including 42 paired samples characterizing the impact site and a nearby background area).

Soil turbidity and the abundance of artifacts with characteristic sizes of 2–15 cm suggest formation of Epimahic Technosols (Alcalic, Amphigypsic, Loamic) in the 1st stage falling sites. The area of Technosols within the surveyed impact areas is 0.94 hectares (<0.0006% of the area of the 1st stage falling regions of the Proton LV in Central Kazakhstan).

The soils of all surveyed sites (Gypsisols and Solonetz) are loamy and non-saline. The concentrations of total and mobile (16±7% of the total) heptyl, water-soluble $NO_3^-$, $NO_2^-$, and $NH_4^+$ decrease from recent to older impact sites. But there is no such trend for Ntot content.

The age of the stage impact site significantly influences only the reduction in the projective cover of *Agropyron desertorum* and the slight increase in projective cover of *Stipa sareptana*. Four to eight years after the impact are sufficient for the species composition of plant communities in Central Kazakhstan to recover and approach the state of the background sites. Recovery of structural indicators of the phytocenosis also occurs in most cases within 10 years. However, the manifestations of digression caused by the technogenic impact persist for a significantly longer time in some of the impact sites and slow down the restoration of dominant species of background communities. No significant differences were found between the species composition of the vegetation in the disturbed and background sites. In Central Kazakhstan, two consecutive impacts (a pyrogenic impact not associated with a rocket launch and the impact of the first stage of the Proton LV) decrease the manifestation of the earlier impact on the characteristics of plant communities.

The composition of the soil microbiome in 21 soil samples with the highest heptyl concentrations does not differ in heptyl-contaminated and control soils in terms of α- and β-diversity of bacteria and fungi at all taxonomic levels, nor in their metabolic potential. No reliable indicator taxa of microorganisms responding to the presence of heptyl and its derivatives in soils were found.

**ABSTRACT**

We compiled the database of hyperaccumulator plants using AI and machine learning algorithms, based on information from 18,500 publications indexed in Scopus and plant trait databases. It contains the following information for 1,548 species from 791 Angiosperm genera (hyperaccumulators and non-hyperaccumulators):
-measured concentrations of 80 chemical elements with publication References;
-classification of plant species by their ability to accumulate 17 heavy metals and metalloids (HMMs) (Ag, Al, As, Cd, Ce, Co, Cr, Cu, Hg, La, Mn, Mo, Ni, Pb, Se, Tl, and Zn, as well as REEs) into 5 groups: hyperaccumulators, strong and weak accumulators, neutrals, and deconcentrators;
-morphological, ecological, anatomical, and physiological plant traits.

Of the 1,548 plant species in the database, 675 species hyperaccumulate at least one of the 17 elements examined, and most of the remaining 873 species are strong accumulators. Phylogenetic analysis revealed several clades with a >50% probability of having reduced or increased potential for hyperaccumulation of Cd, Cr, and any HMM. Genera capable of hyperaccumulation do not cluster on the evolutionary tree of Angiosperm, which reflects the mosaic nature of the location of hyperaccumulators on it and indicates the repeated independent emergence of this trait during evolution. The ChiSquared test revealed an uneven distribution of families across hyperaccumulator and non-hyperaccumulator groups for genera that accumulate at least one HMM. The Salicaceae family has the largest proportion of hyperaccumulator genera, the Anacardiaceae and Lauraceae have the smallest.

The detected hyperaccumulation of one element can be a good predictor of hyperaccumulation of others. A comparison of the external traits of hyperaccumulator and non-hyperaccumulator plants did not reveal any features that reliably differentiate these two groups. However, for 28 traits, the mean values for hyperaccumulators and non-hyperaccumulators differed by more than five times. The lack of statistical significance for such differences in mean values is explained by the small number of species for which the trait is known or the high variance of the trait value in both plant groups. Currently, the most applicable criteria for searching for hyperaccumulators of HMMs include:
-the ability to hyperaccumulate another HMM;
-belonging to a clade with increased hyperaccumulation potential according to TreeBreaker;
-belonging to a family with a high proportion of hyperaccumulators in our database.

**ABSTRACT**

Halogenated organic compounds are widely used in industrial and agricultural sectors, but their improper use and disposal have led to global pollution issues, posing threats to ecosystems and human health. Organohalide-respiring bacteria (OHRB) can remove halogens from halogenated organic compounds through reductive dehalogenation, reducing their toxicity and persistence, thereby offering promising prospects for the remediation of contaminated sites. Nevertheless, most known dehalogenating bacteria exhibit high substrate specificity, with each strain capable of reductively dehalogenating only one or a limited class of halogenated organic compounds. However, the pollution sites often contain multiple structurally diverse halogenated organic pollutants. There is an urgent need to discover OHRB capable of simultaneously reductively dehalogenating multiple halogenated organic compounds to advance the remediation of co-contaminated environments.

We first report the widespread distribution of versatile OHRB in a variety of environments and their potential for reductive dehalogenation of halogenated organic compounds. We found that these versatile OHRB may utilize a single multifunctional dehalogenase to reductively dehalogenate different halogenated organic compounds. Through protein structure prediction and molecular docking analysis, we further discovered that multifunctional dehalogenases can dehalogenate different halogenated organic compounds via distinct active sites and amino acid residues. Additionally, we observed that interspecies interactions within microbial communities, biofloc encapsulation, and functional genes related to environmental stress collectively determine the widespread distribution of versatile OHRB in the environment. Based on these findings, we developed multiple remediation methods suitable for co-contaminated environments, including sludge inoculation and nanoscale zero-valent iron–biological synergistic remediation technologies, which effectively enhanced the remediation of various halogenated organic compounds in contaminated soils and water bodies.

# Literature Data-Driven Prediction of Soil and Groundwater Pollutant Distribution at Regional Scales

**Yikang Cheng**[1*]

[1] *Nanjing TAG-HUB Innovation Technology Co., Ltd., Nanjing, China*

*taghub003@163.com

**ABSTRACT**

Machine learning technologies offer an effective approach to overcoming the limitations of traditional analytical methods, enabling efficient prediction of pollution distribution and risks as well as correlation analysis of influencing factors. However, constructing high-quality datasets remains a core bottleneck for their application at large regional scales. Systematic mining of literature-derived data can address the scarcity of regional soil-groundwater sampling data, serving as a powerful tool for characterizing regional groundwater quality patterns. Preliminary achievements have been made in pollution distribution prediction using published literature data. For example, studies on global groundwater arsenic pollution (*Science*, 2020), per- and polyfluoroalkyl substances (PFAS) distribution (*Nature Geoscience*, 2024), and global agricultural soil toxic metal risk assessment (*Science*, 2025) have verified the application potential and value of literature data in large-scale regional pollution research from multiple dimensions. Nevertheless, existing literature data mining has prominent shortcomings: lack of a unified standardized workflow (low extraction efficiency), inadequate quality control system (unreliable data), and poor matching between environmental covariates (soil physicochemical properties) and pollution data. These issues collectively restrict the applicability of literature datasets and compromise the accuracy of subsequent prediction models. To address these critical challenges, this study developed a systematic workflow for soil-groundwater pollution literature data mining. By optimizing extraction rules, establishing multi-dimensional quality control criteria, and improving covariate-pollution data matching mechanisms, the workflow realizes efficient and accurate extraction/integration of pollution concentrations, key environmental parameters, and spatiotemporal information from domain-specific literature. Practical results show that this workflow significantly improves the efficiency and quality of literature dataset construction, providing stable and reliable data support for training large-scale groundwater pollution prediction models. It further offers scientific and effective theoretical and technical References for formulating regional pollution prevention and control strategies.

**ABSTRACT**

Avoiding the transport of toxic metal ions facilitated by soil-nano-colloids constitutes a critical challenge in agricultural soils, particularly since climate and soil properties contribute to their genesis in an unknown manner, thereby limiting a comprehensive global perspective. Here, we analyzed 105 soil samples collected along a ~3,500 km climatic gradient with two toxic metals of primary concern: cadmium (Cd) and arsenic (As). Results showed that the genesis of nano-colloid-bound Cd and As increases with elevated temperature and precipitation, regulated by pH changes associated with mineral weathering (Cd) and by weathering-induced release of mineral nano-colloids (As). We therefore produced the first global map of nano-colloid-bound Cd and As using deep learning algorithms, revealing higher formation potentials in the eastern compared to the western part of a metal-rich zone in low-latitude Eurasia. Under a high-carbon emission scenario (2.4–4.8°C warming), nano-colloid-facilitated Cd and As transport is projected to rise by 2.7% and 6.1%, respectively. Our findings identify southern North America, southwestern South America, southern Europe, northern and southern Africa, Central Asia, China, and southern Australia as emerging risk regions, and highlight climate-sensitive nano-colloid processes as a key but overlooked component of terrestrial metal cycling under global change.

# Divergent responses of alfalfa-soil nitrogen cycling to PE and PLA microplastics: A metabolic and microbial perspective

**Zhanling Wang[1]*, Ziqi Ye[1], Xinwei Wang[1], Jing Cao[1], Mei Li[1]**

[1]*State Key Laboratory of Water Pollution Control and Green Resource Recycling, School of Environment, Nanjing University, Nanjing 210023, China*

*zhanlingwang@smail.nju.edu.cn

**ABSTRACT**

Increasing input of microplastics (MPs) into agricultural soils poses a significant risk to soil structural integrity and biogeochemical cycles. However, the cascading effects of MPs on soil elemental composition and subsequent plant physiological responses remain poorly understood. This study investigated the impacts of polyethylene (PE-MPs) and polylactic acid (PLA-MPs) at environmentally relevant concentrations (50 and 500 mg/kg) on alfalfa growth, metabolism, and soil microbial functions. Our results revealed that MP degradation initially increased soil organic carbon but induced nitrogen (N) deficiency, particularly in PLA-MPs treatments (11% decrease in N content). This reduction in soil $NH_4^+$-N triggered a compensatory activation of the phenylpropanoid biosynthesis pathway in alfalfa, leading to the accumulation of signaling flavonoids and coumarins, which subsequently stimulated root nodulation. Specifically, high-dose PLA-MPs (500 mg/kg) significantly promoted nodule formation and biomass accumulation, corroborated by enhanced activities of N-metabolism enzymes; in contrast, PE-MPs exhibited negligible effects. Furthermore, PLA-MPs exposure increased N accumulation and utilization efficiency in roots, with glutamate, aspartate, and total protein contents rising by 26%, 24%, and 16%, respectively. This enhanced symbiotic nitrogen fixation eventually replenished soil nitrogen pools during the later growth stages. Microbial analysis showed that high PLA-MPs concentrations significantly boosted the activities of soil nitrate reductase, protease, and urease, and increased the relative abundance of key taxa (e.g., Proteobacteria, Rhizobiales, and Burkholderiales). Co-occurrence network analysis further highlighted that microbial complexity was inhibited by PE-MPs but strengthened by PLA-MPs. Microbial functional prediction confirmed that key N-cycle processes, including nitrogen fixation and denitrification, were significantly upregulated under PLA-MP treatment. These findings provide critical insights into the divergent ecological risks of conventional and biodegradable plastics, offering a scientific basis for sustainable agricultural management in MP-contaminated soils.

# Inhibition mechanism of hexachlorocyclohexane isomers on different methanogen metabolism

**Yaqing Liu[1*], Zhenyou Huang[1], Yan He[2]**

[1] *School of Light Industry and Food Engineering, Guangxi University, Nanning, PR China.*

[2] *College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, PR China.*

*E-mail Address of Presenting Author:yaqing.liu@gxu.edu.cn

**ABSTRACT**

Hexachlorocyclohexane (HCH) is classified as a persistent organic pollutant of global concern due to its environmental persistence, bioaccumulation potential, and documented toxicity, carcinogenicity, and mutagenicity. In anaerobic environments, such as contaminated sediments and groundwater, HCH isomers coexist with complex microbial communities, including methanogenic archaea that are crucial for global carbon cycling and ecosystem function. While the biodegradation of HCH by organohalide-respiring bacteria is well-studied, the direct ecotoxicological effects of HCH isomers on methanogens—key indicators of anaerobic ecosystem health—remain poorly understood. Different HCH isomers may exert distinct toxic effects on methanogens, yet the underlying physiological and biochemical inhibitory mechanisms are unclear. This study aims to elucidate the species-specific impact mechanisms of four prevalent HCH isomers (α-, β-, γ-, and δ-HCH) on the physiological metabolism of three representative methanogens with diverse metabolic traits: *Methanobacterium* sp. strain KD21 (a hydrogenotrophic methanogen), *Methanosarcina mazei* WH (a versatile metabolizer), and *Methanospirillum hungatei* (a hydrogenotrophic, spiral-shaped methanogen).

Through a combination of gas chromatography, biochemical assays, and fluorescence-based cellular stress probes, we systematically evaluated methanogenic activity, oxidative stress response, reactive oxygen species (ROS) accumulation, and energy metabolism under HCH isomer exposure. The results revealed profound, isomer- and species-dependent responses. *M. mazei* WH maintained normal methanogenesis under α-, β-, and γ-HCH exposure but was completely inhibited by δ-HCH. In contrast, *M. hungatei* exhibited significantly slowed methane production rates under α- and β-HCH and complete inhibition under γ- and δ-HCH. *Methanobacterium* sp. KD21 demonstrated an intermediate sensitivity profile, with partial inhibition across several isomers, providing a crucial third data point for comparative analysis.

At the mechanistic level, both γ- and δ-HCH triggered significant oxidative stress, activating antioxidant defense systems in all three methanogens. A redox imbalance induced substantial accumulation of intracellular reactive oxygen species (ROS) in *M. hungatei* cells under γ- and δ-HCH stress, severely impairing cellular integrity and function. *M. mazei* WH, however, generated high ROS levels only under the singular stress of δ-HCH, correlating with its complete metabolic inhibition. This elevated ROS interference cascaded into central energy metabolism, significantly affecting membrane-bound ATPase activity and depleting intracellular ATP pools. Detailed ATPase activity kinetics revealed that high ROS levels induced a biphasic response: an initial compensatory increase in enzyme activity, followed by a progressive decline due to oxidative damage. Specifically: (1) δ-HCH induced severe oxidative stress in both *M. mazei* WH and *M. hungatei*, causing a rapid spike in ATPase activity to a peak, followed by an abrupt collapse, ultimately leading to cell inactivation. (2) γ-HCH selectively and gradually reduced ATPase activity in *M. hungatei* without immediate inactivation and had no measurable effect on the enzyme in *M. mazei* WH, underscoring a threshold-based toxicity mechanism.

Thus, methanogen responses to HCH isomers exhibit significant species- and isomer-specific differences, governed by the interplay between the induction of oxidative stress, the capacity of antioxidant defenses, and the sensitivity of core energy-transducing machinery. This study reveals the specific physiological pathways and interspecies mechanistic basis by which HCH isomers inhibit methanogen metabolism. The findings provide critical theoretical insights for more accurately assessing the ecotoxicological risks of HCH in anaerobic environments, predicting the impact of organochlorine pollution on microbial community structure and methane flux, and informing the development of bioremediation strategies in areas where methanogens represent a vital component of the ecosystem.

# Response and functional restructuring of micro-food webs in heavy metal-contaminated soil

**Xiuli Hao[1, 2*], Panpan Wang[1], Zheng Li[1], Wenli Chen[1], Qiaoyun Huang[1,2]**

[2]*Hubei Key Laboratory of Soil Environment and Pollution Remediation, Huazhong Agricultural University, Wuhan 430070, China*

*xlhao@mail.hzau.edu.cn

**ABSTRACT**

Heavy metal pollution alters soil organic carbon (SOC) composition by reshaping microbial diversity and interactions. Previous studies mainly focus on the influence of heavy metal pollution on microbial communities at individual trophic level, yet the responses of micro-food webs to heavy metal pollution and their feedback to soil carbon pool remain poorly understood. To address this, we conducted a field survey comprising paired paddy and upland soils along a Cu contamination gradient and explored the contribution of micro-food webs to changes of microbial- and plant-derived carbon in soils. Our results showed that microbial-derived C exhibited greater sensitivity to Cu than plant-derived C, showing rapid accumulation below Cu threshold but declining thereafter. In contrast, plant-derived C showed a consistently increased trend before and post-thresholds. Cu availability, protist-bacterial trophic interactions and viral community were identified as key predictors of soil C components. DNA-SIP further evidenced that protists and viruses involved in the degradation of microbial-derived C. To further investigate the potential of functional restructuring of micro-food webs, we conducted a three-year field experiment and explored the effects of soil amendments on protist-mediated hierarchical interactions and soil ecosystem multifunctionality in heavy metal-contaminated soil. Our results showed that application of soil amendments reshaped protistan community assembly by directly influencing soil pH and Cd availability and indirectly promoting the recovery of bacterial prey. Bacterivorous protists mainly contributed to the dissimilarity of protistan communities between single- and triple-amendments. Furthermore, the restoration of protistan communities facilitated re-establishment of their trophic interactions with bacteria, leading to enhanced microbial network complexity. Our work highlights the importance of micro-food webs in influencing soil carbon dynamics and soil ecosystem functions restoration, with significant implications for remediation assessment and sustainable management of heavy metal-contaminated agricultural soils.

**ABSTRACT**

Microbial methane ($CH_4$) oxidation is a major biological pathway mitigating $CH_4$ emissions in paddy ecosystems. Metabolic intermediates produced during $CH_4$ oxidation may serve as electron donors or carbon sources for mercury (Hg) methylators; however, how $CH_4$ oxidation affects Hg methylation in complex paddy ecosystems remains unclear. Here, we combined $^{13}CH_4$-DNA-stable isotope probing (DNA-SIP) experiments in three typical paddy soils with pure culture assays to investigate the effects of $CH_4$ oxidation on Hg methylation. We found that $CH_4$ addition promoted the production of methylmercury (MeHg) and the expression of Hg methylating genes (Deltaproteobacteria-*hgcA*, Achaea-*hgcA*) in paddy soils. $^{13}CH_4$-DNA-SIP analyses indicated that 62 Hg methylators were significantly enriched in the $^{13}C$-DNA heavy fractions, among which *Anaerolineaceae*, *Geotalea*, and *Veillonellaceae* were significantly enriched in the black, yellow and red soils, respectively. Moreover, pure-culture experiments demonstrated that the addition of methanotrophic metabolites stimulated MeHg production. Combined analyses of $^{13}C$-DNA metagenome-assembly genome and metabolomics revealed that metabolites produced during aerobic $CH_4$ oxidation, such as malate, fumarate and butyrate, played crucial roles in the coupling of aerobic $CH_4$ oxidation and Hg methylation. These findings suggest that the coupling of aerobic $CH_4$ oxidation and Hg methylation in rice field ecosystems is a previously overlooked process, potentially contributing to MeHg production in agroecosystems.

## ABSTRACT

Microplastics are recognized as major global environmental pollutants. Agricultural soils serve as a significant sink for microplastics, with inputs from the degradation of agricultural plastic films. While plastic mulches enhance agricultural productivity, their residual fragments and the microplastics generated pose potential threats. However, the impact of functionally specialized films, such as reflective films widely used in orchards, on soil health remains poorly understood. Reflective films are typically composed of polymers like polyethylene terephthalate (PET) coated with aluminum (Al). We hypothesized that the aging of Al-coated reflective films and the release of Al and microplastics would alter soil pH and micronutrient availability, thereby influencing microbial-mediated carbon (C), nitrogen (N), and phosphorus (P) cycling.

Reflective films were subjected to UVA irradiation, simulated rainfall, and soil burial for up to 120 days. Soil burial induced the most severe and rapid aging. XPS analysis confirmed the oxidation of Al to $Al_2O_3$ on the film surface over time, accompanied by Al shedding. The addition of reflective film-derived microplastics (0.5% w/w) after 120 days of incubation significantly reduced soil pH and available phosphorus (AP), while increasing dissolved organic carbon (DOC) and soil organic carbon (SOC). Notably, the availability of key micronutrients (Fe, Mn, Cu) exhibited a concentration-dependent response: it increased at low film fragment levels but decreased at high microplastic concentrations.

Reflective film amendments altered soil microbial alpha diversity and significantly reshaped community composition. There were a marked enrichment of oligotrophic bacterial taxa and a decrease in copiotrophic bacteria. Fungal communities also changed. Co-occurrence network analysis revealed that reflective films increased network complexity, connectivity, and the proportion of positive interactions among microbes.

The abundance of functional genes involved in C, N, and P cycling responded to film concentration. Low concentrations slightly increased gene abundance, while high microplastic concentrations (0.5%) suppressed most genes. Correlation analyses indicated that the reduced availability of Fe, Mn, and Cu was a key factor negatively correlated with the abundance of these functional genes. In contrast, DOC was negatively correlated with genes for starch hydrolysis and nitrate reduction.

The accelerated aging of reflective films in soil is likely driven by interactions with soil minerals and microorganisms. The concurrent aging releases Al and microplastics. The released Al can lower soil pH, which contributes to decreased micronutrient availability. This creates a nutrient-limited environment that selects for oligotrophic bacteria while disadvantaging copiotrophic bacteria involved in traditional C and N cycling. The suppression of key functional genes, closely tied to micronutrient depletion, suggests a mechanism by which reflective film pollution can hinder soil nutrient cycling efficiency.

This study demonstrates that Al-coated reflective films undergo rapid aging in soil environments, releasing microplastics and Al. These additions alter critical soil properties, reduce the bioavailability of essential micronutrients, and drive microbial communities toward oligotrophic dominance. Crucially, these changes collectively suppress the genetic potential for soil C, N, and P cycling. Our findings reveal that reflective film pollution can indirectly impair soil biogeochemical functions through micronutrient limitation. This underscores the necessity for improved disposal management and long-term field studies.

## ABSTRACT

Copper (Cu) contaminated soils pose a critical environmental challenge by altering soil microbial biodiversity and disrupting essential ecosystem functions. Plants, however, may mitigate Cu impacts on soil microbiomes by buffering free $Cu^{2+}$ activity, recruiting microorganisms, and promoting facilitative interactions. To test these mechanisms, we evaluated Cu bioavailability in field-contaminated soils and assessed whether soil microbiomes respond in ways consistent with the cry-for-help strategy and the stress-gradient hypothesis. The study was conducted in the Puchuncaví Valley (central Chile) across three sites representing uncontaminated, moderately contaminated, and highly contaminated soils. Within each site, two compartments were studied: bulk soil (1 m from vegetation) and soil surrounding roots of the native shrub Baccharis linearis. Atotal of sixty samples were analyzed for chemical properties, including total and soluble Cu concentrations and free $Cu^{2+}$ activity, and regarding their microbiome. Specifically, bacterial and fungal communities were characterized using 16S and ITS amplicon sequencing, with analyses of alpha and beta diversity, co-occurrence networks, and the distribution of generalist, opportunist, and specialist groups. On average, Cu contamination reduced bacterial and fungal richness in bulk soils by 53% and 77%, respectively, while in soil surrounding roots bacterial richness declined by 34% and fungal richness remained unchanged. Compositional divergence between bulk soil and soil surrounding roots increased with contamination, particularly among bacteria: no bacterial families differed between compartments at the uncontaminated site, whereas 15 families differed at the highly contaminated site. Co-occurrence network analyses revealed reduced connectivity in contaminated soils, with greater recruitment of specialist taxa in the rhizosphere and dominance of generalist, parasite-associated fungi in bulk soil. Free $Cu^{2+}$ activity was the strongest predictor of microbial community shifts across compartments and recommended for future monitoring. These findings indicate that Cu contamination severely reshapes soil microbial communities, yet native vegetation can partially buffer these effects by providing microbial refuges consistent with the cry-for-help strategy, while the increase in positive bacterial associations under high Cu a ligns with the stress gradient hypothesis. Together, these results highlight the central role of the rhizosphere in su staining microbial functioning and underscore the need to prioritize plant–microbiome interactions in rest oration planning for contaminated environments.

## ABSTRACT

Long-term conservation tillage (CT) practices profoundly influence soil carbon sequestration, yet their molecular-level effects on dissolved organic matter (DOM) stability and associated microbial mechanisms in erosion-prone slopes are poorly characterized. Here, we integrated ultrahigh-resolution mass spectrometry and amplicon sequencing in a typical global erosion zone (red-soil hills, southern China) after 20-year CT practices. Results showed CT practices significantly elevated soil organic matter and transformed DOM composition toward lipid-, protein-, and lignin-like compounds. Microbial diversity substantially increased, with bacterial and fungal genera rising by 23.4%–35.9% and 46.2%–124.4%, respectively. DOM molecular profiles correlated strongly with microbial community assembly and metabolic pathways, particularly aromatic degradation, carbohydrate metabolism, and pentose phosphate pathway. These findings reveal how long-term CT practices—especially contour-tillage combined with straw mulching—enhance DOM stability and soil carbon sequestration via microbial regulation, providing a science-based and transferable strategy for combating land degradation and supporting climate adaptation in vulnerable landscapes worldwide.

## ABSTRACT

Plant root activities lead to significant differences in metabolites between the rhizosphere and non-rhizosphere soil, profoundly affecting microbial distribution. However, how this process drives the migration and propagation of manure-derived antibiotic resistance genes (ARGs) in farmland ecosystems remains unclear. Herein, we used a rice pot microcosm experiment to explore the characteristics of antibiotic resistance and bacterial communities in rhizosphere and non-rhizosphere soils and the driving effects of rhizosphere metabolites on ARG propagation. The experiment included no fertilization (CK) and livestock manure application (M) treatments, with samples collected at different rice growth stages. Integrated metagenomic and non-targeted metabolomic analyses were conducted. The results showed significant differences in some ARGs and bacterial diversity in rhizosphere and non-rhizosphere soils, with varied differential ARGs between different growth stages of rice ($P < 0.05$). A total of 496 ARG subtypes and 176 MGE subtypes were identified. Manure application increased the abundance of ARGs, and specific multidrug ARGs (e.g., *mex*C, *acr*F) were significantly enriched in the manure-amended rhizosphere soil. Metabolomic analysis identified 1095 metabolites. Differential metabolites (DEMs) were significantly enriched in distinct pathways: arachidonic acid metabolism in unfertilized soil, and the biosynthesis of secondary metabolites and glutathione metabolism in manure-applied soil. Structural equation modeling (SEM) analysis indicated that ARG distribution differences between rhizosphere and non-rhizosphere soils were mainly regulated by differential metabolites, which influenced the ARG distribution by altering the succession of soil microbial communities and interacting with mobile genetic elements (MGEs). These results demonstrate the role of differential metabolites resulting from rice root activities in co-regulating ARG distribution, providing new insights into the regulatory mechanisms of soil ARG dynamics in paddy fields and highlighting potential strategies to mitigate antibiotic resistance spread.

# Specific metabolites modulate core microbes and microbial interactions to drive fomesafen dissipation in the soybean rhizosphere

## ABSTRACT

Rhizosphere metabolites mediate organic pollutant dissipation by modulating the rhizosphere microbiome. However, the tripartite mechanistic relationship among metabolite dynamics, microbial community assembly, and pollutant degradation kinetics remains poorly understood. Using an integrated multi-omics approach (16S rRNA amplicon sequencing, untargeted metabolomics, and shotgun metagenomics), this study deciphered the temporal dynamics of rhizosphere metabolites and the microbiome during the dissipation of fomesafen, an herbicide widely used in soybean cultivation, in pot experiments with soybean. Fomesafen dissipation exhibited biphasic kinetics during soybean plant growth, with an initial rapid phase followed by prolonged stabilization, which was synchronized with time-dependent microbiome perturbations of initial enrichment and subsequent attenuation. Metabolomic analysis revealed fomesafen-induced compositional shifts in rhizosphere metabolites, with 2-naphthalenesulfonic acid ( 20.84%) and 2-hydroxyoctadecanoic acid (13.30%) exhibiting opposing regulatory effects on microbial assembly. These metabolites modulated the core microbial assembly and its interactions with potential degraders to ultimately affect fomesafen dissipation. Microcosm experiments confirmed that 2-naphthalenesulfonic acid enhanced while 2-hydroxyoctadecanoic acid inhibited fomesafen dissipation. Our findings highlight the significance of rhizosphere metabolite-mediated interactions between core microbes and potential degraders in driving fomesafen dissipation.

# Speciation Distribution, Transformation, and Interfacial Interaction Mechanisms of Heavy Metals and Phosphate in Contaminated Farmland Soils

**Xiaoming Wang*, Wantong Zhao, Yun Xu, Xionghan Feng, and Wenfeng Tan**

*College of Resources and Environment, Huazhong Agricultural University, Wuhan 430070, China*

**ABSTRACT**

Heavy metal contamination has become a global soil environmental issue. In southern China, agricultural soils are widely affected by heavy metal pollution, predominantly at low to moderate levels. Achieving the safe utilization of moderately and lightly contaminated farmland soils is therefore crucial for ensuring food security. Phosphorus in arable soils is not only an essential nutrient for plant growth but also an inorganic ligand that can significantly influence the mobility, transformation, and fate of heavy metals through synergistic adsorption or site-competition effects.

In recent years, our research group has focused on regionally contaminated agricultural soils in China, conducting systematic investigations into the speciation distribution, transformation characteristics, and interfacial interaction mechanisms of heavy metals and phosphate in soils. Through multiscale studies ranging from the microscopic to the macroscopic level, and by integrating chemical extraction, diffusive gradients in thin films (DGT), statistical correlation analysis, and advanced techniques such as synchrotron-based phosphorus K-edge XANES spectroscopy, in situ infrared spectroscopy, and surface complexation modeling, we comprehensively elucidated the speciation distribution of heavy metals and phosphorus in contaminated farmland soils and their associations with soil reactive mineral. Furthermore, we revealed the effects of phosphate addition on the speciation transformation of iron and heavy metals in flooded soils and clarified the molecular-level mechanisms of co-adsorption between phosphate and typical heavy metal (i.e., Cd) at soil oxide interfaces. These findings provide important scientific evidence and a solid theoretical basis for ecological risk assessment of heavy metals, remediation of contaminated soils, and the safe utilization of agricultural soils.

**ABSTRACT**

The reuse of wastewater for irrigation is expanding rapidly in peri-urban agricultural systems, yet its implications for soil health, groundwater quality, food safety, and farmer livelihoods remain inadequately documented through field-scale evidence. This survey-based study assessed the impacts of wastewater irrigation on soils, groundwater, and agriculture produce under a One Health framework in two major agricultural districts of Punjab, India—Ludhiana and Jalandhar. A total of ten villages (five per district) were selected based on proximity to major wastewater drains, namely Buddha Nullah in Ludhiana and Kala Sanghian Drain in Jalandhar. From each village, 25 composite samples of soil, irrigation water, and crop grains were collected, along with structured farmer perception surveys. Fields irrigated with sewage treatment plant (STP)–treated wastewater, untreated wastewater, and groundwater were comparatively evaluated. Soil quality indicators (pH, electrical conductivity, organic carbon, nutrients, and heavy metals), groundwater parameters, and grain quality were analyzed using standard protocols. Results revealed that irrigation with STP-treated wastewater improved soil nutrient availability and organic carbon status, corroborated by farmer-reported reductions in chemical fertilizer use. However, fields receiving untreated wastewater showed progressive soil quality degradation and significantly elevated concentrations of heavy metals, with chromium emerging as a dominant contaminant across sites. Accumulation of chromium in soils exceeded background levels, raising concerns about long-term soil health, crop safety, and potential groundwater contamination. Farmer perceptions strongly aligned with analytical findings, highlighting both economic benefits and emerging environmental risks. The study underscores that while STP-treated wastewater can enhance soil fertility and reduce fertilizer dependence, inadequate treatment and long-term use of untreated wastewater pose serious threats to soil and human health. Integrating farmer knowledge with soil-based risk assessments is essential to developing safe wastewater reuse strategies within a One Health framework.

**ABSTRACT**

Soil contamination by toxic xenobiotics from industrial activities is a global challenge. This study investigated biogeochemical processes in the petroleum-rich regions of Northern Shaanxi, China, by integrating pollution screening, phytotoxicity simulations, and analysis of functional microorganisms.

Screening across nine petroleum-contaminated sites revealed significant contamination heterogeneity, with Total Petroleum Hydrocarbon (TPH) concentrations ranging from 4,533 to 146,500 mg·kg$^{-1}$. The concentrations of 16 Polycyclic Aromatic Hydrocarbons (PAHs) ranged from 554.10 to 5,516.73 ng·g$^{-1}$, with carcinogenic PAHs comprising over 30%, indicating substantial ecological risks.

Based on field data, a microcosm experiment using maize (*Zea mays L.*) was conducted to assess ecological impacts within the soil-plant continuum. Three treatment groups-TPH, Aliphatic, and Aromatic hydrocarbons—were applied across a concentration gradient of 5,000-100,000 mg·kg$^{-1}$ for TPH, with equivalent concentrations for other hydrocarbon components. The results revealed a "low-promotion, high-inhibition" hormesis effect, with 10,000 mg·kg$^{-1}$ TPH identified as the threshold for physiological defense activation and 30,000 mg·kg$^{-1}$ TPH as the critical toxicity threshold. Aromatic hydrocarbons exhibited greater phytotoxicity than aliphatic hydrocarbons, significantly inhibiting chlorophyll synthesis and intensifying lipid peroxidation.

Given Aromatic Hydrocarbons as the key toxic factor, microbial responders in contaminated fields were investigated. Bioinformatics analysis of the nine sites PAHs levels was strongly correlated with the *Proteobacteria* phylum. Despite geographical variations, *Pseudomonas sp.* emerged universally as the dominant taxon associated with aromatic hydrocarbon degradation, highlighting its ecological role in mitigating aromatic stress.

In conclusion, this study bridges pollution screening and mechanistic toxicology. By establishing 30,000 mg·kg$^{-1}$ TPH as the toxicity threshold for plants, identifying aromatics as the critical toxic component, and pinpointing *Pseudomonas sp.* as the primary functional degrader, these findings provide a basis for ecological risk assessment and targeted bioremediation strategies in the Loess Plateau.

*juzhengshan@lcrc.org.cn

**ABSTRACT**

To address the core ecological reconstruction bottleneck of "water and nutrient deficiency" in the dump sites of typical grassland open-pit mining areas, this study took the dump site of Zhahanaoer Coal Mine as the research object, using local sandy soil and red clay in the mining area as reconstruction substrates. A three-layer structure of "dump subsoil—water-nutrient retention and waterproof layer—clay-sand mixed soil" was constructed, with five clay-sand ratios (1:0, 1:1, 1:2, 1:5, 0:1) and three management measures (fertilization, waterproof layer, and combined fertilization + waterproof layer). The effects of different reconstruction schemes on soil physical and chemical properties, water movement, microbial diversity, enzyme activity, and plant growth were systematically explored, and a comprehensive evaluation was conducted using the entropy-weighted TOPSIS method. The results showed that the medium clay-sand ratios (1:1, 1:2) exhibited a better balance between water retention and nutrient supply. Fertilization significantly improved soil nutrient levels and plant biomass, and the waterproof layer effectively enhanced soil moisture conditions, promoted fungal diversity, and increased some enzyme activities; the combination of the two showed a synergistic effect. Available potassium, urease activity and electrical conductivity were the key indicators distinguishing treatment effects, among which the combination of 1:5 clay-sand ratio + fertilization + waterproof layer achieved the optimal comprehensive restoration effect. The synergistic reconstruction technology of "structural restoration—nutrient supplementation" developed in this study reveals the complex interactions between texture proportioning and management practices within the reconstructed soil system of the dump site. It demonstrates that optimizing suitable sand-clay mixture ratios and management models can significantly improve soil moisture, nutrient availability, and microbial functionality, thereby enhancing vegetation growth and carbon sequestration potential. This provides a scientific basis and scalable engineering solution for the rapid vegetation restoration of dump sites in typical grassland open-pit mining areas, holding important theoretical and practical significance for promoting the construction of green mines.

**Key words:** grassland open-pit mining areas; ecological reconstruction; sand-clay ratio optimization soil; plant effects

# Genotypic Variability in Bioaccumulation and Dietary Risks of PFAS across 30 Wheat Cultivars: A Field Assessment

**ABSTRACT**

Soil contamination by per- and polyfluoroalkyl substances (PFAS) in agricultural ecosystems poses a significant threat to global food security. While soil-to-plant transfer is a recognized pathway, the influence of crop genetic factors remains poorly integrated into risk assessment frameworks. In this study, the occurrence, bioaccumulation, and genotypic variability of $\Sigma_{25}$PFAS were systematically investigated across 30 wheat cultivars. These cultivars were grown under identical field conditions in a region affected by industrial activities involving fluorochemicals. Grain samples were collected at the stage of maturity. PFAS concentrations were quantified using high-performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS). A striking 3-fold heterogeneity in total grain PFAS concentrations was observed among the 30 genotypes. Genetic diversity was identified as a primary driver of PFAS accumulation in wheat grains. Among $\Sigma_{25}$PFAS, short-chain perfluoroalkyl carboxylic acids (PFCAs) showed significantly higher soil-to-grain transfer efficiencies compared to long-chain congeners. Four dominant species (PFBA, PFPeA, PFHxA, and PFOA) accounted for the majority of the total PFAS burden. Different partitioning patterns of four dominant analogs were exhibited within the grains, even under identical soil concentrations. Moreover, plant height was found to facilitate the accumulation of PFAS, particularly PFPeA and PFHxA, in wheat grains. Furthermore, the estimated daily intake (EDI) and hazard quotients (HQ) derived from grain consumption were calculated for 30 cultivars. A threefold difference in HQ estimations was observed between high- and low-accumulating genotypes. It is suggested that neglecting inter-cultivar variability may lead to substantial uncertainties in regional dietary risks. The potential misclassification of exposure risks for local populations was also highlighted. These findings underscore the importance of integrating genetic heterogeneity into environmental regulatory frameworks. The results suggest that leveraging low-accumulation cultivars offers a cost-effective and sustainable strategy to mitigate PFAS transfer into the human food chain. Regional food security in contaminated agricultural ecosystems could be ensured through targeted cultivar selection.

# Comparative Study on the Efficiency of Multiphase Extraction Combined with Bioremediation and Thermal Enhanced Coupling Process

**Gubai Luo**[1*]

[1] *Center International Group Co., Ltd., Beijing, China.*

*E-mail: luogubai@centerint.com

## ABSTRACT

Petroleum hydrocarbon contamination in soil and groundwater of decommissioned petrochemical sites causes long-term adverse effects and prominent eco-environmental risks. Multiphase extraction coupled with bioremediation has become the core in-situ remediation technology for such contaminated sites. To explore the strengthening mechanism and application advantages of temperature regulation on remediation performance, two comparative experiments were conducted in this study, namely conventional multiphase extraction- biostimulation (MPE-BS) and thermally enhanced multiphase extraction-biostimulation (MPE-HEBS). The dynamic variations of soil temperature, microbial abundance, microbial metabolic activity, and volatile organic compound (VOCs) concentration in extracted gas were systematically monitored. The removal characteristics of total petroleum hydrocarbons (TPH) in the fractions of $C_6$–$C_9$ and $C_{10}$–$C_{40}$ in soil and groundwater were quantitatively analyzed, and a comprehensive evaluation was performed combined with significant difference analysis.

The results showed that both processes could effectively reduce petroleum hydrocarbon pollutants, and there were significant differences in remediation effects between the two groups ($P < 0.05$). The MPE-HEBS process could stably increase in-situ soil temperature and break the restriction of low-temperature environments. Compared with MPE-BS, MPE-HEBS possessed higher microbial abundance and stronger carbon dioxide metabolic activity in soil gas, as well as more stable proliferation of indigenous degrading microorganisms. The relative abundance of *Pseudomonas* and *Thermicanus* increased significantly. Meanwhile, thermal enhancement elevated the peak concentration of VOCs and advanced the peak time, which greatly accelerated the desorption, volatilization and removal of pollutants. In the middle remediation stage, the removal rates of petroleum hydrocarbons with different carbon chain fractions in the MPE-HEBS group were 15.3%–28.5% higher than those in the MPE-BS group. At the end of remediation, lower residual pollutant concentration and better overall removal performance were achieved in the MPE-HEBS group. This study can provide theoretical basis and technical References for the efficient in-situ remediation of petroleum hydrocarbon-contaminated sites in decommissioned petrochemical and refining areas.

# More Than Containment: An Innovative Attempt to Solve Groundwater Contamination at Landfills —— The Application of a Nation's First Full-Process Technical System Integrating Source, Pathway, and End-of-Pipe Treatment

[1] *Ying Chao, Center Environmental Technology Co., Ltd., China*

[2] *Ruyue Zhou, Center Soil Remediation Institute (Shenzhen) Co., Ltd., China*

Chaoying@centerint.com

**ABSTRACT**

Globally, landfilling remains one of the primary methods for municipal solid waste disposal. However, significant differences exist among countries in the level of pollution control at landfill sites. Due to China's large population base, high waste generation, and a lengthy history of resource recovery efforts, there remains substantial numbers of legacy landfill sites in China, with municipal solid waste landfills accounting for a high proportion. As a result, various environmental problems have been continuously exposed, with groundwater pollution caused by leachate leakage being particularly prominent. This has become a key bottleneck threatening the safety of China's groundwater resources and constraining high-quality ecological development. Currently, a singular "containment-oriented" model is generally adopted for groundwater contamination control at Chinese landfill sites, focusing primarily on the physical blocking of leachate migration pathways. While this model can, to some extent, prevent further contaminant migration, it cannot reduce leachate generation at the source, nor can it effectively remediate already contaminated groundwater. Thus, there is an urgent need to break through traditional thinking and construct comprehensive and systematic technical system. To address this need, this study takes a comprehensive remediation project at an actual municipal solid waste landfill site (focusing on groundwater contamination) as its research vehicle, conducting a national-first attempt to apply a full-process technical system integrating "source– pathway – end-of-pipe treatment." Based on multi-source data fusion, the study achieved precise identification of pollution sources, dynamic monitoring of contaminant plumes, as well as calibration and simulation of the target landfill. On this basis, multidimensional technologies including source reduction, pathway interception, pollution remediation, and dynamic tracking were further coupled, forming a closed-loop control mechanism based on "monitoring-feedback-regulation" of groundwater quality. This study aims to overcome the traditional limitations of "only blocking without treating, and only treating without preventing," systematically solving the problem of groundwater contamination at landfills, and providing a technical References and practical demonstration for similar projects in China.

## ABSTRACT

Using nano-hydroxyapatite (nHAP) to immobilize cadmium (Cd) is a promising approach for soil remediation. However, biotic factors, such as earthworms, might affect its effectiveness by altering soil biochemistry and the Cd cycling process. Nonetheless, the relative contributions of crop types and their varieties, along with earthworms, in nHAP-mediated Cd remediation remain poorly understood. A field experiment was conducted to evaluate the effects of nHAP, earthworms, and their combination on soil biochemical characteristics and Cd accumulation across different crop types and varieties. The experiment consisted of 20 treatments, each with a plot size of 4.5 m² and three replicates. The treatments applied 15kg·ha$^{-1}$ nHAP and 11 worms·m$^{-2}$. Cd uptake was measured in two corn (*Zea mays*) varieties - Jin Zhongyu (YD) and Yue Sweet-9 (YG), as well as in two leafy vegetables (*Brassica campestris*) varieties Guang Fu-35 (DG) and Bi Qingtian (DD). Soil biochemical properties and Cd speciation were analyzed in non-plant soil, bulk soil, and rhizosphere soils. Our findings indicated the distribution of Cd fractions in rhizosphere soil varied between leaf vegetables and corn: higher contents of bioavailable Cd (exchangeable and water soluble) were observed in the DD treatment compared to others, while stable Cd forms (residual and oxidizable) were more prevalent in the YG treatment. Total microbial biomass was lowest in non-planted soil and highest in leafy vegetable soil, especially in the DD under the nHAP-earthworm co-application. nHAP increased soil microbial biomass more effectively in corn treatment, whereas earthworms shifted the microbial community toward greater dominance of Gram-positive bacteria ($G^+$) and fungi. Bacterial dominance in soil remained consistently higher in leafy vegetable treatment across all amendment treatments. The DD vegetable variety absorbs up to 35% more Cd than the corn varieties, with higher bioaccumulation in the edible tissues. The amendments had opposing effects on Cd uptake by plant: nHAP decreased Cd accumulation, while earthworms increased it. Crucially, their combined effect significantly increased Cd accumulation in the leafy vegetable but reduced it in the corn, particularly in the YD variety, revealing crop-variety-specific responses in Cd uptake patterns. Principal component analysis (PCA) indicated that low Cd uptake was linked with elevated pH, higher exchangeable Ca and increased urease activity, a predominance of Gram-negative ($G^-$) bacteria, and a shift of Cd toward stable forms (oxidizable and residual). Conversely, increased Cd uptake was correlated with increased $G^+$ bacteria, fungi biomass, and invertase activity, enlarging pools of exchangeable and water-soluble Cd. This study provides critical insights into predicting Cd transfer into the food chain, demonstrating that effective remediation strategies must account for specific crop types and soil biochemical activity.

**ABSTRACT**

Background and aim: High-accumulation plants intercropped with economic crops, coupled with passivators, represent a novel approach for remediating cadmium (Cd)-contaminated soil. Methods: We employed a pot experiment to investigate the effects of intercropping coupled with passivation on plant growth, Cd accumulation, and soil Cd content. Results: The results demonstrated that intercropping marigold (*Tagetes erecta L.*) with water spinach (*Ipomoea aquatica*), coupled with passivation treatment, reduced the content of bioavailable and total Cd in soil by 45.07–48.78% and 13.12–17.95%, respectively. This approach promoted the transformation of Cd from weakly acidic and reducible forms to oxidizable and residual forms, with the proportion of residual Cd being significantly higher than that in treatments involving intercropping alone or application of passivators only. The combined intercropping and passivation treatment significantly enhanced Cd accumulation in both marigold and water spinach by 4.80–25.53% and 106.44–134.90%, respectively, compared with that of intercropping-only and passivation-only treatments. Furthermore, this integrated approach reduced heavy metal concentration in edible parts of water spinach, while significantly increasing Cd accumulation in its below-ground biomass. Conclusions: These findings highlight the potential of integrating intercropping with passivation for remediation of Cd-contaminated soil, particularly demonstrating that the marigold-water spinach intercropping system serves as an effective strategy for mitigating Cd pollution in soils.

# Root acid phosphatases and microbial biomass phosphorus induced Cd tolerance and P acquisition in wheat inoculated with P solubilizing bacteria.

**ABSTRACT**

Microbial bioremediation has emerged promisingly to improve crop tolerance to cadmium (Cd). Moreover, Cd tolerance and phosphate acquisition in plants positively correlated under P solubilizing bacteria inoculation, yet there is no evidence on specific mechanisms influencing Cd tolerance and plant P acquisition. The present study evaluates Cd tolerance in rock P-amended durum wheat in response to inoculation with P solubilizing bacteria (PSB) [three individual isolates *Bacillus siamensis*, *Rahnella aceris*, *Bacillus cereus* and their consortium ($PSB_{Cs}$)] and consequently reveals key rhizosphere mechanisms involved in both Cd tolerance and P use efficiency. Results show that overall inoculation improved plant growth, rhizosphere parameters and nutrient uptake (P, N, K) under increasing Cd concentrations [8 ($Cd_8$) and 16 ($Cd_{16}$) ppm $Cd^{2+}$]. Under $Cd_{16}$, *Rahnella aceris* induced the most significant plant responses in terms of biomass [shoots (31%), roots (40%), and spikes (92%)], rhizosphere available P (234%) and root inorganic P (109%) compared to uninoculated plant. Microbial biomass P (MBP) and root acid phosphatases (APase) were 33-and 13-times higher, respectively, than in uninoculated plants. In addition, inoculation (particularly using $PSB_{Cs}$) significantly decreased Cd translocation factor (TF) ($Cd_8$: −17% and $Cd_{16}$: −22%) and Cd bioaccumulation factor (BAF) ($Cd_8$: −6% and $Cd_{16}$: −40%) concomitantly to enhanced root morphological traits and P contents in shoots and spikes. Furthermore, PSB inoculation under Cd constraint increased (rhizosphere available P/MBP) and (root APase/rhizosphere APase) ratios that significantly ($p<0.05$) correlate with plant P uptake in shoots and spikes. Increase in both ratios was concomitant to a significant decrease in TF and BAF of Cd exemplified by negatively significant correlations ($r^2=0.70$ and $r^2=0.57$, $p<0.05$). This finding elucidates the key role of bacterial inoculation that presumably triggered Cd tolerance and aboveground P owing to increased (rhizosphere available P/MBP) and (root/rhizosphere APase) ratios in PSB-inoculated wheat.

**ABSTRACT**

Nitrogen is a limiting nutrient for degraders function in hydrocarbon-contaminated environments. Biological nitrogen fixation by diazotrophs is a natural solution for supplying bioavailable nitrogen. Here, we determined whether the diazotroph *Azotobacter chroococcum* HN can provide nitrogen to the polycyclic aromatic hydrocarbon-degrading bacterium *Paracoccus aminovorans* HPD-2 and further explored the synergistic interactions that facilitate pyrene degradation in nitrogen-deprived environments. We found that *A. chroococcum* HN and *P. aminovorans* HPD-2 grew and degraded pyrene more quickly in co-culture than in monoculture. Surface-enhanced Raman spectroscopy combined with $^{15}N$ stable isotope probing (SERS-$^{15}N$ SIP) demonstrated that *A. chroococcum* HN provided nitrogen to *P. aminovorans* HPD-2. Metabolite analysis and feeding experiments confirmed that cross-feeding occurred between *A. chroococcum* HN and *P. aminovorans* HPD-2 during pyrene degradation. Transcriptomic and metabolomic analyses further revealed that co-culture significantly upregulated key pathways such as nitrogen fixation, aromatic compound degradation, protein export, and the TCA cycle in *A. chroococcum* HN and quorum sensing, aromatic compound degradation and ABC transporters in *P. aminovorans* HPD-2. Phenotypic and fluorescence in situ hybridization (FISH) assays demonstrated that *A. chroococcum* HN produced large amounts of biofilm and was located at the bottom of the biofilm in co-culture, whereas *P. aminovorans* HPD-2 attached to the surface layer and formed a bridge-like structure with *A. chroococcum* HN. This study demonstrates that distinct syntrophic interactions occur between *A. chroococcum* HN and *P. aminovorans* HPD-2 and provides support for their combined use in organic pollutant degradation in nitrogen-deprived environments.

# Biohydrogen Utilization in Legume-rhizobium Symbiosis Reveals a Novel Mechanism of Accelerated Tetrachlorobiphenyl Transformation

**Yongfeng Xu*, Ying Teng, and Yongming Luo**

*State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*yfxu@issas.ac.cn

**ABSTRACT**

Molecular hydrogen ($H_2$) is an important green energy source and plays vital roles in environmental remediation. Legume-rhizobium symbioses are not only a major producer of $H_2$ in terrestrial ecosystems but also an important resource for the *in situ* biodegradation of environmental pollutants. However, the role of $H_2$ in pollutant biotransformation by symbiotic associations is unknown. Here, symbiosis between *Glycine max* and *Bradyrhizobium diazoefficiens* were used as a model system to investigate whether biohydrogen utilization promotes the transformation of the tetrachlorobiphenyl PCB77. Both a $H_2$ uptake-positive ($Hup^+$) strain (wild type) and a $Hup^-$ strain (a *hupL* deletion mutant) were inoculated into soybean nodules. Compared with $Hup^-$ nodules, $Hup^+$ nodules increased dechlorination significantly by 61.1% and reduced the accumulation of PCB77 in nodules by 37.7% ($p < 0.05$). After exposure to nickel, an enhancer of uptake hydrogenase, dechlorination increased significantly by 2.2-fold, and the accumulation of PCB77 in nodules decreased by 54.4% ($p < 0.05$). Furthermore, the tetrachlorobiphenyl transformation in the soybean root nodules was mainly testified to be mediated by nitrate reductase (encoded by the gene *NR*) for tetrachlorobiphenyl dechlorination and biphenyl-2,3-diol 1,2-dioxygenase (*bphC*) for biphenyl degradation. This study demonstrates for the first time that biohydrogen utilization has a beneficial effect on tetrachlorobiphenyl biotransformation in a legume-rhizobium symbiosis. In a broader view, this work highlight the previously unrecognized but important role of biohydrogen uptake in the phytoremediation of halogenated organic compounds.

# Variations in root functional traits facilitate the adaptation of pioneer plants to rare earth element mine tailings

**Zhu Shi-Chen[1,2*], Xu De-Xiang[1], Liu Wen-Shen[1], Qiu Rong-Liang[1] and Tang Ye-Tao[1]**

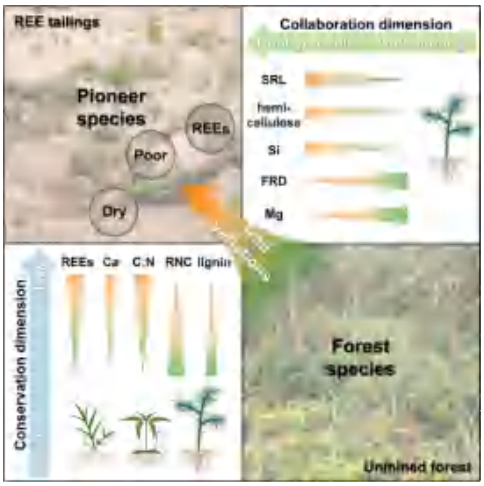
[1] *School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, China*

[2] *Guangdong Academy of Forestry, Guangzhou 510520, China*

*zhusc@sinogaf.cn

**ABSTRACT**

To satisfy the growing global demand for rare earth elements (REEs)—key components in high-tech products and low-carbon technologies—mining activities have resulted in numerous anthropogenically degraded tailings, causing large areas characterized by soil degradation, vegetation loss, and biodiversity decline. These tailings exhibit REEs contamination, nutrient deficiency, and soil compaction. Even after a decade of abandonment, only a few pioneer plant species—mainly the grass species *Miscanthus sinensis* Anderss., the fern species *Dicranopteris linearis* (Burm. f.) Underw., and the tree species *Pinus massoniana* Lamb.—have managed to establish sparse populations in REEs mine tailings. But the mechanisms enabling these pioneer species to survive in stress tailings remain poorly understood.



The trade-offs in plant root traits significantly influence the adaptation and community dynamics in heterogeneous habitats. However, the role of inter- and intraspecific root trait variation in the adaptation of pioneer plants in stressed tailings remains limited. A clear understanding of root trait strategies is essential for guiding ecological restoration with nature-based solutions in severely degraded mining landscapes.

In this study, we assessed root morphological and chemical traits of 16 dominant species from unexploited forest sites adjacent to rare earth elements (REEs) mine tailings, and three pioneer species (*M. sinensis, D. linearis, P. massoniana*) across a gradient of soil stress—including REEs toxicity, nutrient deficiency, and compaction—from forest to REEs tailings.

In the two-dimensional root economics space (RES), the contents of cellulose, hemicellulose, and silicon were coaxial with the collaboration gradients ("do-it-yourself"–"outsourcing") and inversely related to fine root diameter. Meanwhile, root REEs content aligned with conservation gradients ("fast"–"slow"), indicating a slow strategy.

Interspecific variations did not show a distinct strategy pReferences for pioneer species compared to non-pioneer plants. However, notable intraspecific variations were observed, particularly in stress-related traits such as root N content, C:N ratio and REEs content, which exceeded interspecific variations. All three pioneer species exhibited a shift toward "slow" strategies, while *P. massoniana* also transitioned toward "do-it-yourself" strategies, driven by increased soil bulk density, elevated bioavailable REEs content, and reduced soil carbon and nutrient levels in the tailings.

Synthesis and applications: Our findings highlight the pivotal role of root chemical traits and intraspecific plasticity in facilitating the adaptation of pioneer plants to extreme REE tailing environments, particularly the capacity of shifting toward conservative ("slow") strategies and self-reliant ("do-it-yourself") nutrient acquisition under stress. This provides practical guidance for selecting suitable pioneer species in the phytoremediation of REE-contaminated tailings, where high phenotypic adaptability may be critical for establishment and survival.

[4] *New Zealand Institute for Bioeconomy Science, Christchurch, New Zealand*
mingyuan.liu@pg.canterbury.ac.nz

**ABSTRACT**

Worldwide, coastal cities are planning the retreat from low-lying areas due to climate change, where heavy metal contamination is common. In Christchurch, New Zealand, some 600 ha of the city became unusable following the Canterbury Earthquake Sequence (CES) in 2010-11. Soils in the "Red Zone" (RZ) contain Pb, Cu, and Zn derived from historic construction materials, coal-tar residues, and stormwater inputs. As these contaminants are typical of urban residential soils worldwide, the RZ profile represents the kinds of contaminated soils expected in managed retreat. As large-scale excavation or capping is impractical, phytoremediation offers a feasible, nature-based solution, but evidence is limited for New Zealand conditions, particularly regarding local plant species and amendment-enhanced stabilisation. One contamination hotspot contained up to 22,000 mg $kg^{-1}$ Cu, 13,000 mg $kg^{-1}$ Zn, and over 1,000 mg $kg^{-1}$ Pb. Toxicity tests carried out in the greenhouse with this RZ soil blended with non-contaminated soil showed that the lowest concentration that produced a significant effect of biomass on Lolium perenne was 100% RZ soil. This concentration decreased to 12.5% on Phaseolus vulgaris. L. perenne still grew at 100% RZ, whereas P. vulgaris showed clear symptoms of stress.

Lysimeter trials (2.3 L; 100% RZ soil) quantified how seven organic amendment treatments influence metal leaching and plant performance. Treatments included two pine biochars, compost, two biochar – compost mixtures, a biosolids – sawdust blend, and an unamended control. Amendments were applied at ~4% of soil dry mass (equivalent to ~60 t $ha^{-1}$). One type of biochar – compost treatment most effectively reduced Cu, Zn, and Pb mobility while promoting healthy ryegrass growth, demonstrating synergistic benefits for both immobilisation and plant establishment. Biosolids and Biochar-I treatment increased Zn leaching compared to unamended control, and Biochar-I treatment increased Cu/Pd leaching compared with unamended control.

This integrated greenhouse – lysimeter – field framework identifies which organic amendments — such as biochar, compost, and biosolids—and which plant species can effectively stabilise metals under real conditions, providing practical guidance for restoring contaminated residential land undergoing managed retreat.

# Transforming Spent Coffee Grounds (SCG) into an Environmental Asset- Its Characterization and Optimization for Soil Amendment and Remediation Applications

**Mhlophe Prudence [1*], Bass, Adrian [1], Crawford, John[1,] and Toney. Jaime[1]**

[1]*University of Glasgow. School of Geography and Earth Sciences*

p.mhlophe.1@research.gla.ac.uk

**ABSTRACT**

Global coffee consumption continues to escalate rapidly, significantly increasing spent coffee grounds (SCG) produced. An estimated 18 million wet tonnes were produced worldwide in 2021 (Kim et al., 2024). SCG are an abundant organic waste stream with potential for soil remediation; however, their direct application, without processing, can cause more problems. This study investigates the potential of SCG and SCG-derived biochar as amendments to soil for immobilizing heavy metals in contaminated urban soils.

The SCG were oven-dried at 40°C for 48-hours. Half the grounds were stored, and the other half were pyrolyzed at 550°C. Six small batches resulted in average yields between 20.5 and 23.3%. These were then modified with $H_2O_2$ solution (30%) at a rate of 1: 20w/v. The resultant substrates were analysed before use in a soil column experiment.

The analyses show that pyrolysis increased pH in the pristine biochar, as expected, while those modified with $H_2O_2$ decreased in pH both SCG and biochar. BET (Brunauer-Emmett-Teller) analysis revealed an average of an approx. 40% increase in surface area due to pyrolysis. Modification of SCG resulted in a 6% reduction in surface area, while biochar modification resulted in a 14% increase in surface area. FTIR and NMR analyses showed that SCG contains some oxygen-containing functional groups, such as carboxyl (COOH), hydroxyl (-OH), carbonyl (C=O), and phenolic groups, which are essential for pollutant remediation. Modification with $H_2O_2$ enhanced these, especially on the biochar, where they had been lost through pyrolysis. Conversion of SCG to biochar also increased thermal stability, which has implications for carbon sequestration and long-term environmental stability. These findings suggest that SCG-derived materials offer a promising, circular economic approach to urban soil remediation, converting coffee waste into valuable environmental remediation agents while reducing heavy metal mobility. Next steps in this research will analyse the efficacy of these on heavy metal-contaminated soils.

**ABSTRACT**

Cadmium (Cd) contamination is a pervasive constraint in agricultural soils, impairing crop growth and disrupting nutrient cycling, particularly phosphorus (P) transformation. Microbial P mineralization is largely mediated by phosphatase-producing bacteria carrying phoC and phoD, yet how these two functional guilds jointly and differentially respond to Cd stress remains poorly understood.

To address this gap, we conducted a pot experiment with four treatments (control, inoculation with microbial solution, cadmium addition, and inoculation with cadmium) to evaluate how cadmium pollution and microbial inoculation reshape soil phosphorus cycling microbes and their functional capabilities. We found that cadmium stress significantly altered soil properties and phosphatase activity, reshaping the communities of phoC and phoD. The response of phoC bacteria to inoculation was particularly strong, exhibiting greater tolerance to Cd and a higher tendency to be activated by inoculation, thus promoting soil remediation. In contrast, phoD showed a greater loss of diversity and was more sensitive to Cd and pH, with a narrower ecological niche indicating limited recovery potential. Functional gene predictions based on amplicon sequencing results revealed significant differences among three important functional modules: cadmium addition inhibited the phosphorus cycling and heavy metal stress response modules, while microbial inoculation selectively restored the enzyme-related phosphatase module in contaminated soils. Correlation analysis and SEM jointly indicated that P enzyme-related functional genes are a crucial microbial functional pathway directly regulating plant cadmium accumulation, rather than P cycling functional genes or heavy metal stress response genes.

Our results demonstrate that phoC and phoD communities exhibit both shared and contrasting ecological responses to Cd × inoculation, and that their functional divergence governs P-cycling potential under heavy-metal stress. By identifying the P_enzyme module as the key microbial–plant interface, this study provides mechanistic insight and a clear functional target for developing microbe-assisted strategies to mitigate Cd risks in contaminated farmland.

# Metabolic complementary Between Cupriavidus and Pseudomonas Facilitates 2,4,6-Trichlorophenol Degradation

**Lei Zhang[1], Kaiwen Yang[1], and Xiaojun Zhang[1]**

[1] *State Key laboratory of Microbial metabolism;Joint International Research Laboratory of Metabolic & Developmental Sciences; Department of Microbiology; School of Life Sciences and Biotechnology; Shanghai Jiao Tong University, Shanghai, China*

xjzhang68@sjtu.edu.cn

**ABSTRACT**

Halogenated aromatic compounds with high degrees of chlorine substitution are generally recalcitrant to direct oxidative biodegradation due to their high redox potentials (Hug et al., 2013). Among them, 2,4,6-trichlorophenol (TCP) is widely used in paper bleaching, dyes, pesticides, and pharmaceuticals. Owing to its persistence, carcinogenicity, and ecological toxicity, TCP has been classified as a priority environmental pollutant. Industrial effluents contain TCP reaching several hundred mg/L, far exceeding the World Health Organization guideline of 200 μg/L for drinking water. Consequently, bioremediation of TCP often relies on anaerobic reductive dechlorination followed by aerobic oxidation (Ghochlavi et al., 2022). However, complete reductive dechlorination is rarely achieved by organohalide-respiring bacteria, leading to the accumulation of partially dechlorinated and still-toxic intermediates. Only *Cupriavidus necator* spp. have been reported to mineralize and degrade TCP completely in aerobic condition (Lykidis et al., 2010, Sánchez and González, 2007).

In this study, we identified an efficient aerobic TCP-degrading microbial consortium composed of *Cupriavidus* sp. and *Pseudomona*s sp., capable of completely removing up to 450 mg/L TCP using TCP as the sole carbon and energy source. Metagenomic analysis revealed that *Cupriavidus* encoded a complete TCP catabolic pathway, while *Pseudomonas*, though unable to degrade TCP independently, harbored genes for downstream intermediate processing and likely benefited from metabolites released by *Cupriavidus*. Co-culture experiments confirmed enhanced degradation efficiency compared to *Cupriavidus* monocultures, indicating a metabolically complementary interaction.

These findings highlight the potential of cooperative microbial metabolism in facilitating high-concentration TCP mineralization and provide insight into functional division of labor during the biodegradation of recalcitrant halogenated pollutants.

# Root foraging for metals as a key trait of hyperaccumulators may be obscured in soil systems: Evidence from experiments and a meta-analysis

**Lanfang Hu[1], Yue Cao[1], Rongliang, Qiu[1,2]**

[1] *School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou 510275, China*

[2] *College of Natural Resources and Environment, South China Agricultural University, Guangzhou 510642, China*

**ABSTRACT**

Root foraging for metals is increasingly recognized as a distinctive trait of hyperaccumulator species, yet its occurrence varies widely among species, elements, and experimental conditions. Here, we sought to clarify (i) the factors that influence the detectability of metal-directed root foraging and (ii) the functional advantages this trait provides. We combined split-root experiments in hydroponic and soil systems using hyperaccumulating (HE) and non-hyperaccumulating (NHE) ecotypes of *Sedum alfredii* together with a meta-analysis of published datasets on hyperaccumulators root responses to heterogeneous metal distribution. The HE exhibited a rapid and consistent foraging response in hydroponics, allocating 62.1% of its root biomass to the Cd-enriched compartment within 5 days and maintaining a similar allocation (62.2%) after 21 days. In contrast, this response was not detectable in sticky paddy soil, where the HE allocated only 47.3% of its root biomass to the Cd-rich side over 70 days. The NHE showed stable avoidance of Cd-rich patches in both cultivation systems. Meta-analysis revealed that, beyond plant traits, soil texture, soil source, and the origin of metal heterogeneity were the dominant determinants of whether foraging behavior could be observed. The contrasting ecotypic responses indicate that Cd foraging is a characteristic trait associated with hyperaccumulation: the HE predominantly translocated Cd to shoots, whereas the NHE retained most Cd in roots. Across studies, positive root responses to metal-rich patches increased local morphological investment and were positively correlated with whole-plant biomass and metal uptake. Together, our findings demonstrate that soil environments especially soil texture can obscure the intrinsic foraging capacity of hyperaccumulators, and that metal-directed root foraging is an adaptive trait tightly linked to growth maintenance and metal hyperaccumulation.

## ABSTRACT

Chloroethenes and heavy metal(loid)s (HMs) frequently co-occur in industrially contaminated groundwater, posing serious risks to ecosystems and human health. While in-situ bioremediation is an effective approach for treating chlorinated ethenes such as tetrachloroethene (PCE) and trichloroethene (TCE), its performance is often limited by the inhibitory influence of coexisting HMs, resulting in the accumulation of toxic intermediates such as dichloroethene (DCE) and vinyl chloride (VC). Despite extensive studies on the dechlorination of parent compounds, the relationships between low-chlorinated product kinetics and HM exposure levels remain poorly understood, as do the mechanisms of HM-induced inhibition on microbial reductive dechlorination.

In our study, arsenic and chromium were selected as representative HMs to systematically elucidate the differential inhibitory mechanisms and microbial community responses under combined chloroethene-HM stress, focusing on dechlorination kinetics, electron-donor availability, and core functional microorganisms. Leveraging the natural coexistence of sulfate-reducing bacteria (SRB) and organohalide-respiring bacteria (OHRB), we further proposed a sulfate-amendment strategy for the synergistic remediation of chloroethene-HM composite pollution. By optimizing sulfate input (50–75 μM) according to the type and concentration of coexisting metals, the strategy significantly enhanced reductive dechlorination efficiency under various HM exposures. Concurrently, SRB-mediated sulfide generation promoted metal sulfide precipitation, achieving over 95% removal of 50 μM As(III), Ni(II), Pb(II), and Cu(II), thereby realizing simultaneous detoxification and pollutant degradation. Eventually, the integration of our strategy with electrokinetic bioremediation (EK-BIO) was validated in laboratory and pilot-scale experiments. The 98-day EK-BIO pilot test achieved over 90.0% TCE removal and a 74.0% chloroethene-to-ethylene conversion efficiency, providing both mechanistic insight and practical guidance for the in-situ remediation of chloroethene-HM co-contaminated sites.

**ABSTRACT**

Rare earth elements (REEs) are critical inputs to many clean technology applications. Phosphogypsum, which is a waste generated during phosphorus fertilizer production, is identified as a promising secondary source of these elements. However, the behaviour of REEs in this material and their transfer to trees remains poorly understood. Therefore, the study aimed to assess REE contents in technogenic soils formed on phosphogypsum waste dumps and to evaluate the potential use of silver birch (*Betula pendula* Roth) in the REE phytomining process. The investigation was conducted on two heaps in Łąka village (southern Poland) and Wiślinka village (northern Poland). Fieldwork comprised sampling of biomass (leaves and fine roots) from mid-sized birches, accompanied by soil sample collection at defined depth intervals (0–10, 10–20, 20–40, and 40–80 cm).

Total REE contents in soils and biomass were determined by ICP-OES after microwave digestion, while the mobile fraction was quantified using BCR step 1 (acid-soluble/exchangeable) as a proxy for bioavailability. Bioaccumulation (BF) and translocation (TF) factors were calculated as indicators of REE uptake from soil and internal transport between plant organs.

The studied soils were characterized by high total contents of REEs within the following ranges (in mg $kg^{-1}$): La (1298–1441), Ce (1992–2178), Nd (634–696), Pr (188–205), Y (145.4–165.8), Sm (87.9–97.5), Eu (24.9–27.4), Gd (73.8–80.9), Tb (8.08–8.70), Dy (35.0–39.0), Ho (5.37–5.98), Er (11.6–12.2), Tm (1.14–1.22), Yb (5.07–5.45), Lu (0.53–0.55), and Sc (<1). The summed lanthanides approached ~4365–4798 ppm (≈0.44–0.48%). This pronounced enrichment identifies phosphogypsum-derived technogenic soils as a substantial secondary REE reservoir and a promising target for assessing REE bioavailability, uptake, and internal redistribution in silver birch, as well as the feasibility of REE phytomining on phosphogypsum waste heaps.

## ABSTRACT

Chloroethenes and BTEX compounds (benzene, toluene, ethylbenzene, and xylene) are typical organic pollutants commonly found in industrial sites in China, and their co-contamination has become a key concern in the field of site remediation. In-situ bioremediation has been proven to be a cost-effective and environment-friendly approach for co-contaminated sites remediation. Furthermore, thermally enhanced biodegradation (TEB), referring to thermal treatment with elevated temperatures was promising in promoting microbial growth and metabolic activities thus biodegradation efficiency. However, the microbial degrading for chloroethenes and BTEX under natural anaerobic condition is unclear, and TEB effects on co-contaminants biodegradation behaviors and indigenous microbial communities also remain largely unexplored.

In our study, the typical intermediates dichloroethene (DCE), vinyl chloride (VC) and nontoxic end-product ethene of tetrachloroethene (PCE) and trichloroethene (TCE) biodegradation were detected under natural condition, implying the presence of complete reductive dechlorination. Moreover, the detection of organohalide-respiring bacteria (OHRB), reductive dehalogenase genes (*tceA*, *vcrA*, *bvcA*) and also BTEX-degrading genes (*tmoA* and *cat2,3*) provided supporting evidence for biodegradation potential of co-contaminants in groundwater with indigenous microbial community. Subsequentially, a series of TEB experiments under anaerobic condition were conducted to evaluate the effects on the biodegradation of TCE and benzene co-mingled contaminants using indigenous microbial consortiums. The results showed that the highest TCE biodegradation rate, 0.35 μmol $L^{-1}$ $day^{-1}$, was observed at 30 °C, whereas the biodegradation of benzene was enhanced to a less extent. The functional gene analysis results revealed that enriched *tceA* and *tmoA* genes contributed to TCE and benzene biodegradation at 30 °C, respectively. Additionally, it was found that benzene was degraded via anaerobic oxidation pathway with identification of intermediates, phenol, toluene and benzoate, along with sulfate reduction and iron reduction under co-contamination condition. Furthermore, functional degrading genera were also enriched at evaluated, consistent to the enhanced biodegradation behaviors. This study provides TEB mechanisms from insights of the microbial and functional genes responses of native consortia, underscoring the potential of TEB as a practical and sustainable remediation technology for complex chlorinated solvents and BTEX co-contaminated groundwater.

## ABSTRACT

Remediation costs are strongly controlled by the volume and mass of contaminated soil, making accurate plume delineation essential for effective remediation planning and cost reduction. However, most contaminated soil sites are characterized by small sample sizes, sparse borehole networks, and zero-inflated concentration data, posing substantial challenges for conventional plume estimation approaches. Traditional geostatistical methods, such as Kriging, are particularly sensitive to borehole number, spatial configuration, and depth-specific replicates, and are unable to explicitly represent preferential flow processes.

In this study, we extend the Integrated Nested Laplace Approximation with a Stochastic Partial Differential Equation (INLA-SPDE) framework to estimate petroleum hydrocarbon (PHC) plume volume and mass, focusing on benzene and the CCME F1 fraction. A tracer-based covariate was incorporated to represent preferential flow effects within the spatial model. This application represents a novel extension of INLA-SPDE beyond its prior use for general soil properties to contaminated site assessment.

Model performance was evaluated using three synthetic plumes with known geometry and two real remediation sites, and compared against Hurdle and Kriging-based approaches across 100 repeated estimation runs. Results demonstrate that the INLA-SPDE framework provides robust and stable plume estimates under extremely sparse sampling conditions, achieving accurate volume and mass estimation with as few as 5 boreholes and maintaining prediction errors within 50% of ground-truth References. Incorporation of the tracer covariate substantially improved plume predictions for the more hydrophobic and strongly sorbing CCME F1 fraction, while offering limited improvement for the more mobile benzene.

Overall, this study highlights the suitability of INLA-SPDE as a decision-support tool for contaminated site management, particularly in data-limited environments where conventional geostatistical methods fail to provide reliable plume estimates.

**ABSTRACT**

Microbe-mediated remediation becomes a desire method for removal of persistent organic pollutants (POPs) due to its eco-friendly and sustainable nature. The improvement of practical feasibility requires constructing comprehensive species pool, while it is still limited by the rapid recognition of potential bacterial resources from environment. Here, based on the relative abundances of bacterial OTUs and pollutant concentrations, we established indexes to assess their tolerance to organochlorine pesticides (OCPs) and flame retardants (FRs) that are atmospheric transported and naturally accumulated in forest soil via forest filter effect. By exploring the tolerance pattern from tropical to temperate forests across China, we demonstrated that diversity, community composition, and relative abundances of POP-tolerant bacteria were significantly related to POPs' distribution and concentration. By recognizing over a hundred of genera composed of POP-tolerant species, we found that OCP-tolerant taxa were wide-distributed, while bacterial communities were more responsive to the contamination level of FRs and FR-tolerant taxa were accumulated along the increase of FRs pollution. Our indexes successfully recognized well-known POPs-degrading genera, including *Rhodococcus*, *Bacillus*, *Arthrobacter*, *Stenotrophomonas*, and *Pseudomonas*, as well as a series of versatile taxa affiliated with families Ktedonobacteraceae, Acetobacteraceae, Solirubrobacteraceae, and Nocardiaceae, which were extremely rare and likely ignored in laboratory-scale experiments. Together, our findings provide valuable clues to expand the library of POPs-degrading candidates that is helpful in screening bacterial resources for bioremediation.

**ABSTRACT**

Studying the complex responses of natural microbiomes is crucial for fully understanding the environmental impacts of antibiotics. Current research largely focuses on the inhibitory effects of antibiotics, but lacks in-depth insights into the resilience and functional feedback mechanisms of indigenous microbial communities under combined antibiotic stress.

This study took mixtures of sulfonamide and tetracycline antibiotics—frequently detected in groundwater—as the research object, and investigated their effects on soil microbiomes with different exposure histories: two types of soils, namely pre-exposed soils containing residual antibiotics and pristine control soils. The results showed that these antibiotic mixtures exert strong selective pressure, significantly altering the structure and succession of microbial communities. Network analysis further identified keystone taxa that are essential for maintaining community stability and function.

Most importantly, microbiomes with a historical exposure history not only exhibited greater resilience, but also showed significantly enhanced antibiotic degradation capacity. This finding indicates that such microbiomes can serve as efficient "living bioenhancers" with inherent potential for bioremediation applications. Moreover, this conclusion was validated using genome-scale metabolic modeling (GSMM) technology, which revealed that the metabolic interactions among these microbes are more intense. The findings of this study establish a critical link between chemical pressure and microbial adaptive functions, and provide a new paradigm for applying pre-adapted microbiomes in environmental restoration and risk assessment.

## ABSTRACT

Brownfields contaminated with heavy metals and polycyclic aromatic hydrocarbons (PAHs) pose significant environmental and human health risks. Biochar- and microorganism-assisted bioremediation has emerged as a promising, sustainable approach for restoring such sites. Biochar, produced from the pyrolysis of biomass, improves soil physicochemical properties, immobilizes heavy metals through adsorption and complexation, and reduces PAH bioavailability. Simultaneously, biochar provides a favorable habitat and carbon source for indigenous and introduced microorganisms, enhancing microbial survival, activity, and diversity. Microorganisms contribute to remediation through metal transformation, sequestration, and enzymatic degradation of PAHs. The synergistic interaction between biochar and microorganisms enhances contaminant stabilization and degradation while improving soil fertility and ecosystem recovery. The assisted phytoremediation of heavy metals was tested under controlled greenhouse conditions. Different variants: single microorganisms' application, raw biochar, inoculated with microorganism biochar and water absorbing material (BIOWAG) with biochar were applied to contaminated soil, and white mustard (*Sinapis alba* L.) plant was used as a testing plant. Results of the experiment showed that use of BIOWAG with biochar component and microorganism inoculation was the most efficient method of supporting plant growth and inducing metal accumulation in upper plant parts, thus supporting the phytoremediation process of metal removal, with no adverse effects on the plant. This integrated strategy offers an effective, low-cost, and environmentally friendly solution for the remediation and sustainable reuse of polluted brownfields.

## ABSTRACT

An important area of research is the development of agrobiotechnologies based on the management of the natural soil microbiome, the creation of microbial preparations that decompose xenobiotics, and the use of microbiological methods to increase the proportion of biological nitrogen in plant nutrition. The development of environmental technologies is crucial for improving land management and protecting the environment. This research focuses on assessing the genetic potential of soil microbial communities and their application in the development of fundamental soil science and environmental technologies. Promising areas are formulated related to the use of microbial potential of soils for the purpose of bioremediation of territories from ecotoxicants, development of technologies of self-purification of soils based on stimulation of natural microbial communities, as well as application of microbial preparations of biodegradation of petroleum products. The purpose of this work was to assess the metabolic potential of soils contaminated with petroleum hydrocarbons for processes aimed at the destruction of hard-to-reach compounds and the transformation of oxidized and reduced forms of nitrogen when biochar or mineral easily soluble salts are added. Samples of chernozem, chestnut, gray forest, peat, sod-podzolic soils, podzol, as well as buried soils and permafrost soils were studied. Using gas-chromatographic, molecular-biological, and bioinformatics methods, the metabolic potential of soils contaminated with petroleum hydrocarbons was assessed for processes aimed at the destruction of hard-to-degrade compounds and the transformation of oxidized and reduced forms of nitrogen when biochar or mineral salts were applied. Adding organic biochar to oil-contaminated samples of podzolic soils, mineral compounds of potassium chloride and nitrate salts to chernozem, or a complete mineral fertilizer ($N_{40}P_{50}K_{50}$) to peat soil with incomplete liming (0.5 hydrolytic acidity) resulted in a significant increase in the number of copies of functional genes (*xylE, alkB, alkM, Bss*) involved in the decomposition of petroleum hydrocarbons and the reduction of residual petroleum products. It has been shown that the addition of biochar to oil-contaminated soils increased the number of copies of genes that mark the nitrogen cycle (*amoA, nirK,* and *nifH*), which can be useful for developing effective bioremediation strategies for oil-contaminated areas. For each of the studied soils, the most oil-resistant bacterial genera were identified.

## ABSTRACT

Petroleum hydrocarbons (PHCs), including gasoline and diesel, are widespread soil contaminants that degrade soil quality and pose ecological and human health risks. Understanding their dissipation under realistic environmental conditions, such as nutrient availability, temperature, and moisture levels, helps identify conditions that enhance natural degradation and guide low-cost, minimally intrusive in-situ remediation strategies. This study characterized the dissipation kinetics of co-mingled gasoline- and diesel-contaminated soils under varying temperatures (4 °C, 14 °C, and 24 °C). Additional investigated treatment conditions included a variation of moisture content (35%, 65%, and 90% of field capacity) and nutrient concentrations (no nutrient addition, addition of macronutrients only, and addition of macro and micronutrients Soil was spiked to 53,600 mg $kg^{-1}$ total PHC (TPH), including 14,500 mg $kg^{-1}$ of volatile petroleum hydrocarbon (VPH) components. Soil samples were collected on Days 0, 7, 14, 28, 49, and 77 for residual PHC concentrations in the soil. The first-order model provided the best fit for the dissipation trends observed in the study. For the VPH fraction, dissipation half-lives decreased as temperature increased, from 29.7 days at 4 °C to 20.0 days at 14 °C and 8.5 days at 24 °C, with corresponding first-order rate constants increasing from 0.0233 to 0.0346 and 0.0820 $day^{-1}$. Total PHCs showed a similar temperature response but with slower kinetics, with half-lives declining from 180.5 days at 4 °C to 141.7 days at 14 °C and 82.8 days at 24 °C, alongside rate constants increasing from 0.00384 to 0.00489 and 0.00837 $day^{-1}$. Both the VPH and TPH showed a significant increase in degradation rates between 14–24 °C than between 4–14 °C, with VPH consistently displaying higher temperature sensitivity ($Q_{10}$ = 2.24 vs. 1.74 for TPH between 14–24 °C). At 24 °C, residual TPH and VPH were significantly higher at higher moisture levels. At 14 °C, both fractions had significantly lower residual concentrations at 35% field capacity. At 4 °C, no significant effect of moisture level was observed for TPH. However, VPH showed significant differences between the 35% and 90% moisture levels, with the lowest residual concentrations occurring at 35% field capacity. Nutrient effects followed a similar temperature-dependent pattern. Nutrient effects followed a similar trend. No significant nutrient influence was observed at 4 °C for both VPH and TPH, but at 14 °C and 24 °C, TPH removal was significantly higher with macro + micronutrient addition, whereas VPH removal was significantly higher under no-nutrient conditions.

These findings provide practical insight into how temperature, moisture, and nutrient conditions shape the dissipation of co-mingled PHCs in soil. By generating temperature-dependent kinetic parameters such as half-lives, rate constants, and $Q_{10}$ values under controlled but realistic conditions, this work supports more informed decisions when evaluating the potential for natural attenuation or planning low-impact in-situ remediation strategies in cold climates.

# Temporal Dynamics and Metabolic Profiling of Vetiver Root Exudates Under Atrazine Stress

**Faming Zhang[1*], and Yi Zheng[1,2], Shixian Sun[3]**

*[1] College of Yunnan Rural Revitalization Education, Yunnan Open University, Kunming 650223, People's Republic of China*

*[2] School of Resource and Environment, Yunnan Agricultural University, Kunming 650201, People's Republic of China*

*[3] School of Ecology and Environment, Southwest Forestry University, Kunming 650224, People's Republic of China*

**ABSTRACT**

Root exudates are key mediators for plants to regulate the rhizosphere microenvironment and enhance the degradation of organic pollutants in soil. To clarify the response patterns of root exudates from *Chrysopogon zizanioides* under atrazine stress, a 60-day pot experiment was conducted to investigate the variations in root exudates of *Chrysopogon zizanioides* exposed to atrazine. Two treatments were set up: no atrazine addition (CK) and atrazine addition at a concentration of 2 $mg \cdot kg^{-1}$ (AT). Root exudate samples were collected on the 10th, 20th, 30th, 45th, and 60th days, respectively. Gas chromatography-mass spectrometry (GC-MS) was employed for compound identification and peak area quantification. The results were listed below:

1. During the 60-day incubation, a total of 24 classes of compounds were detected. The 10 most abundant classes were alkanes, alkenes, esters, alcohols, amides, ketones, acids, phenols, aldehydes, and benzenes in sequence, accounting for 34.33%, 16.96%, 15.74%, 6.22%, 4.02%, 3.74%, 3.50%, 2.68%, 2.53%, and 2.24% of the total number of compounds, respectively.
2. The total number of the four classes of compounds (alkanes, alkenes, esters, and alcohols) accounted for more than 70% of the total, and their abundance exhibited a unimodal distribution over time, peaking on the 30$^{th}$ day. The number of acids and nitriles was significantly higher in the middle and late stages of incubation (30–60 d) than in the early stage (10–20 d).
3. The five classes of compounds with relatively high relative concentrations were amides ((Z)-13-docosenamide, (Z)-9-octadecenamide), alkanes (docosane, 2,6,11-trimethyldodecane), esters (1,3-dimethyl 2-(pyridin-3-ylmethylidene), bis(2-methylpropyl) 1,2-benzenedicarboxylate), nitriles (oleanitrile), and acids (erucic acid) in sequence.
4. At the mid-stage of incubation (on the 30$^{th}$ day), the total compound number of root exudates, as well as the number of upregulated acids and alcohols, in the ATZ added treatment was higher than those in the ATZ non-added treatment.

In conclusion, ATZ exposure not only increased the total compound number of root exudates, but also specifically induced the massive secretion of compounds with potential detoxification or antioxidant functions, including acids and alcohols. This may be the key physiological mechanism for *Chrysopogon zizanioides* to adapt to ATZ stress and perform hyperaccumulation.

**Keywords:** Atrazine; *Chrysopogon zizanioides*; Root exudates

# Sequential Causal Machine Learning Assisted Design of Biochar for Laccase Immobilization

**Yin Lu[1,2], Dawen Gao[1,2]**

[1] *Centre for Urban Environmental Remediation, Beijing University of Civil Engineering and Architecture, Beijing, China*

**ABSTRACT**

The sequential causal relationships among preparation conditions, biochar properties, and immobilized laccase activity pose critical challenges in optimizing biochar preparation conditions for enzyme immobilization. Here, a novel sequential causal machine learning model was coupled with reinforcement learning to optimize preparation conditions and ensure immobilized laccase activity. For biochar properties and immobilized laccase activity, excellent prediction accuracy was achieved utilizing Random Forest ($R2 = 0.72 \pm 0.11$) and Adaptive Boosting ($R2 = 0.86 \pm 0.12$). Interpretability analysis elucidated that preparation conditions exerted nonlinear effects on biochar properties and immobilized laccase activity, mainly driven by raw material types and specific surface area. Reinforcement learning optimization of biochar design achieved 2.18 U/g laccase immobilized activity with agricultural waste as optimal raw material under optimized preparation conditions. Experimental validation showed that the optimized biochar achieved advantageous immobilized laccase activity ($2.03 \pm 0.07$ U/g), environmental adaptability, storage stability, and effective benzo[a]pyrene removal ($51.25 \pm 0.87\%$). This study provides a feasible approach to analyze the nonlinear causal sequential relationships among biochar preparation conditions, biochar properties, and immobilized laccase activity, enabling targeted design of biochar preparation conditions to optimize immobilized laccase activity.

# Effects of Amendments on the Anaerobic Bioremediation of Organohalides in Contaminated Soil and Groundwater

**Sydney Kennedy-Flynn[1*], Sampurna Nandy[2], Petr Kuznetsov[2], Ania Ulrich[2], Miles Dyck[1]**

[1]Department of Renewable Resources, University of Alberta, Canada

[2]Department of Civil and Environmental Engineering, University of Alberta, Canada

*kennedyf@ualberta.ca

**ABSTRACT**

Organohalide and petroleum hydrocarbons are commonly found in soil and groundwater at contaminated oil and gas industrial sites. Specifically, tetrachloroethylene (PCE) and its daughter compounds (trichloroethylene, dichloroethylene, and vinyl chloride) along with co-contaminants benzene and toluene pose numerous health risks to humans and wildlife. The objective of this research is to evaluate the effectiveness of biostimulant amendments in increasing the rate of dechlorination of PCE and its daughter compounds in the presence of benzene and toluene.

Soil and groundwater were taken from a brownfield industrial site in Edmonton, Alberta, Canada. Microcosms were prepared with soil and groundwater from the site and then spiked with benzene, toluene, and PCE. Triplicate microcosms were left untreated or treated with biostimulants- ERDENHANCED™, or lactate. The microcosms were kept in an anaerobic chamber to maintain reducing conditions, and regular GC measurements of concentrations of contaminants and other gases (methane, carbon dioxide, ethene) were done by headspace injection. qPCR for bacterial species *Dehalococcoides* and 16s microbial sequencing were performed to examine community shifts throughout the experiment. Microcosms have been re-spiked and re-amended to examine repeatability. Microcosms amended with ERDENHANCED™ had increased microbial presence compared to the lactate treatment or the unamended microcosms. Amended microcosms had faster removal rates compared to unamended microcosms. This work provides insights on the role of amendments in remediation and their complex interactions within the soil microbiome, namely the selective enriching of dechlorinating microbes.

# In Situ Enhanced Reductive Dechlorination for Chlorinated Aliphatic Hydrocarbon–Contaminated Sites

**Wuxing Liu[1*], Ke Zhao[1], and Jinyu Hou[1]**

[1] *Department of Soil Environment and Remediation, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*liuwuxin@issas.ac.cn

**ABSTRACT**

Chlorinated aliphatic hydrocarbons (CAHs) are widely used industrial solvents whose long-term leakage has caused extensive soil and groundwater contamination. Due to their high density, low solubility, and persistence, CAHs migrate as dense non-aqueous phase liquids into aquifers and low-permeability zones, forming recalcitrant contamination sources. In situ enhanced reductive dechlorination (ERD) is a low-carbon and sustainable remediation strategy that relies on anaerobic microbial processes to transform CAHs into non-toxic end products such as ethene. However, its field application is often constrained by incomplete dechlorination, toxic intermediate accumulation, limited electron-donor availability, and insufficient microbial stability.

Field investigations at an aged CAH-contaminated site revealed that long-term contaminant stress strongly reshaped subsurface microbial communities. With increasing depth, higher CAH concentrations and anaerobic stability were associated with increased microbial diversity, greater community convergence, and more stable co-occurrence networks. Deep soils were enriched with organohalide-respiring bacteria, fermentative microorganisms, and iron- and sulfate-reducing bacteria, forming functionally cohesive assemblages adapted to CAH stress. Community assembly analysis showed that deterministic processes dominated microbial structuring under high contamination, whereas stochastic processes were more important in shallow soils.

Guided by these site-scale insights, a highly efficient 1,1,2-trichloroethane (1,1,2-TCA)-dechlorinating microbial consortium was enriched from contaminated groundwater. The consortium rapidly and completely transformed 1,1,2-TCA to ethene via vinyl chloride as the sole intermediate, achieving dechlorination rates exceeding those previously reported. Functional analyses revealed a clear division of labor, with Trichlorobacter catalyzing dihaloelimination of 1,1,2-TCA and Dehalococcoides completing vinyl chloride hydrogenolysis, supported by fermentative and syntrophic partners supplying key metabolites and cofactors.

To overcome electron-donor transport limitations in low-permeability media, a nano-emulsified vegetable oil (nanoEVO)–based biostimulation strategy was developed. The nanoEVO exhibited small droplet size, high stability, and sustained electron-donor release. Bioreactor experiments demonstrated that nanoEVO significantly enhanced indigenous microbial activity, increased Dehalococcoides abundance and reductive dehalogenase gene expression, and promoted efficient and complete removal of 1,1,2-TCA and its intermediates.

Overall, this study demonstrates that ERD is an eco-engineering process driven by contaminant-selected microbial communities and can be effectively regulated through targeted biostimulation. Integrating site-scale microbial ecology, functional consortia, and engineered electron-donor delivery provides a robust framework for improving in situ bioremediation of CAH-contaminated environments.

# Dual inhibition mechanisms drive antagonistic effects during phenanthrene and pyrene co-degradation by Pseudoxanthomonas: Pathway competition and substrate pReferences

**Chao Cai[1*], Jiaqing Liang[1]**

[1] *State Key Laboratory for Ecological Security of Regions and Cities, Institute of Urban Environment, Chinese Academy of Sciences, Xiamen, China*

* ccai@iue.ac.cn

**ABSTRACT**

The biodegradation of polycyclic aromatic hydrocarbons (PAHs) involves complex metabolic interactions among multiple degradation pathways. However, how interactions among different pathways influence the overall degradation efficiency remains poorly understood. In this study, *Pseudoxanthomonas* sp. G3, an efficient degrader of phenanthrene (PHE) and pyrene (PYR), was used to investigate pathway interactions under mixed-PAH conditions. Genomic and metabolomic analyses revealed that strain G3 degrades PHE and PYR through three pathways: the phthalate pathway (with phthalic acid as the dead-end product), a shared catechol pathway, and the benzoate pathway. Notably, PYR induced the benzoate pathway, representing a previously unreported metabolism of PYR by bacteria. Integrated analyses revealed that PHE inhibits PYR degradation via dual mechanisms. Specifically, PHE preferentially utilizes the PYR-induced benzoate pathway, thereby diverting metabolic flux and impeding PYR degradation. Moreover, the benzoate pathway further inhibits the catechol pathway, intensifying suppression of PYR degradation. These findings elucidate mechanistic insights into the interactions among the biodegradation pathways under mixed-PAH stress and provide a theoretical basis for targeted improvement of the efficiency and predictability of mixed-PAH degradation.

# The Fundamentals of Disturbed Land Reclamation

**Vladimir Androkhanov**

*Institute of Soil Science and Agrochemistry of Siberian Branch of Russian Academy of Sciences,*

*Novosibirsk, Russian Federation*

androhan@yandex.ru

**ABSTRACT**

The problems of restoration of disturbed territories and biocenoses, which can effectively neutralize the negative consequences of mineral development, remain very relevant at present. The formation of disturbed areas in which almost all components of the natural environment are disturbed and destroyed makes it possible to study the restoration of ecosystems from scratch, which is of great theoretical interest. It is also necessary to recognize that the development of methods for the effective restoration of disturbed lands without fundamental knowledge of the laws of restoration of individual components of ecosystems is impossible. Many years of research on technologically disturbed areas, carried out in various natural and technogenic conditions, made it possible to formulate the fundamental foundations of reclamation work. 1. Determination of the main characteristics and individual specifics of technogenic landscapes. 2. Formulation of the remediation goal and determination of performance targets. 3. Assessment of reclamation resources and prospects for their use to create favorable conditions for landscape restoration. 4. Calculation of reclamation efficiency and monitoring of restored areas. 5. Assessment of soil and ecological state taking into account the level of restoration of soil and vegetation cover.

*antonio.aguilarg@upct.es

## ABSTRACT

Ecological restoration of potentially toxic mine tailings in semi-arid environments poses major challenges due to extreme climatic conditions and poor soil quality (high salinity, low fertility, weak structure, and high levels of potentially toxic elements -PTEs- such as metals and metalloids). Since conventional remediation techniques are often ineffective or economically unfeasible in these contexts, integrated and nature-based solution (NBS) strategies that combine soil conditioning with microclimatic regulation are suitable alternatives to promote sustainable recovery.

This study presents a multifactorial field experiment integrating organic amendments (biochar and municipal organic solid waste) and microclimatic regulation through forest brush barriers (fascines) to enhance soil recovery in PTE-polluted tailings in the Cartagena–La Unión mining district (SE Spain). Several plant species (*Pinus halepensis*, *Tetraclinis articulata*, *Atriplex halimus*) were placed to simulate revegetation conditions and assess the suitability of these restoration strategies for plant establishment. Over one year, seasonal dynamics of physicochemical and biological indicators were monitored to evaluate how these factors interact to improve soil functionality and resilience.

Organic amendments significantly increased pH, total and soluble organic C and N, enzymatic activities (β-glucosidase and dehydrogenase), microbial respiration, and invertebrate feeding activity, while reducing water-soluble Zn and Cd concentrations. Simultaneously, fascines induced contrasting microclimatic conditions that influenced soil biochemical responses. Shady microsites exhibited lower soil temperatures in warm months, greater biological activity, and higher organic C and N contents, although no consistent improvement in soil moisture was detected. These results indicate that microclimatic orientation modulates biological processes and can enhance amendment performance under semi-arid constraints.

The combined application of organic inputs and fascines generated more stable soil conditions and greater biological resilience than either approach alone. This integrated strategy reduced PTEs mobility and improved soil structure and functionality, facilitating native vegetation establishment and promoting natural recovery. Therefore, the proposed approach represents a low-cost, circular, and scalable solution for restoring degraded mining areas and mitigating the extra limitations of semi-arid climates.

# Exogenous Chemicals Used to Alleviate or Salvage Plants under Flooding/Waterlogging Stress: Their Biochemical Effects and Perspectives

**ABSTRACT**

Plant flooding/waterlogging stress (FWS) can be a threat to food security worldwide due to climate change. To mitigate its potential devastation, numerous exogenous chemicals (ECs) have been used to demonstrate their effectiveness on alleviating FWS for the last 20 years. This review has summarized the most recent findings on use of various ECs as either nutrients or regulatory substances on crop plants under FWS and their roles involved in improving root respiration of seedlings, optimizing nutritional status, synthesizing osmotic regulators, enhancing the activity of antioxidant enzymes, adjusting phytohormone levels, maintaining photosynthetic systems, and activating flood-tolerance related gene expressions. The effect of ECs on alleviating plants under FWS proves to be beneficial and useful but rather limited unless they are applied on appropriate crops, at the right time, and with optimized methods. Further research should be focused on use of ECs in field settings and on their potential synergetic effect formore FWS tolerance

**ABSTRACT**

Selective gold extraction using absorbents represents a promising sustainable technology for wastewater treatment in gold mining and the smelting process. To facilitate convenient gold recycling, the absorbed gold ions necessitate an effective gold ion reduction process to simultaneously convert $AuCl_4^-$ into metallic gold.

The extraction of Au ions necessitates the successive dechlorination of $AuCl_4^-$ to $AuCl^-$ (i.e., $AuCl_4^- \rightarrow AuCl_3^- \rightarrow AuCl_2^- \rightarrow AuCl^-$) and the nucleation to Au particles. However, a method for precisely controlling stepwise reaction conditions to dynamically match the multistage reduction for ultra-efficient gold recovery has been in suspense. Herein, the aminated hydrocarbon with inherent hydroxyl (-OH) performed rapid stepwise $AuCl_4^-$ dechlorination by cascade reduction. The tandem active sites of -OH and amine ($-NH_2$) showed an unprecedented reduction rates (0.091 g/min/mg) while still maintained high gold reduction capacity (3652.0 mg/g). The high propensity for dehydrogenation revealed that -OH serves as a quick-acting electron donor that initiates a cascade reaction by lowering the energy barrier from $AuCl_3^-$ to $AuCl_2^-$. Then, $-NH_2$ serves as a powerful capture site with complementary electrons for the subsequent dechlorination from $AuCl_2^-$ to $AuCl^-$, which finally nucleates to gold clusters. Notably, -OH and $-NH_2$ periodically supported cascade reduction and thus could selectively extract more than 99.9% of gold ions, even from a strong acidic solution. These findings will inspire innovative designs for sequence-controlled reactions in scalable gold recovery.

*pspark@snu.ac.kr

## ABSTRACT

Waste rock piles generated during coal mining and preparation processes have caused various problems, including slope collapse and the occurrence of acid mine drainage. Due to declining coal demand, the number of active coal mines in Korea decreased from 347 in 1988 to complete closure expected by 2025. Consequently, it is essential to focus on the restoration processes and their effects on abandoned coal mine sites today.

To manage waste rock piles in coal mines, restoration efforts such as covering the underlying waste materials with soil, seeding understory vegetation and planting trees are being implemented. Although numerous studies have examined the restoration of abandoned coal mine sites using vegetation, research on how vegetation affects changes in soil properties by vegetation remains limited. Therefore, this study compared the physico-chemical properties of restored soil according to different vegetation types.

Organic matter inputs on the ground, soil depth, root size and root distribution in the soil profile, stone content, soil texture, soil pH, cation exchange capacity (CEC), total organic carbon (TOC), total nitrogen (TN), carbon-to-nitrogen ratio (C/N) and available phosphate (AP) were analyzed at an abandoned coal mine restored with two vegetation types: understory vegetation or tree (*Betula pendula*)).

The root ratios in the soil profile ranged from 5% to 75% in the top soil layer, and from 1% to 40% in the underlying waste rock layer at the birch tree site. These values were higher than those at the understory vegetation site, where root ratios ranged from 1% to 50% in the top soil layer and from 7% to 10% in the underlying waste rock layer. In the top soil layer, AP and TN were 21.34 ppm and 0.13%, respectively, at the birch tree site, compared to 14.84 ppm and 0.07% at the understory vegetation site, showing a significant difference ($p < 0.05$). CEC was 21.41 cmol/kg at the birch tree site, and 17.05 cmol/kg at the understory vegetation site, indicating a highly significant difference ($p < 0.0001$).

This study demonstrates that planting trees is a more effective long-term restoration method for improving soil quality in abandoned mining areas than seeding understory vegetation. Tree planting site exhibit higher levels of key nutritional factors, such as CEC, TN, and AP. Additionally, this research provides data to support future restoration efforts and monitoring of abandoned coal mine sites.

## ABSTRACT

Rare earth mine tailings and associated soils are often severely degraded, posing long-term ecological risks and constraining land reclamation efforts. Phytomining, which employs hyperaccumulator plants to extract rare earth elements (REEs) while simultaneously improving soil quality, has emerged as a promising remediation–utilization strategy for mined lands. However, the lack of efficient and economically viable approaches to valorize REE-rich biomass remains a major barrier to large-scale implementation. Here, we develop a direct in situ doping strategy to convert cerium (Ce)-enriched hyperaccumulator biomass into color-tunable CaS:Ce phosphors while co-producing renewable syngas. Through solvothermal pretreatment with sulfuric acid and ethanol, Ce, Ca, and S are selectively enriched into a reactive char matrix, which is subsequently transformed into luminescent CaS:Ce phosphors via steam gasification. The resulting phosphors exhibit broad green–yellow emission with high photoluminescence quantum yields (18.5–37.4%). Compared with conventional REE recovery pathways, the process reduces energy demand by 89.1%, carbon emissions by 88.1%, and overall costs by 90.5%. By integrating soil remediation through REE phytoextraction with high-value utilization of hyperaccumulator biomass, this approach offers a sustainable pathway for restoring degraded mined lands while producing functional REE-based materials. The findings demonstrate a scalable remediation–resource recovery model that aligns with circular-economy principles and enhances the feasibility of phytotechnology-based restoration of mined soils.

**ABSTRACT**

What drives the growth of spontaneous vegetation on mine residue deposits across different climates in Namibia? Is spontaneous vegetation a solution for cost-effective greening of mine residue deposits in Namibia? Would irrigation improve the growth of spontaneous vegetation? Could semi-purified mine waste water be used for such irrigation? Which kind of soil material does spontaneous vegetation need for optimal growth? These questions are being investigated at two locations in Namibia with different climatic conditions in order to develop sustainable and climate-adapted management strategies for the greening of mine residues and the use of mine water. One site is the mine residue deposit of Rosh Pinah lead and zinc mine in Southern Namibia. The other location comprises the mine and smelting residue deposits of the copper mine and smelter in Tsumeb in Northern Namibia.

At Rosh Pinah, with an average annual precipitation of only about 24 mm, species such as *Caroxylon vermiculatum, Zygophyllum spec.* or *Stipagrostis spec*. are colonizing the mine residue deposit. In contrast to this arid climate, at Tsumeb, with an average annual precipitation of 563 mm, species such as *Dodenaea viscosa* or *Cambretum imberbe* or *Phoenix dactilifera* are spreading on mine residue deposits. At both locations, the plants only occur on sandy surface soils. Almost no vegetation is occurring where the upper layer of the deposits consists of silt or salt crusts. Additionally, almost no vegetation occurs where black sand, gravel and stones have been used to cover the deposits to prevent dust resuspension. In vegetated areas, roots grow several decimeters deep into the mine residues. Thus, the local contaminations with high concentrations of copper, zinc or lead do not prevent plant growth as the study shows. Differences are much more found regarding soil texture and the related water balances in the most upper layer. Therefore, sensors are installed to record soil water dynamics at different depths of the deposits and kf and pF values are determined in the laboratory. The objective is to determine optimal soil conditions of the upper horizons for colonization by spontaneous vegetation. In a second step, on site field experiments will take place to elaborate the optimal thickness of these upper soil layers for plant growth. This experiment will also investigate the potential of mine water to be used for irrigation during the initial growth phase and to cope with extensive drought periods. The results will be made available through a decision matrix including the choice of plants, the usability of local water resources and the needs for soil meliorations for application to other mine residue deposits.

## ABSTRACT

Red mud, a saline-alkaline and metal-contaminated byproduct, poses severe ecological risks. This study elucidates the synergistic remediation mechanisms of biochar (BC) combined with arbuscular mycorrhizal fungi (AMF) in an Arundo donax-soil system. We specifically investigated biochar loaded with Funneliformis mosseae (BC-FM) and that loaded with Rhizophagus intraradices (BC-RI). The BC-FM treatment significantly enhanced the plant antioxidant system and photosynthetic capacity while reducing the content of exchangeable arsenic (As) and soil pH, thereby inducing a "photosynthesis enhancement-As immobilization" synergy. In contrast, the BC-RI treatment markedly increased plant biomass and soil microbial α-diversity, while simultaneously reducing the contents of soil lead (Pb) and sodium ions ($Na^+$), and enhancing alkaline phosphatase activity-thus demonstrating a "Pb fixation-microbial diversity-soil phosphorus (P) activation" cascade. Rhizosphere network analysis identified key bacterial genera, with Longimicrobiaceae driving soil organic carbon accumulation in the BC-FM treatment and Lechevalieria enhancing alkaline phosphatase (ALP) activity in the BC-RI treatment. These findings support a novel "fungal species-heavy metal valency matching" principle, where RI preferentially targets cationic Pb,while FM targets anionic As. This principle establishes a three-dimensional synergistic model: "Heavy metal transformation – concurrent salinity-alkalinity mitigation – microbial function activation". The results provide a foundational strategy for zonal red mud remediation: applying BC-RI in Pb-dominated areas and BC-FM in As-contaminated areas.

# Formation and Migration Patterns of Polycyclic Aromatic Hydrocarbons in Underground Coal Fires: A Case Study of a Typical Coal Fire Zone

**Zhang Pengcheng[1,2], Xin Haihui[1,2*], Zhang Kaikai[3], Qi Xuyao[1,2]**

[1] *State Key Laboratory of Coal Mine Disaster Prevention and Control, China University of Mining and Technology,Xuzhou, China*
[2] *Faculty of Safety Engineering, China University of Mining & Technology, Xuzhou, Jiangsu, China.*
[3] *School of Environment and Spatial Informatics, China University of Mining & Technology, Xuzhou, Jiangsu, China.*
* xinxhh@cumt.edu.cn

**ABSTRACT**

Coal seam fires represent a persistent global disaster that damages both resources and ecosystems in coal- producing nations. China suffers from some of the world's most severe coal fires, with over 200 active fire zones in its central and western regions, covering a total area exceeding 50 million m². Our investigation, involving more than 200 samples from over 20 fire zones in Xinjiang, Ningxia, Inner Mongolia, etc (see 1), revealed abnormal groundwater pH and polycyclic aromatic hydrocarbon (PAH) enrichment around these areas. In newly covered soil layers at the formerly extinguished Wuda fire zone in Inner Mongolia (successfully controlled during 2011-2015), the Liuhuanggou fire zone in Xinjiang (controlled in 2000, now re-ignited), and the Sangonghe fire zone in Xinjiang (controlled in 2003), total PAH concentrations were 30 to 100 times above background levels (see 1), with a peak value of 165 mg/kg. This underscores the urgent need for fundamental research into the reaction kinetics of organic pollutants from underground coal fires and collaborative mitigation strategies.

Figure 1 Field survey of soil pollutants in coalfield fire zones

This study employs molecular reaction kinetics to investigate reaction dynamics, examining real-time structural transformations during reactions. It addresses uncertainties in organic pollutant formation pathways and the lack of coordinated control theory under high-temperature, oxygen-deficient conditions characteristic of coal fires. A stepwise PAH formation pathway driven by radical recombination—specifically 'cleavage-condensation and dehydrogenation-cyclisation'—is proposed. Furthermore, a critical transformation threshold for PAHs was established: within the high-temperature, oxygen-deficient coal fire environment, oxygen concentration ≥3% and temperature ≤400℃ (See 2). Addressing the complexity of pollutant migration driven by the dynamic evolution of coal fire fissures, we pioneered a thermal buoyancy-driven model for organic pollutant migration. This breakthrough overcomes the limitations of traditional gravity-field pollution diffusion, providing crucial theoretical support for understanding and controlling the migration of organic pollutants from coal fires.

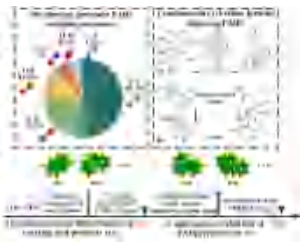

Figure 2: Mechanism of PAH Production and Prevention and Control Technologies in Coalfield Fire Zones

**ABSTRACT**

Lead (Pb) is a highly toxic and persistent environmental pollutant that poses significant risks to human health. Biochar has demonstrated effective Pb immobilization, and phosphorus-modified biochar exhibits enhanced adsorption capacity for $Pb^{2+}$. In this study, rice straw biochar (BC) was modified using phosphorus-containing compounds at different ratios to produce five variants: unmodified BC, phosphate rock powder blended with rice straw at 1:1 (SBC1) and 1:5 (SBC5), and calcium dihydrogen phosphate mixed at 1:1 (NBC1) and 1:5 (NBC5). Isothermal adsorption tests revealed that BC, SBC1, and SBC5 followed the Langmuir model, with maximum adsorption capacities of 60.00 mg/g, 106.19 mg/g, and 273.08 mg/g, respectively, while NBC1 and NBC5 conformed to the Freundlich model, exhibiting maximum capacities of 217.91 mg/g and 251.36 mg/g. Kinetic experiments indicated that $Pb^{2+}$ adsorption by all biochars followed pseudo-second-order kinetics, with BC primarily relying on chemisorption. Post-adsorption, the equilibrium solution pH decreased, and phosphorus concentrations in modified biochars initially declined before a slight increase. SBC5 and NBC1 exhibited superior Pb adsorption and removal efficiency, predominantly through precipitation, whereas unmodified BC immobilized Pb via chemisorption. These differences may be attributed to variations in phosphorus content and specific surface area. XRD analysis confirmed that no new phases formed in BC after the reaction with Pb, whereas SEM-EDS detected the presence of Pb in the residues. In contrast, phosphorus-modified biochars formed $Pb_5(PO_4)_3Cl$, with Pb accumulating on surfaces or within pores at high concentrations. FTIR spectra indicated minimal peak shifts in BC but notable changes in modified biochars: C-O exhibited a blue shift, while C=O and P-O displayed red shifts, suggesting precipitation of Pb-containing compounds. These findings provide a theoretical foundation for rice straw waste recycling and soil Pb pollution remediation.

**Key words** phosphorus modified biochar, biochar, $Pb^{2+}$, pH

## ABSTRACT

Rising carbon emissions have contributed to drastic weather changes that threaten agricultural productivity, while mining activities in South Africa have further degraded arable soils leading to soil acidity and reduced fertility. These pressures threaten food security and socioeconomic stability, underscoring the need for sustainable strategies that mitigate atmospheric carbon and restore soil health. Vetiver grass has potential, however, its effectiveness in mine-degraded soils remains under investigated globally. Therefore, this study assessed the effects of vetiver grass on soil acidity, electrical conductivity (EC) and organic carbon (OC) in mine-affected soils using a 6×2×2 factorial microplot experiment at the University of Limpopo. The first factor comprised of six composite soil samples collected in proximity to a Gold Mine. The second factor included the presence or absence of vetiver grass, while third factor consisted of two rehabilitation periods (3 and 6 months). Pre and post soil samples were analysed for soil pH in water ($H_2O$) and potassium chloride (KCl), EC and OC. Furthermore, root and shoot vetiver biomass was determined post each rehabilitation period. Results showed that all the three factors and their interaction significantly ($p<0.05$) influenced OC, EC, and soil pH. Rehabilitating the soil for 3 months led to significant increases in OC and EC but resulted in a decline in acidity, particularly in forest soils. Extending the rehabilitation to 6 months generally reduced these soil variables but enhanced soil acidity, root and shoot vetiver biomass. The decline, however, did not go below the initial baseline before the rehabilitation process. Increased vetiver growth was strongly negatively correlated with the decline in EC and soil pH, indicating active modification of the soil environment through root exudation and ion uptake. Overall, this study shows that vetiver grass significantly alters soil properties during rehabilitation by reducing EC, neutralizing acidity and increasing OC. However, the magnitude of these changes is highly dependent on the initial condition of the mine-affected soils. As extended rehabilitation periods revealed the potential re-emergence of soil acidity, 3 months is the most effective period for the regulation of soil pH and EC.

**ABSTRACT**

Metal mining has driven widespread ecosystem degradation globally, producing severely degraded habitats characterized by landscape destruction, heavy metal contamination, nutrient depletion, soil physical structure deterioration, and water erosion. Primary succession on such substrates is exceedingly slow, and ecological restoration is often limited to a small subset of pioneer species. Root functional traits, which are phenotypic traits reflecting plant growth, reproduction, survival, and responses to environmental changes, hold significant importance for understanding how plants adapt to and modify their environments. Variation in root traits strongly influences plant growth strategies. However, the belowground strategies that enable the establishment and persistence of pioneer plants in metal -contaminated and toxic substrates remain poorly understood.

Here, we compiled the China Pioneer Plant Trait Database (CPPTD) by synthesizing information from hundreds of publications, integrating global trait databases (e.g., TRY, GROOT), and incorporating field surveys conducted in mining areas of South China. We classified pioneer species into functional groups based on life form and mycorrhizal type, and quantified species positions within the conventional two-dimensional root economics space (RES), defined by the “collaboration” and “conservation” gradients, using key root traits, including specific root length, root diameter, root tissue density, and root N concentration. In addition, we evaluated defense-related trait trade-offs using root carbon composition together with metal bioconcentration factors.

The results indicate that pioneer species broadly conform to global RES trade-offs, representing the “collaboration” gradient from do-it-yourself to outsourcing, and the “conservation” gradient from fast to slow. However, interspecific differences between pioneer and non-pioneer species are generally small along nutrient-acquisition gradients, suggesting that nutrient acquisition is not the primary strategy driving pioneer colonization in highly contaminated habitats. In contrast, defense-related traits are strongly associated with root heavy metal bioconcentration factors, revealing tight linkages between root carbon allocation patterns and bioconcentration potential. Field observations of the dominant pioneer species *Miscanthus sinensis* further suggest that inorganic defense-related traits may trade off with organic defense traits, such as root carbon composition, and contribute more strongly to tolerance under heavy metal stress.

Overall, these findings support an expanded acquisition–defense trait trade-off framework for species colonizing contaminated mining areas, providing a trait-based mechanism for clarifying pioneer strategies and informing species selection for ecological restoration and phytoremediation.

**ABSTRACT**

Open-pit mining in arid and semi-arid regions causes severe soil degradation, and the initial restoration stage (0–5 years) is critical for ecosystem recovery trajectory and efficiency. Harsh environments and limited water resources lead to slow natural recovery, highlighting an urgent need for effective artificial interventions. This study aimed to explore the impact of short-term artificial restoration on soil microbial communities and functional traits, providing scientific support for early reclamation of similar open-pit mines. Using a space-for-time substitution approach, a three-tiered evaluation framework (soil bacterial communities – microbial functional genes – physicochemical properties) was established. High-throughput metagenomic sequencing analyzed four treatments: 3-year natural recovery (CK), 2-year (ER2) and 5-year (ER5) artificial "ecological package" restoration, and undisturbed native desert steppe (TC). The ecological package included drought-tolerant native seeds, water-retaining hydrogel, slow-release NPK fertilizer, and composite microbial inoculant, adapted to arid and semi-arid conditions. Results showed that compared to CK, the ecological package did not alter bacterial evenness (Shannon, Simpson indices) but significantly increased species richness (Chao1, ACE indices). It reshaped community composition: ER2 and ER5 enriched r-strategist taxa like *Proteobacteria* and reduced *Actinobacteria*, associated with soil nutrient availability. Network analysis revealed stronger interspecific interactions in ER2 (11,118 edges) than CK (9,823 edges), while ER5 (6,160 edges) stabilized, approaching TC (8,148 edges). Functional genes involved in carbon (*abfA, accA*), nitrogen (*nifA, nxrA, nxrB,nosZ, nirS*), and phosphorus (*ppa, ugpA, phoB,gcd*) cycling were significantly enriched in ER2, indicating early "functional activation". By year 5, gene abundance moderately decreased, reflecting a transition from high-energy activation to efficient low-energy steady state. Redundancy analysis identified soil organic carbon, ammonium, and nitrate as core drivers. A phased nutrient management strategy was proposed: prioritize carbon and nitrogen supplementation in 0–2 years to stimulate microbial activity, and targeted phosphorus supplementation after 5 years to sustain soil functionality. This study clarified the dynamic evolution of microbial communities and functional traits during early restoration. The three-tiered framework and phased strategy provide scientific basis and practical guidance for ecological reclamation of open-pit mines in harsh arid and semi-arid regions.

# High-Throughput Detection Method for Microplastics Based on Fluorescence Spectroscopy and Machine Learning

**Cheng Gu**[1*]

[1] *State Key Laboratory of Water Pollution Control and Green Resource Recycling, School of Environment, Nanjing University, Nanjing 210023, P.R. China*

*chenggu@nju.edu.cn

**ABSTRACT**

The ecological risks posed by microplastics (MPs) are increasingly severe. MPs have been confirmed to be widely present in various complex environmental media, including marine and freshwater systems, sediments, soils and organisms[1]. However, significant knowledge gaps remain in the current scientific understanding of key scientific issues regarding the formation, migration, and transformation processes and mechanisms of MPs in actual environmental media. This is largely attributed to the lack of technologies for rapid and accurate identification and quantitative detection of low-concentration MPs in complex media[2]. Currently, there is still a lack of methods capable of achieving imaging alongside rapid, high-throughput qualitative and mass concentration detection[3]. To address this gap, this study developed a detection method based on the autofluorescence of microplastics.

In this study, a novel aging treatment method was applied to 7 common types of MPs in the environment, significantly altering their fluorescence properties. Based on the fluorescence spectrum data of these 7 MPs and machine learning algorithms, a high-throughput rapid detection technology framework for MPs was established. A dedicated fluorescence spectrum database was built by the 3921 sets of fluorescence spectrum data of the 7 MPs collected by confocal laser scanning microscope (CLSM), and a stacked model was further constructed. This model achieved an identification accuracy of 89% for the 7 MPs. To verify the method's applicability, mixed MP samples, commercial MP samples, and river water spiked samples were tested. The results showed that the recognition rates of all samples exceeded 80%, demonstrating the method's excellent environmental adaptability and target recognition performance. Furthermore, a three-dimensional (3D) model was constructed to analyze the 3D fluorescence images of MPs collected by CLSM for calculation of MP volume. Combined with the fluorescence qualitative results of microplastic types, particle density was determined to achieve quantitative analysis of microplastic mass. Moreover, the fluorescence method demonstrated 86% accuracy in lake water sample detection, validated by Fourier transform infrared microscope (μ-FTIR) results. Quantitative analysis achieved ng-level detection precision per particle. This validation confirms the method's applicability to actual environmental samples. Additionally, imaging times for qualitative and quantitative detection were 50 s and 20 s respectively within a single field of view (1 mm * 1 mm), significantly faster than traditional μ-FTIR detection speeds.

In summary, this research centers on the auto-fluorescence characteristics of aged MPs, integrating fluorescence spectral imaging and 3D fluorescence imaging technologies. It utilizes machine learning for qualitative identification and three-dimensional modeling for quantitative analysis, ultimately establishing a high-throughput rapid detection system for MPs. This technique provides a novel tool for the rapid screening and accurate quantification of MPs, and is expected to offer crucial support for research on MP migration mechanisms and the standardization process of pollution risk assessment.

## ABSTRACT

The global proliferation of microplastics has evolved from an environmental crisis into a profound challenge for human health. Characterizing these particles across complex matrices—from soil environments to biological tissues—requires a leap "Beyond Detection" toward holistic lifecycle analysis.

This report discusses an intelligent Raman framework designed to facilitate full-lifecycle investigations. Integrating automated identification with single-cell functional analysis—conceptualized as "Raman+"—this methodology provides high-fidelity characterization and multidimensional insights into particle identity and biological interaction. Such a framework spans the trajectory from environmental fate to biological endpoints, establishing an analytical foundation for systematic, closed-loop studies of the microplastic continuum while enhancing research fidelity and throughput.

**ABSTRACT**

Plastic debris has emerged as a significant hotspot for elemental biogeochemical transformations. In this presentation, we demonstrate that photo-weathering of plastics facilitates the formation of surface carbonyl groups, which mediate the reduction of silver ions to silver nanoparticles. Concurrently, oxidative weathering of plastics under light-independent conditions induces the production of methylmercury in environments. This methylation proceeds via an biotic reaction cascade comprising three-sequential steps: (1) release of plastic-derived dissolved organic matter (P-DOM), (2) complexation between P-DOM and Hg(II), an (3) intramolecular transfer of methyl groups. Model estimates demonstrate that polypropylene in the water column produce MeHg via this abiotic pathway at rates from 1.4×10−5% d−1 to 7.4×10−2% d−1 in China and 2.0×10−6% d−1 to 9.9×10−3% d−1 in other regions of the world. Plastic debris is therefore a significant, albeit hidden, driver of abiotic methylmercury formation in waters under darkness. Our study uncovers novel pathways through which the ongoing plastic pollution alters metal cycling, posing a burgeoning threat to planetary health.

# Precise tracking of nanoparticles in plant roots

**Xian-Zheng Yuan[1*], Xiao-Dong Sun[1], and Yue Wang[1]**

[1] *School of Environmental Science & Engineering, Shandong University, Qingdao, China*

*E-mail: xzyuan@sdu.edu.cn

**ABSTRACT**

Precise determination of nanoparticle fate in plants is a central challenge in sustainable agriculture. However, conventional method approaches often produce ambiguous results because of background interference, probe leakage, sample-preparation artifacts, and insufficient spatial resolution. Here, we establish a dual-step analytical strategy for precise tracking of nanoparticles in plant roots by integrating fluorescence imaging at the tissue level with electron microscopy at the cellular level. In this framework, vascular bundles and fluorescence co-localization are used as internal References for uptake visualization, while mass-thickness contrast and metal-doped particles provide direct ultrastructural evidence for nanoparticle localization and internalization.

Using this strategy, we systematically investigated the behaviors of both carbon-based nanoplastics and metal-based nanoparticles in representative plant systems. In *Arabidopsis thaliana*, nanoplastics with different surface charges exhibited distinct uptake patterns, tissue distributions, and phytotoxic effects, accompanied by inhibited root growth and enhanced reactive oxygen species accumulation. In duckweed, nanoplastics entered through both roots and fronds, again showing strong charge-dependent differences in uptake and physiological responses. Importantly, Pd-doped nanoplastics enabled direct verification of nanoplastic uptake in root tissues, providing a robust solution to the long-standing challenge of accurately identifying polymeric nanoparticles in planta.

We further reveal that magnetite nanoparticles can enter roots through an epidermis-based pathway that is not restricted to lateral-root emergence sites, extending the current understanding of exogenous particle entry into plants. In addition, nanoparticle coating chemistry strongly affects interactions with root exudates, thereby regulating particle behavior, root uptake, and biological outcomes. Small-molecule-coated magnetite nanoparticles effectively alleviated iron chlorosis in multiple plant species.

Overall, this work provides a reliable framework for tracking of nanoparticles in plants and demonstrates that surface chemistry is a key determinant of nanoparticle uptake, transport, and function. These findings offer new guidance for nanoplastic risk assessment and the rational design of plant-beneficial nanomaterials.

**ABSTRACT**

Microplastics (MPs) are ubiquitous in agricultural soils and can indirectly affect soil nitrogen (N) cycling by altering soil physicochemical properties and microbial communities. Previous studies have shown that MP exposure often leads to a decrease in soil nitrate-N ($NO_3^-$-N) content; however, the relative contributions of different transformation processes, such as denitrification, anaerobic ammonium oxidation (Anammox), dissimilatory nitrate reduction to ammonium (DNRA), and microbial assimilation, remain difficult to distinguish and quantify. To address this, this study selected non-biodegradable MPs (polyethylene, PE; polyvinyl chloride, PVC; polystyrene, PS), biodegradable MPs (polylactic acid, PLA; polyhydroxyalkanoates, PHA), and aged MPs as research objects. Controlled incubation experiments, employing $^{15}N$-tracing combined with membrane inlet mass spectrometry (MIMS) in paddy soils and the robotized continuous-flow incubation system (RoFlow) in upland soils, were performed to investigate the effects and mechanisms of MPs on $NO_3^-$-N transformation in agricultural soils. The results showed that in paddy soils, short-term exposure to MPs (PE, PVC, and PS) significantly stimulated denitrification and Anammox rates but inhibited the DNRA process, leading to increased N loss. In contrast, long-term exposure to aged PE-MPs suppressed denitrification. Further mechanistic analysis revealed that with prolonged exposure, aged MPs increased carbon (C) availability, while $NO_3^-$-N in paddy soils remained chronically limited; the resulting C and N supply imbalance constrained the activity of denitrifiers. In upland soils, MPs derived from PVC greenhouse films did not alter gaseous N emissions under aerobic conditions, but the abundance of denitrification functional genes increased significantly. Denitrification potential assays under anoxic conditions confirmed that such MPs promote nitrous oxide ($N_2O$) emission. This is attributed to the high content of plasticizers (phthalate esters, PAEs) contained in the MPs, which can be utilized as a C source by heterotrophic denitrifiers, providing electron donors. Another type of MPs, tire wear particles (TWPs), promoted complete denitrification in upland soils; however, their leachate inhibited $NO_3^-$-N transformation and $N_2O$ reduction, thereby increasing $N_2O$ emission. Analysis of dissolved organic matter (DOM) molecular composition revealed that labile DOM molecules favored complete denitrification. Moreover, the assimilation of $NO_3^-$-N under C source input induced by MPs should not be overlooked. For example, biodegradable MPs (e.g., PHA) primarily drive microbial assimilation leading to a decrease in $NO_3^-$-N, rather than denitrification loss. This indicates that biodegradable MPs favor reactive N retention, but simultaneously stimulate soil C emissions and increase the proportion of labile DOM, with fungi playing a dominant role in this process. In summary, this study systematically reveals the differential mechanisms by which various types of MPs regulate $NO_3^-$-N transformation in agricultural soils, offering insights into C and N availability, DOM molecular characteristics, and microbial communities, and providing a scientific basis for assessing the ecological risks of MPs in agricultural soils.

**ABSTRACT**

Microplastics, as a new type of pollutant, are widely present in aquatic environments, soil, air, and other ecosystems. Rainfall is the most direct and efficient means of forming surface runoff and is considered a significant driver of atmospheric microplastic deposition. However, it is important to note that ground-based microplastics remain the primary source of microplastics in runoff. Soil is a highly complex multiphase system. Its structure, composition, and intricate micro-ecological environment determine that the migration behavior of microplastics within soil is extremely complex and highly uncertain. Microplastics entering soil via rainfall runoff may cause accumulation, thereby weakening soil water retention capacity, altering physicochemical properties, disrupting biodiversity, and inhibiting plant and animal growth. Soil microplastic accumulation forms the material basis for pollution, while its ongoing migration process is a critical factor affecting soil ecological quality. This study employs artificial rainfall simulation experiments to investigate microplastic migration in soils of varying textures. It analyzes migration mechanisms for microplastics of different particle sizes under varying rainfall intensities, reveals the impact and patterns of rainfall runoff on soil microplastic migration, and assesses how rainfall intensity, soil texture, and microplastic particle size influence migration behavior. Rainfall intensity significantly influenced runoff generation and microplastic loss in soils of different textures, with smaller-sized microplastics exhibiting greater sensitivity to rainfall intensity changes. In sandy loam, loam, and clay loam soils, runoff generation increased rapidly during the initial rainfall phase before stabilizing. Across all soil textures, microplastic loss decreased with increasing rainfall duration, and higher rainfall intensity resulted in greater microplastic loss within the same timeframe. Initial runoff generation increased rapidly in all soil textures during the early rainfall phase before stabilizing. Microplastic loss decreased with longer rainfall duration, with higher intensity yielding greater loss. Sandy loam exhibited the highest loss, followed by loam, and lowest in clay loam, reflecting differences in soil particle composition and pore structure. Increased rainfall intensity promoted vertical migration of microplastics, with smaller particle microplastics exhibiting more pronounced migration. Sandy loam showed the highest migration rate, while clay loam had the lowest. Rainfall intensity, migration depth, and runoff volume significantly influenced loss rates, with their interactions collectively affecting microplastic migration behavior.

**ABSTRACT**

The Danjiangkou Reservoir, the second largest reservoir in China, serves as the water source for the Middle Route of the South-to-North Water Diversion Project. As a new type of pollutant, the MPs in the Danjiangkou Reservoir may pose significant risks to the drinking water safety of millions of people. Particular attention should be paid to soil MPs in the water-level fluctuation zone (WLFZ) of Danjiangkou Reservoir, as this ecotone intercepts upstream pollutants and regulates substance transport. The seasonal water level fluctuations could transform this zone into a significant source or sink for reservoir MPs. However, the distribution and migration of MPs in this ecologically critical zone remain poorly characterized.

To address this knowledge gap, this study selected the WLFZ (150-170 m) of Danjiangkou Reservoir and conducted large-scale sampling of soil and shoreline water samples before the rainy season. The aim was to investigate the distribution and characteristics of MPs in the WLFZ and to identify the key influencing factors. The results showed that the abundance of soil MPs in the WLFZ ranged from 144 to 1050 items/kg. The MPs abundance in the Dan Reservoir was higher than that in the Han Reservoir. Specifically, the mainstream exhibited higher MPs abundance than the tributaries in the Dan Reservoir, whereas the tributaries in the Han Reservoir were larger than the mainstream. The abundance of soil MPs in bare land and farmland was significantly higher than in grassland and woodland. The MPs are predominantly the size of 0.1-1 mm, the shape of fibers and pellets, the color of transparent and blue, and the polymer types are mainly polypropylene (PP) and polyethylene (PE). Among all influencing factors, human activities (distance from village and population density) and land use were identified as determinants of MPs abundance. The hydrological environment of the reservoir, including water level fluctuations, reservoir bays and banks, and mainstreams and tributaries, influenced the redistribution of MPs. Therefore, we emphasize the importance of controlling human activities and agricultural farming to prevent and control MP pollution. This study systematically reveals the distribution of MPs pollution in the WLFZ and provides a key scientific basis for the prevention and control of MPs pollution.

**ABSTRACT**

The ubiquitous distribution of microplastics (MP) has emerged as a global environmental concern, amplified by their migration into soil through various pathways, including water flow and bioturbation. As the most abundant animals on Earth, soil nematodes are vital to soil ecosystem functioning and may also influence the spreading of the smallest MP in soil, which remains underexplored. Here, we examined transportation of small MP (≤10μm) by several bacterivores nematode species, and examined the underlying mechanisms using Petri dish experiments. All tested nematodes significantly enhanced the spreading of MP from the center of the dishes, with smaller MP (1 and 2 μm) transported further than larger ones (5 and 10 μm). Over 21 days of cultivation, Caenorhabditis remanei showed the highest transport capacity, moving 10 ng of MP at a mean distance of 3.56 cm for 1 μm MP, 3.73 cm for 2 μm MP, 1.03 cm for 5 μm MP, and 0.45 cm for 10 μm MP. Behavioural observations revealed that all nematodes ingested and defecated 2 μm MP and transported 1-10 μm MP through surface adhesion to, and detachment from the cuticle. Cuticle adhesion emerged as the primary mechanism for nematode mediated MP transport. The relationship between nematode traits and the transportation of 2 μm MP was further examined across nine nematode species. Correlation analysis indicated that the nematodes' ability to transport MP was significantly associated with their mobility ($r = 0.881$, $p = 0.002$) and minimum body length ($r = 0.760$, $p = 0.018$). This study provides the first evidence that nematodes may play a crucial part in the redistribution of small MP. Similar transport mechanisms of MP are likely to occur also in (especially light textured) soils, and nematode mediated MP transport in soil is currently ongoing, and will also be presented.

**ABSTRACT**

Microplastic research on soils over the past decade has drawn a clear picture: The complexity of soils combined with the complexity of microplastics results in an immense variety of different impacts on terrestrial properties and organisms. Microplastics with their diverse shapes, polymer types and sizes can react with the dynamic biotic and abiotic systems of soils in countless ways. While numerous negative effects have been reported, such as reduced plant growth (Li et al., 2023) and enzymatic activity (Zhao et al., 2021), microplastics appear to also have positive effects on the soil environment. For instance, they may improve soil aeration (Rillig et al., 2021), contribute carbon to the soil matrix (Qiu et al., 2022) and even reduce greenhouse gas emissions (Ren et al., 2020). These findings could imply that microplastics may be beneficial to terrestrial ecosystems rather than only detrimental. But is it that simple?

Our paper offers a discussion on the severity and immediacy of microplastics and whether they could be a solution to certain soil and environmental issues by considering the negative and positive effects of microplastics and drawing comparisons to other contaminants and adjacent areas, from which lessons could potentially be learned.

**ABSTRACT**

Microplastics (MPs) are increasingly recognized as emerging contaminants in terrestrial ecosystems, yet their effects on soil health and plant performance remain poorly understood. Terrestrial environments, particularly agricultural soils, are considered major sinks for MPs due to their persistence and accumulation. These particles can affect soil structure, microbial activity, and plant development, but the underlying mechanisms are still largely unexplored.

In agricultural systems, MPs can enter soils through various management practices such as irrigation with reclaimed water, application of sewage sludge and compost as fertilizers, the use of plastic films for mulching, or atmospheric deposition. Once incorporated, they may alter soil physical and biological properties, potentially compromising soil fertility and productivity.

To better understand these processes in Mediterranean agroecosystems, this study aims to assess microplastic contamination in agricultural soils of Catalonia (NE Spain) and to investigate relationships between MP's abundance and composition, soil physicochemical properties, fertilization regimes, and management intensity. Soil samples were collected from fields with different crops, soil types, and management practices. MPs were extracted through density separation and organic matter removal, and polymers were identified using Laser Direct Infrared (LDIR) spectroscopy. Soil parameters including pH, organic carbon, organic matter, nutrients, and texture were also analyzed.

Findings from this first phase will inform the design of controlled greenhouse experiments, where soils will be spiked with environmentally relevant concentrations of MPs to study their effects on soil health, microbial communities, and plant growth. Preliminary results will be presented, contributing to the development of standardized assessment methods and sustainable management strategies to mitigate plastic pollution in agroecosystems.

# Comparative Degradation and Environmental Impacts of Biodegradable Mulch Films in Agricultural Soils of the United States and China: Toward Sustainable Plastic Management

**Xueyu Zhou[1*], Markus Flury[1]**

[1] *Department of Crop & Soil Sciences, Puyallup Research & Extension Center, Washington State University, Puyallup, WA 98371, USA*

*xueyu.zhou@wsu.edu

**ABSTRACT**

As an alternative to conventional polyethylene (PE) mulches, the rapid adoption of biodegradable plastics, such as polybutylene co-adipate co-terephthalate (PBAT), helps to prevent long-term soil contamination. However, the degradation performance and environmental consequences of these materials remain uncertain across diverse soils. This study incorporates cross-continental data from representative agricultural regions in China and the United States to examine the degradation dynamics, remaining micro- and nanoplastic formation, as well as effects of soil health and sustainability. Field experiments with consistent mulching and sampling methodologies were conducted in different regions in China and the U.S. Results showed that PBAT-based mulches may transiently increase micro- and nanoplastics concentrations in soils before reaching complete mineralization. Despite site-certain temperature and moisture regimes having a significant impact on breakdown rates, PBAT degradation substantially increased soil organic carbon and microbial biomass. Comparative analysis revealed regional disparities in policy and recycling frameworks: while U.S. efforts concentrate on field-based biodegradable product trials and certification, China's recent agricultural film recycling mandates have reduced PE residue accumulation. This study also emphasizes the need for integral surveillance of micro- and nanoplastics to encourage circular and environmentally sound plastic utilization.

# From snowpack to soil: microplastic pathways in alpine ecosystems

**Benech A.[1*], Pintaldi E.[1], Colombo N.[1], Rivoira L.[2], Padoan E.[1], Freppaz M.[1]**

[1]*University of Turin, Department of Agricultural, Forest and Food Sciences, Grugliasco, Italy*

[2]*University of Turin, Department of Chemistry, Torino, Italy*

* andrea.benech@unito.it

**ABSTRACT**

Microplastics (MPs) are increasingly recognized as emerging pollutants even in high-elevation ecosystems, where they can be transported over long distances and accumulate within snowpack, soil, and aquatic systems. In this study, the occurrence and distribution of MPs in winter snowpack, alpine soils, and pond sediments was investigated in the LTER site Istituto Mosso (2650-2900 m a.s.l., NW Italian Alps), located inside a large ski area, aiming to assess deposition pathways and environmental sinks in high-elevation areas.

Surface snowpack was sampled during 2020-2021 and 2021-2022 winters, revealing comparable concentrations of ~200 MPs $L^{-1}$ of melted snow in both winter seasons. This similarity suggests that winter tourism, which was absent in the first winter season due to COVID-19 restrictions, did not substantially contribute to MP levels, highlighting atmospheric transport as the dominant source. In both years, MPs were mostly fibers composed of LDPE, consistent with long-range atmospheric transport due to their low density and airborne persistence. To investigate the fate of these MPs, soils, at three depths (0-5, 5-10, 10-20 cm), and sediments from two nearby ponds were sampled in summer 2024. A total of eight soil profiles were sampled, distributed across two typical alpine tundra vegetation communities: snowbed communities (SB) and *Carex curvula* grasslands (CC). SB sites are characterized by longer snow cover duration and deeper snowpacks than CC, potentially influencing MPs accumulation and retention. MPs were found in all soils, with higher concentrations in SB than in CC. The highest concentrations occurred in surface soil layers (6,200 and 4,000 MPs $kg^{-1}$ in SB and CC, respectively) and decreased markedly with depth, becoming negligible in the deepest layer. This vertical pattern indicates limited downward transport and preferential accumulation in the topsoil. MPs were also detected in pond sediments at both sites (~3,500-5,900 MPs $kg^{-1}$). LDPE fibers predominate across all soil and pond sediment samples.

Overall, these findings demonstrate that MPs reach remote, high-elevation environments mainly via atmospheric deposition, accumulate in seasonal snowpacks, and subsequently persist in the topsoil and ponds sediments. Their presence in both terrestrial and aquatic compartments suggests that alpine environments act as sinks for MPs, with potential implications for ecosystem functioning even in regions perceived as pristine.

# Mineralization determines microplastic effects on soil organic carbon

**Jie Wang**[1*]

[1] *Beijing Key Laboratory of Farmland Soil Pollution Prevention and Remediation, College of Resources and Environmental Sciences, China Agricultural University, Beijing 100193, China*

*E-mail: jiewangcau@cau.edu.cn

**ABSTRACT**

Replacing conventional plastics with biodegradable polymers may mitigate microplastic pollution, but the degradation of these carbon-based materials can alter the decomposition of native soil organic mater (SOM) through priming effects. The net impact of this interaction on soil carbon balance remains poorly constrained. Here, we used a stable isotope tracing approach, incubating C4 (maize)-based polylactic acid (PLA) microplastics in three C3-soils with varying COM content and microbial properties. We show that the PLA mineralization rate is the master variable that dictates the soil carbon priming and formations. In soils with low-to-middle SOM (~ 1.9 – 4.6%), high PLA mineralization rates (500-860% higher compared to the other soil) were coupled with a strong negative priming effect and efficient formation of new, stable mineral-associated carbon. In contrast, low PLA mineralization in the high-SOM soil (~ 5.8%) triggered a significant positive priming effect that overwhelmed new carbon formation, resulting a net loss of bulk soil carbon. We further found this mineralization-priming relationship in controlled by the native soil microbial functional capacity. Our findings reveal that the pre-existing soil properties determine whether biodegradable plastics will ultimately induce net carbon sequestration or net carbon loss. The mechanism that the soil carbon dynamics is depended on PLA mineralization mechanisms should be considered in further plastic biodegradation under changing soil environments.

## ABSTRACT

Considering that plastic mulch film is the most prevalent plastic used in agricultural soils, and that only in China approximately 10% of the total sown area is covered by plastic mulch (Hao, 2025), it is not surprising that the highest proportion of the mass of microplastics in crop soils comes from the use of conventional PE or PP mulch films, or the polymeric mixture of PP+PE (Zhu et al., 2022). Plastic residues from conventional mulch films in China commonly reach 60–300 kg/ha, and levels rise when films aren't properly removed or recycled (Xue et al., 2021).The removal of plastic mulch films from the crop is a time and energy consuming and adds a significant cost, as plastic can become entangled with crop roots, making complete removal harder, but also it may tear and break during removal or release micro- and nanoplastics during use, thus unintentionally leaving residues even when properly disposed of. Therefore, to combat the pollution left by conventional plastic films in soil, biodegradable plastic alternatives were proposed as an alternative to tackle plastic residue problems in croplands, with PBAT being the most commercialized biodegradable plastic film in China. Since these plastics are engineered to biodegrade, they are typically not removed after each harvest; instead, they are intended to be incorporated into the soil through tillage after use, facilitating for farmers the burden of the removal.

Although biodegradable plastics were expected to alleviate in part the white pollution provoked by mulch film use, a new environmental issue raised: during degradation, similar to conventional plastics, some of these biodegradable alternatives were demonstrated that can generate macro- and microplastics in even greater amounts than traditional plastics. However, these plastics residues are considered "short-term" microplastics as they continue further breakdowns and degrading. Yet while this happens, these biodegradable microplastics can also accumulate through successive cultivation cycles, break-down quickly by human handling that accelerates the fragmentation (Wang et al., 2021) during harvest and post-harvest, and incorporate into the soil and migrate by the action mainly of tillage mixing, and roots downward movement, but also can penetrate through soil cracks and pores spaces across soil layers (Wang et al., 2025) and by soil biota which also helps to break degrade further those plastics fragments (Huang et al., 2025), potentially causing adverse effects on soil health and crop growth.

Despite this, biodegradable microplastics can be considered a double-edged sword with a possible positive outcome: although certain types of biodegradable plastics may harm soil health, these residues are mainly composed of carbon that can be quickly used by microorganisms. As during degradation, the release of carbon and soluble compounds may induce a priming effect on soil carbon dynamics and, concomitantly, on nitrogen cycling. Consequently, the combined effects of their incorporation and biodegradation in the soil may provide an unexpected possible benefit to the soil micro-ecosystems; leading to a short-term increase in soil organic carbon and microbial carbon utilization.

The indirect effects of mulching on soil physicochemical properties arise from the plastic film direct contact with the soil and the subsequent accumulation of macro and microplastic residues within it. Mulch films can cause changes through the modification of the near-surface micro-climate by raising soil temperature, reducing water evaporation, and stabilizing moisture levels, which in turn alters nitrogen-cycling processes and changes the composition and activity of soil microbial communities (Sintim et al., 2019). Additionally, it affects the soil's microstructure by enhancing aggregate stability and modifying organic carbon forms (Yan et al., 2025), ultimately impacting directly soil carbon dynamics and indirectly soil nitrogen dynamics. Nonetheless, it is important to point out that changes in the soil of a field crop are the result of numerous processes, both abiotic and biotic, that take place over extended periods of time.

Authors such as Uzamurera et al., (2023) and Wang et al., (2024a) found that the incorporation of PBAT plastic residues into soil increases the content of a specific type of microplastics, biodegradable microplastics, which are less persistent than conventional ones but can nevertheless accumulate in significant amounts across the soil profile. Liu et al., (2025) found that those biodegradable microplastics when remaining in the field can indeed affect the SOC and its flux by providing a readily available source of labile carbon, which stimulates microbial activity and promotes short-term increases in soil organic carbon (SOC) levels, particularly in the form of particulate organic carbon (POC), and such microorganisms boost their activity that leads to a decrease in microbial biomass carbon and dissolved organic carbon and modifies mineral associated organic carbon and easily oxidable organic carbon, but negatively affecting soil enzymes associated to C and N. Suggesting that PBAT alters the form and flow of carbon rather than uniformly enhancing it. Those authors also indicated that plastic polymer type plays an important role in changing soil carbon-related indicators, with the change usually positively associated with biodegradable plastic microplastics. Similar results were found in Wang et al., (2024b) in which from analyses of long-term usage of biodegradable plastic the authors found that biodegradable plastics effectively increased soil organic carbon but decreased dissolved organic carbon and microbial biomass carbon when compared to PE conventional plastic mulch films.

However, evidence remains inconclusive. A laboratory study by Zhou et al., (2024) found that contrarily to the results seen on field experiments, introducing biodegradable microplastics into soil significantly increased dissolved organic carbon and microbial biomass carbon while significantly decreasing available nitrogen, nitrification rates, and β-glucosidase activity, and it had an insignificant effect on soil bacterial community structure, but it increased the relative abundance of some bacteria types. Sintim et al., (2020) also reported only minor effects of biodegradable plastics on soil microbial communities and functions, emphasizing instead that local climate, soil properties, and spatiotemporal variation are possibly the dominant drivers of carbon dynamics and physicochemical changes relative to the incorporation of biodegradable plastic mulches. With different crops in different places reporting different responses to biodegradable plastics.

In summary, without excluding the many field-scale drivers (crop growth stage, soil type, climate, and soil biota, including microbial and fungal communities), the application and subsequent tillage of biodegradable PBAT mulch films can induce dynamic and measurable shifts in soil carbon and nitrogen cycling. However, while PBAT mulch film microplastics residues may enhance short-term microbial processes and carbon inputs, it can also simultaneously promote the depletion of other forms of labile carbon and possibly limit nitrogen availability through microbial competition.

This presentation combines a field investigation that examined soils that used biodegradable PBAT for two consecutive years and were incorporated into the soil via tillage after maize harvest and compared with replicated treatments that used conventional PE mulch and no mulch as a control. And laboratory experiments that were conducted to assess how the only presence of microplastics derived from biodegradable PBAT mulch film or from PE mulch film in the soil affects soil organic carbon and labile carbon pools determinations. In field soils, we measured key carbon and nitrogen parameters, microorganisms activities (bacterial and fungal), and profiled soil and plastic metabolites at the time of sampling. Furthermore, in this work, we synthesize and critically discuss the existing literature to reconcile findings and clarify mechanisms through which biodegradable mulch incorporation may (i) increase soil organic carbon content, (ii) exert variable effects on labile carbon fractions, and (iii) impose detrimental effects on soil nitrogen pools and on soil enzymes associated with carbon and nitrogen cycling.

**ABSTRACT**

Plastic mulch film can increase temperature, keep soil moisture and increase crop yield, widely used in agricultural production. However, due to the low recovery rate of mulch film recycling, the residual mulch film in the soil is easily fragmented or degraded into microplastics under light exposure, mechanical shear force and biological actions. Thus, plastic mulch film has become one of the essential sources of microplastics in soil. Polyadipate/butylene terephthalate (PBAT) is a biodegradable plastic polymer with ideal ductility, heat resistance, tear resistance and biodegradability. PBAT is one of the most active and best biodegradable materials in the research of biodegradable plastics, which has been widely applied to make biodegradable mulch films in recent years. However, studies have shown that PBAT only exhibits a good degradation effect under specific conditions, and the limited existing PBAT degrading strains are difficult to degrade PBAT mulching film effectively under mild environmental conditions. In this study, a few PBAT degrading bacterial strains were screened and isolated from the agricultural soil in Shandong province, which has a long history of plastic mulching film utilization. With a comprehensive analysis of the indicators, such as OD value of the bacterial cultures, the morphologic changes and weight loss rate of PBAT films, an efficient PBAT degrading bacterial strain was successfully isolated. The morphological, physiological and molecular identification of the strain were also carried out. Finally, the dynamic degradation of PBAT by the isolated strain was characterized, including the changes of molecular weight, roughness, chemical functional groups, hydrophobicity, surface morphology and biofilm composition characteristics of PBAT microplastics. The results of this study will provide a new bioresource for the biodegradation of PBAT plastics, and will provide a scientific basis for revealing the degradation mechanism of biodegradable plastic mulching films.

## ABSTRACT

Micro-nanoplastics (MNPs) are widespread emerging environmental and food contaminants. The ability of MNPs to influence the fate and effects of other environmental pollutants (EPs) in terrestrial environments and in edible plants is a topic of great concern. Investigations were conducted to evaluate if co-exposure to MNPs (polystyrene, PS; 20 or 1000 nm; or polyvinyl chloride, PVC, <10 µm, unaged or aged) had an impact on the accumulation of other EPs (arsenic, lead, chromium, boscalid, PFOS) in lettuce or wheat. Under hydroponic conditions, lettuce was co-exposed to PS at 10 or 50 mg/L, and to 1 mg/L of each EP. In a soil study with lettuce, the PS and EPs were at 50 and 10 mg/kg, respectively. Phytotoxicity was enhanced by PS under both growth conditions, particularly nanoscale PS (nPS), although impacts were less in soil-grown plants. Nanoscale PS had a greater impact than microscale PS (µPS) on As fate; the As translocation factor from roots to shoots was increased 3-fold in plants co-exposed to nPS (50 mg/L). PS dose and size had a variable impact on boscalid uptake and translocation. Fluorescent microscopy analysis of lettuce co-exposed to MNPs and EPs suggests that nPS enters the roots and translocates to the leaves, while µPS remains mostly in the roots. Pyrolysis-GC/MS showed that in soil, EPs significantly increased the translocation of nPS in lettuce shoots from 4.43±0.53 to 46.6±9.7 mg/kg, while the concentration of µPS in the shoots was unchanged with EPs. Separately, co-exposure to unaged PVC increased the root and shoot accumulation of As, Cr, and Pb by 3.1-, 2.1-, and 1.5-fold, respectively; for aged PVC, the toxic element increases were 3.9-, 2.6-, and 2.1-fold, respectively. Soil-based experiments with wheat under similar co-exposure conditions are ongoing, as are molecular analyses to elucidate key mechanisms of action. These findings demonstrate that co-exposure of MNPs with other EPs can significantly impact co-contaminant accumulation and toxicity, presenting an unknown risk to humans and other receptors.

# Impacts and degradation of microplastics (MPs) in agricultural soil

**Xiao-San Luo*, Zhihuai Chen, Tingting Zhang, and Yuhan Yin**

*Department of Agricultural Resources and Environment, Nanjing University of Information Science & Technology, Nanjing, China*

*E-mail Address: xsluo@nuist.edu.cn

**ABSTRACT**

As a typical type of emerging contaminants, microplastics (MPs) accumulated in soil not only affect the health of the soil-plant system, but also influence the biogeochemical processes and environmental effects of important biogenic elements such as nitrogen (N). However, relevant information about the effects of different types and properties of MPs on soil N migration/transformation and plant N uptake/metabolism is still limited. Therefore, we chose vegetable soils and lettuce (Lactuca sativa L.) as objects, and combined fields, pots and soil culture experiments to investigate the effects of different MPs on N migration and transformation processes in the soil-vegetable system. The impacts of different degradability of MPs (degradable: polylactic acid, PLA, and polybutylene adipate terephthalate, PBAT; undegradable: polyethylene, PE), doses and particle sizes on soil N transformation and lettuce N metabolism were investigated. It helps to reveal the impact mechanisms of typical MPs pollution on soil N-related biogeochemical cycles and to provide a scientific basis for agri-environmental risk assessment.

Furthermore, understanding MPs degradation in soil is also crucial for assessing its environmental impacts and pollution remediation. However, the ageing or degradation mechanisms of MPs mediated by soil iron oxides remain poorly understood. We investigated the degradation of polyethylene microplastics (PE-MPs) in agricultural soil amended with goethite (α-FeOOH) gradiently through quantitative incubation experiments. The results demonstrate that an appropriate dosage of goethite can significantly promote the degradation of PE-MPs in soil, ant the changes in goethite addition influence PE-MPs degradation indirectly by altering the transformation dynamics of iron oxides within the soil, rather than affect directly. Such study provides insights into the effects of goethite on MPs degradation in soil, implying possibility and potential of soil MPs pollution remediation by iron oxides.

## ABSTRACT

Soil microplastics (MPs) pollution, including tire wear particles (TWPs), has become a global environmental problem, which potential risks to soil ecosystems and human health are of increasing concern. However, because the heterogeneity and complexity of MPs distributed in the environment, conventional risk-assessment methods have difficulty accurately quantifying their ecological risks. In this study, based on a soil MPs three-dimensional characteristic abundance dataset, we constructed a three-dimensional probability density distribution model of MPs density, size and shape in soil using normal-inverse Gaussian (NIG), exponential and bimodal distribution models; by accurately converting between number concentration and mass concentration. Monte Carlo simulation together with the three-dimensional probability density distribution model were used to calculate the three-dimensional characteristics of MPs in soil. This study established a soil MPs three-dimensional characteristic-toxic effect dataset; based on the characteristics of soil MPs pollution, we adjusted threshold effect concentrations for the ingestible particle-size ranges of polydisperse MPs, optimized species sensitivity distribution (SSD) curves, and identified the earthworm *Eisenia fetida* as a sensitive soil organism. We further conducted a multi-level meta-analysis (experimental data n = 288) combined with an XGBoost model to quantify the effects of tire wear particles (TWPs) on soil microbial diversity, plant growth, animal growth, and greenhouse gas emissions, and to predict global-scale regional patterns covering 60 major countries across continents. Results show that microbial diversity decreased by approximately 8.27%; plant growth decreased by approximately 15.92%; soil animal growth decreased by approximately 18.29%; and overall greenhouse gas emissions increased by approximately 57.02%. High concentration, specific particle size, additives (6PPD and benzothiazoles (BTHs)), and heavy metals (Zn) are significant modifying factors; soil physicochemical properties and concentration are the main covariates. Model projections indicate significant heterogeneity in impacts across latitude, developmental level and climatic conditions; a 1.5 °C warming scenario and future vehicle-growth scenarios exacerbate risks in certain regions. The study indicates that TWPs exhibit cross-trophic amplification effects and pose potential threats to soil function and climate regulation, and that follow up mechanistic experiments as well as the establishment of monitoring and remediation standards are needed.

## ABSTRACT

Microplastic pollution is a global environmental concern in terrestrial ecosystems, yet less is known about microplastic effects on nitrogen-fixing bacterial communities and rhizobia nodulation, the interactions between bacterial communities, nodulation, and soil properties, and how these effects influence plant growth. To address this gap, we conducted a greenhouse experiment using red clover (Trifolium pratense L.) as a phytometer grown in soils amended with microplastic fibres (polyamide, polyester, and polypropylene; 0.4% w/w). At harvest, we assessed soil physicochemical properties, total and nitrogen-fixing bacterial communities, nodulation, root traits, and plant growth. Our results show that the effects of microplastics ranged from positive to negative on these parameters, as a function of polymer type. For example, polyamide and polypropylene impacted positively soil carbon (10.38% and 11.48%, respectively) but negatively specific root length (51.73% and 58.63%, respectively), whereas polyester negatively affected both soil aggregation (17.93%) and nodule number (71.11%). Relative importance analysis revealed that soil nitrogen, root and nodule mass, and the abundance of *Azospirillum* and *Pelobacter* were the strongest predictors of shoot growth. Microplastics further modified the direction and strength of correlations among root, soil, and microbial variables, for instance, most necessarily converting the weak association between shoot mass and *Azospirillum* abundance into a strong positive relationship. These findings reveal that microplastics restructure plant–soil–microbe interactions by altering nitrogen-fixing bacterial communities and nodulation, emphasizing the complex, context-dependent interactions within the plant–soil–microbe system and highlighting the importance of considering microplastic polymer-specific effects when assessing their ecological impact.

# Aging of plastic polymers used in agriculture affects sorption of pesticides and their subsequent release

**Maria De Nobili[1,*], Elisa Pellegrini[1], Ali Khakbaz[1] and Marco Contin[1]**

[1] *Department of Agricultural, Food, Environmental and Animal Sciences, Udine University, Udine, Italy*

**ABSTRACT**

In the last decades, modern agriculture has made massive use of plastic based materials that are only in part recovered and in large part dispersed at the soil surface. Exposure to sunlight, during use or after incorrect disposal, causes rapid loss of plasticizers, so that the materials become more brittle and prone to fragmentation, with the consequent production of micro-plastics and their dispersion in soil and water. Photochemical reactions fueled by UV radiation increase this environmentally harmful phenomenon by inducing the breaking of bonds and the incorporation of oxygen with the production of polar functional groups, which modify the surface characteristics of the material.

We hypothesized that these modifications may affect the behavior of micro-plastics towards contaminants and examined the absorption and desorption isotherms of three herbicides, namely Linuron, DNOC and Atrazine on two polymers that are among the most widely employed in agriculture: nylon 66 (PA6) and HDME. The polymers were subjected to artificial aging by exposing them to an UV-light source (254 nm) for ten days. Modification of the polymers'stucture was monitored by ATR FTIR spectrometry and revealed, in both cases, increased presence of oxygen bound C. In particular, HDME displayed an increase at 1720 $cm^{-1}$ (C=O in carbolxyls) and PA6 at 1050 $cm^{-1}$ (C-O stretching).

Sorption isotherms for the new and aged plastics were constructed by measuring UV absorption of 0.2 m filtered solutions at the wavelength of maximum absorbance of each pesticide after either 24h and 8 days of equilibration. The eventual pH changes of the solutions equilibrated with the new and aged plastics and that of the plastics equilibrated with the pesticides were recorded. The observed increase in polarity of aged plastics caused an increase of sorption for all the three pesticides on HDME, whereas on aged PA6, albeit Atrazine sorption increased, those of Linuron and particularly of DNOC were reduced. Desorption isotherms were also obtained for Atrazine and Linuron sorbed on PA6. The percent amount desorbed after 24h or 8 days from aged plastics was larger for both pesticides, but, after 24h desorption, the aged plastics still retained larger amounts (x/m) of pesticides than the corresponding non-aged materials. Linuron and Atrazine have similar log Kow values, namely 2.76 vs. 2.63, but displayed different desorption trends from the same type of polymer. This behaviour is likely to be caused by the lower solubility of Atrazine. This preliminary study shows that aging not only modifies the sorption capacity of pesticides by polymers, but may also affect their desorption. Plastic fragments can retain contaminants for a long time, they therefore can act as carriers to distant ecosystems such as the marine environment and their aging reduces, but does not block the release of sorbed pesticides. This behaviour strongly depends both on the polarity of the material and the solubility of the pesticide.

## ABSTRACT

The use of biodegradable mulch (BDM) instead of conventional plastic mulch film has the potential to reduce the accumulation of legacy plastic in agroecosystems. The fate of BDM polymer carbon (C) in soil, however, remains poorly understood, especially the fraction of polymer-C that enters microbial catabolic (mineralization) versus anabolic (immobilization) pathways. We present a novel approach that allows tracking of polymer-C into $CO_2$, macro- and micro-plastic residues, living microbial biomass, and soil organic matter (SOM) through the combination of $CO_2$ emission, $^{13}C$- and $^{14}C$- phospholipid fatty acid (PLFA) analysis, and plastic polymer analysis. After exposing a clear BDM pieces (2 cm × 2 cm) in an agricultural soil for up to one-year, we found that 22 ± 9% (mean and standard deviation) of the polymer-C remained as macroplastic residues (>1 mm), 19 ± 3% was present in microplastic particles (<1 mm), 22 ± 1% was emitted as $CO_2$, 0.9 ± 0.1% was present in living microbial biomass, and 37 ± 9% was present in microbial necromass or SOM. Similar values were observed for black BDM (21 ± 3%, 10 ± 2%, 21 ± 4%, 0.8 ± 0.0%, 47 ± 6%, respectively). Our findings indicate that, within one year of soil incubation, a fraction of the macroscopic BDM pieces fragmented into microplastics, but also a fraction of polymer-C was mineralized and emitted as $CO_2$ and another substantial fraction transferred into SOM. Our research advances knowledge on reducing reliance on polyethylene-based plastics and offers practical implications for improving agroecosystem sustainability.

***Keywords:*** Biodegradation; Carbon cycling; Microbial community; Natural abundance; PLFA.

***Synopsis:*** Our results demonstrate that 37 to 47% of polymer-C in BDM enters into SOM within one year of soil incubation, indicating that long-term use of BDM has short term benefit to improve soil carbon status.

**ABSTRACT**

Recent studies on microplastics (MPs) have mainly focused on aquatic environments and organisms, because the complex composition of soils makes it difficult to separate and analyze MPs in soil. Therefore, establishing soil-specific analytical methods is required and this study aimed to separate various types of microplastics (polypropylene; PP, high density polyethylene; HDPE, polystyrene; PS, polyethylene terephthalate; PET) from soils and to analyze using a pyrolyzer-gas chromatography/mass spectrometry (Pyr-GC/MS). Microplastics were separated based on density differences by sequentially applying 40% ethanol, deionized water, 5 M NaCl, and 7.5 M NaI solutions, and recovery of each MPs was evaluated by filtering and weighing MPs with stainless steel (SF) and glass fiber (GF) filters. The combined SF+GF filter showed the highest recovery (101.16%), followed by GF (97.61%) and SF (86.26%). The recoveries were 133.31% for PP, 70.62% for HDPE, 103.48% for PS, and 101.36% for PET. The co-detection of HDPE in PP fraction separated with 40% ethanol suggested that small HDPE particles, having similar density to PP, floated with the 40% ethanol solution. Consequently, a single-density separation using 7.5 M NaI followed by pyr-GC/MS quantification was established as an effective method for determining MPs in soils. Applying this method to agricultural soils revealed that the concentrations of MPs were found to range from 4.28 to 76.8 mg/kg. Furthermore, soil microplastic behavior was assessed through rainfall simulation after spiking soils with 0.05% of each polymer type (PP, HDPE, PS, and PET). Under simulated rainfall of 50 mm/h repeated three times, both leaching and runoff rates were approximately 0.3%. Among the MPs, PS showed the highest leaching rate, whereas the low-density PP exhibited the greatest runoff potential. These results indicate that approximately 99% of the added MPs remained in the soil, suggesting their long-term persistence and possibility posing potential ecological impacts on soil ecosystems and plants.

## ABSTRACT

Plastic-based materials have been wildly used for crop production and increasing amounts of plastic waste are deposed in farms. The waste disposal results in the plastics being decomposed and fragmented to form microplastics (MPs) in the field, which are less than 5 mm in size. And then the MPs accumulation in farmland soil would be at risk of food safety and environmental protection. However, it is difficult to precisely measure soil MPs for assessing the impacts of MPs pollution on crop production and human health. The bottlenecks of measuring soil MPs are still on recovering MPs from soil, identifying MPs material, and counting or weighing MPs. There is not a well standardized method to measure soil MPs and delineate MPs distribution in a farm. In the present study, the plastic materials of low-density polyethylene (LDPE) and polypropylene (PP) were used to conduct a recovery test with three farmland soils (i.e. Chaikongtso, Tapaisa, and Pinchen). MPs in the ranges of particle size (i.e. 4–1.7 mm, 1.7–0.149 mm, and 0.149–0.053 mm) were prepared, respectively. Then, 1 g MPs was drawn from every class and added into a pot with 47 g of air-dried soil, thoroughly mixed to prepare a 6% MPs-added soil sample, and further proceeded with three dry–wet cycles to mimic the soil under real field conditions. Next, the MPs-added soil samples were through three rounds of density separation in a 1 L settling cylinder and filtration through sieves of 10, 100, and 270 mesh to separately recover the three particle sizes of MPs. The filtered MPs were oven-dried and then weighed to calculate the recovery. In results, the MPs either LDPE or PP were extracted from the soil by using the floatation sieving method to achieve the average recovery of about 91%. The extractions of MPs in size of the fractions of 4–1.7 mm and 1.7–0.149 mm could be recovered almost 100%; however, in the small size fraction (i.e. 0.149–0.053 mm) the recoveries of MPs extraction were lower and about 60–70%. The settlements in the cylinder bottom were further examined under the optical microscope, and we found the fine particles of MPs aggregated with soil particles. This revealed that the MPs in size of lower 0.149 mm (i.e. to pass through 100 mesh) couldn't float up completely on the top fluid level of soil suspension in the cylinder. Thus, the small size fraction of MPs in soil would be underestimated by using the method to measure. Even though, the sedimentation-based extraction coupled with sieving provided stable recoveries of about 90% for MPs extraction from soil, and this has potential for a preliminary survey of MPs pollution in agricultural soils.

## ABSTRACT

Agricultural plastic mulch films are a major source of plastic pollution of croplands. In China, which uses about 68% of the plastic mulch film produced globally (ca. 1.4 million tonnes $y^{-1}$), soils have been heavily contaminated with mulch fragments. Here, we collected a national dataset of macroplastic residues (> 5 mm) in soil, including 3145 sampling sites, and provincial plastic film usage from 1992 to 2019 in China, and we established a linear model between the residue amount and historical cumulative usage within each province. Using the model, we quantified the amount of macroplastic residues in Chinese croplands on a national scale during the past 30 years and predict plastic pollution until 2050. Our results reveal the total national amount of plastic mulch residue in 2020 to be 2.07 million tonnes with a 95% CI of [1.67, 2.58]. This accumulated amount of plastic in Chinese soils roughly equals the annual amount of plastic films used globally (2.08 million tonnes in 2018), and is about 8% of national historically used plastic mulch film (27.3 million tonnes) remaining in soil as legacy plastic. Plastic concentrations in Chinese croplands in 2020 range from 7.7 kg $ha^{-1}$ in Anhui to 399 kg $ha^{-1}$ in Xinjiang, with an average value of 119 kg $ha^{-1}$ (equivalent to 0.03 g $kg^{-1}$ soil). We predict that the total amount and average concentration of plastic residues in Chinese croplands will reach 6.24 million tonnes and 357 kg $ha^{-1}$ (equivalent to 0.1 g $kg^{-1}$ soil) in 2050 under current plastic usage. There is an urgent need for regulatory actions to control plastic pollution in Chinese agriculture.

## ABSTRACT

Agricultural systems worldwide are increasingly threatened by emerging pollutants, particularly microplastics, which have now been identified as persistent and globally distributed contaminants in terrestrial ecosystems. Modern agriculture extensively relies on plastic-based materials—mulch films, drip irrigation lines, greenhouse covers, compost bags, and nursery trays—whose fragmentation over time results in the accumulation of microplastics (<5 mm) in soils. Among these, low-density polyethylene (LDPE), commonly used in both black and white forms, is the most prevalent due to its chemical stability and slow degradation rate. Microplastics disrupt soil structure, impair microbial diversity, alter nutrient cycling, reduce water retention, restrict root growth, and enhance the mobility of toxic heavy metals, thereby posing significant risks to soil health, crop productivity, and food safety.Given these concerns, the search for environmentally safe, biologically driven mitigation strategies has intensified. Beneficial microbial inoculants—particularly Trichoderma spp.—have emerged as promising solutions due to their ability to promote plant growth, solubilize nutrients, produce organic acids and enzymes, suppress soil-borne pathogens, and enhance plant tolerance to abiotic stress. Recent evidence suggests that Trichoderma may also influence the behavior of contaminants such as microplastics, potentially modifying their mobility, transformation, or stabilization in soil.With this global context, the present study was conducted during the Rabi season of 2024–25 at Banaras Hindu University, India, to evaluate the interactive effects of LDPE microplastics and Trichoderma spp. on soil health and lettuce performance. The objectives were to: (i) examine the effects of black and white LDPE microplastics (2.5% and 5% w/w) on soil physical, chemical, and biological properties; (ii) assess their impact on lettuce growth, biomass, physiology, nutrient uptake, and heavy metal accumulation; (iii) determine whether Trichoderma spp., alone or combined with vermicompost, mitigates the adverse impacts of microplastics; and (iv) evaluate the feasibility of microbial bioremediation as a sustainable approach to improving soil resilience and crop performance in plastic-contaminated environments.A controlled net-house experiment was conducted using sandy clay loam Inceptisol collected from the university research farm. Lettuce (Lactuca sativa L.), a shallow-rooted and pollution-sensitive leafy vegetable, served as the test crop. Nine treatment combinations were formulated, comprising control soil, two concentrations of LDPE microplastics (2.5% and 5% w/w in black and white forms), and their integration with Trichoderma spp. and vermicompost. Soil and plant parameters—including bulk density, porosity, water-holding capacity, organic carbon, available nutrients, dehydrogenase activity (DHA), physiological stress markers (malondialdehyde and proline), chlorophyll content, growth attributes, yield, tissue nutrient content, and heavy metal accumulation—were systematically assessed. ATR-FTIR spectroscopy was used to examine the potential translocation of microplastic particles into lettuce tissues.Microplastic addition significantly impaired soil physical structure. Bulk density increased to 1.13–1.14 Mg $m^{-3}$ under microplastic-only treatments, compared with 1.00–1.05 Mg $m^{-3}$ in Trichoderma-amended soils. Particle density declined to 2.01–2.09 Mg $m^{-3}$ due to the replacement of dense mineral particles by lightweight LDPE fragments. Correspondingly, soil porosity decreased to 45.5–46.2%, and water-holding capacity dropped to 43.7–45.7%, indicating disrupted soil aggregation, reduced aeration, and impaired root-zone moisture dynamics.Microplastics also decreased soil organic carbon (from 0.39% in control to 0.21% in 5% black LDPE and 0.20% in 5% white LDPE treatments), reduced available nitrogen and phosphorus, and suppressed micronutrient availability (Mn, Cu, Fe). Moreover, LDPE contamination enhanced the mobility of toxic heavy metals (Cr, Cd, Ni, Pb), increasing their environmental and food safety risks.Soil biological activity declined sharply: dehydrogenase activity dropped to 88.43 µg TPF $g^{-1}$ $hr^{-1}$ under 5% black LDPE, compared with 108.31 µg TPF $g^{-1}$ $hr^{-1}$ in the control, indicating impaired microbial metabolism. Lettuce grown under these conditions exhibited reduced plant height, leaf number, leaf area (52.2–70.4 $cm^2$), leaf area index (0.07–0.10), and chlorophyll content. Fresh biomass decreased to 118.3–140 g $pot^{-1}$ and dry biomass to 13.7–16.7 g $pot^{-1}$. Elevated levels of malondialdehyde (66.00 nM $g^{-1}$ FW) and proline (2.014 µmol $g^{-1}$ FW) under 5% black LDPE confirmed severe oxidative and osmotic stress. Heavy metal accumulation in lettuce foliage increased, particularly Cr and Pb under 2.5% white LDPE. ATR-FTIR analysis revealed no detectable polyethylene particles in aerial tissues, suggesting anatomical or physiological barriers to microplastic translocation or detection limitations at small particle sizes.Application of Trichoderma spp., particularly when combined with vermicompost, significantly counteracted the adverse effects of microplastics. Soil amended with Trichoderma showed reduced bulk density, improved porosity, enhanced water-holding capacity, and higher organic carbon content. Biological activity improved markedly, as reflected by increased DHA. Trichoderma also moderated heavy metal mobility, likely through biosorption, chelation, and microbial transformation mechanisms.

Lettuce plants treated with Trichoderma and vermicompost exhibited higher plant height, greater leaf expansion, enhanced chlorophyll content, improved root elongation and branching, reduced oxidative and osmotic stress, significantly better nutrient uptake, and superior fresh and dry biomass. These improvements led to substantially higher foliage yield and quality, demonstrating the strong bioameliorative potential of Trichoderma in microplastic-stressed soils.Overall, this study provides clear evidence that microplastic contamination severely disrupts soil health, nutrient dynamics, microbial functioning, and plant physiology. However, Trichoderma spp., particularly when integrated with vermicompost, offers an efficient, low-cost, and eco-friendly strategy to restore soil quality, enhance crop productivity, and reduce heavy metal accumulation in plants grown in microplastic-contaminated soils. The findings contribute to global efforts under the International Union of Soil Sciences (IUSS) toward sustainable soil management, pollution mitigation, and the protection of food quality and ecosystem health

## ABSTRACT

Microplastics (MPs), defined as polymer fragments smaller than 5 mm, are currently among the most widespread pollutants. This size range encompasses a highly diverse set of particles, from fragments that are almost visible to sub-micrometre particles. Such variation can complicate both extraction and analysis, given that the physical and chemical behaviour, environmental fate and ecological effects differ markedly within this range. Initially, research on microplastics focused primarily on aquatic environments; however, recent studies have shown that soils can also accumulate substantial amounts of MPs. Their extraction, characterisation, and quantification are challenging due to the heterogeneous nature of soil matrices, and no standardised methodologies are currently established.

This study investigates the presence and typology of microplastics in sandy soils from a coastal area in Molise region (Campomarino), in southern Italy, periodically affected by wildfires. Four sites were sampled: three located in fire-affected areas and one unaffected control site. Multiple extraction methods were employed to isolate MPs. Dry-sieving through 2 mm, 1 mm, and 0.8 mm meshes yielded three fractions, which were initially examined under a Nikon SMZ645 stereomicroscope and subsequently, with an attenuated total reflectance-Fourier transform infrared (FTIR-ATR) for qualitative analysis to identify the MPs samples. The FTIR spectra were compared with an internal standard polymer library. The fraction below 0.8 mm underwent density separation using sodium iodide (NaI), sodium chloride (NaCl), and zinc chloride ($ZnCl_2$), allowing the isolation of particles with lower density than the mineral fraction. Surface morphology was analysed using a SEM-EDS provided high-resolution imaging to observe degradation features, while elemental analysis (EDS) indicated the presence of surface contamination, both organic and mineral (Fig. 1). Approximately 212 particles were extracted from 10 kg of control soil. They were classified by shape as fibres, fragments, films, and spherical particles exhibiting significant surface degradation, rupture or fracture, which was likely caused by physical, chemical and biological degradation. Spectral analysis revealed that the main polymers present are high- and low-density polyethylene (HDPE and LDPE), polyethylene terephthalate (PET) and polypropylene (PP) (Fig. 1).

This study highlights that the identification and quantification of microplastics in complex matrices such as soil require complementary analytical methods. Moreover, the development of standardised protocols is essential to ensure comparability among studies and to achieve a clearer understanding of microplastic pollution.

**ABSTRACT**

Microplastics (MPs), a growing environmental concern, have attracted widespread attention due to their potential threats to soil health. While the environmental behaviors of conventional and biodegradable microplastics are relatively well studied, their specific impacts on the rhizosphere microbial community and the propagation of antibiotic resistance genes (ARGs) remain insufficiently understood. This study aims to systematically investigate the complex interactions among microplastics, microbes, and ARGs in the soil-plant system.

To accomplish this, a pot experiment with wheat was conducted, involving seven treatments: a control without MPs and groups amended with 0.02%, 0.2%, or 2% (w/w) of either non-biodegradable polystyrene MPs (PS-MPs) or biodegradable poly(butylene adipate-co-terephthalate) MPs (PBAT-MPs). After five months of greenhouse cultivation, the rhizosphere soil was collected for analysis.

Metagenomic sequencing was performed using the Illumina NovaSeq 6000 platform to reveal changes in soil microbial community structure and their association with ARGs. The study found that species diversity increased with higher concentrations of the same type of microplastic. Additionally, specific differences in microbial community composition were observed; for example, the relative abundance of Acidobacteriota decreased significantly in the PBAT 0.2% and 2% treatment groups. Furthermore, PCoA analysis showed varying degrees of separation between the experimental groups and the control group. To gain deeper ecological insights, microbial co-occurrence networks will be constructed. Through this network inference, ARGs will be linked to their potential microbial hosts. Additionally, path analysis will be employed to identify possible pathways through which microplastics may indirectly influence ARG dynamics by altering microbial community structure and soil properties.

This study aims to provide crucial scientific evidence to better understand the ecological effects of both conventional and biodegradable MPs. The findings will help assess the potential risk of MPs acting as vectors for the environmental spread of ARGs. They will offer a solid theoretical foundation and data support for a comprehensive risk assessment of plastic pollution in agricultural ecosystems.

## ABSTRACT

Microplastics (MPs) and nanoplastics (NPs) are considered emerging contaminants in terrestrial ecosystems, particularly in agricultural soils. Despite the global concern, their impact on soil properties and crop growth in tropical agroecosystems remains poorly understood. Polystyrene (PS) represents one of the widely used polymers and a major contaminant in soils worldwide. In this study, we investigated the effects of synthesized PS-MPs (5–10 µm) and PS-NPs (100–150 nm) on soil nutrients and lettuce growth. We synthesized PS-MPs and PS-NPs in the laboratory and confirmed their morphology and size by scanning electron microscopy (SEM) and Fourier-transform infrared spectroscopy (FTIR), ensuring chemical identity and surface integrity before use. These particles were incorporated into a tropical Typic Rhodustalf soil at concentrations ranging from typical agricultural contamination to industrial pollution scenarios (0.002–0.2% w/w) in a controlled greenhouse pot experiment with lettuce (*Lactuca sativa*) over 45 days. Soil and plant quality indicators include soil pH, electrical conductivity (EC), available phosphate, ammonium N, nitrate N, and fresh and dry biomass were monitored at harvest. Plant height, chlorophyll content, and leaf number were measured weekly. Factorial ANOVA revealed that PS-MPs and PS-NPs significantly altered soil nutrient dynamics at the highest concentrations, increasing ammonium, nitrate, and available phosphorus, with PS-MPs exerting stronger effects than PS-NPs. Conversely, they had no detectable impact on soil pH, EC, plant growth or biomass during the 45-day exposure period. These results demonstrate a temporal disconnect wherein soil nutrient cycling is disrupted before observable effects on plant development emerge, primarily at contamination levels representing industrial pollution rather than typical agricultural soils. Long-term studies are therefore needed to determine whether sustained exposure at field-relevant concentrations compromises soil fertility and crop productivity in tropical agricultural systems.

**ABSTRACT**

Biodegradable plastic mulches (BDMs) offer the agronomic advantages of polyethylene (PE) films while, in principle, reducing end-of-season plastic waste. Yet current test methods (e.g., ASTM D5988) quantify only relative $CO_2$ evolution, leaving unknown how much BDM-derived carbon enters non-respired soil pools, or which microbes truly drive degradation. Here, we quantify the fate of BDM-derived carbon in soil and identify its microbial degraders using separately labeled $^{14}C$- and $^{13}C$-labeled poly-L-lactic acid (PLA).

We synthesized $^{14}C$- and $^{13}C$-enriched PLA via azeotropic polycondensation and amended triplicate 100 g agricultural soil microcosms (0.1% w/w PLA), incubated at 25 °C for one year. Continuous NaOH trapping is capturing cumulative $^{14}CO_2$, and at day 365 we will destructively harvest microcosms to partition $^{14}C$ among microbial biomass, dissolved organic carbon, particulate organic matter, mineral-associated soil organic matter (MAOM), and residual polymer, yielding a closed $^{14}C$ mass balance. In parallel, a set of $^{13}C$-PLA microcosms was destructively sampled weekly for eight weeks to capture peak mineralization, and heavy DNA was separated via CsCl density gradients. 16S rRNA amplicon sequencing of heavy versus light DNA identified bacterial taxa actively assimilating PLA-derived carbon.

Preliminary $^{14}CO_2$ data indicate that approximately 5-10% of added PLA-C was respired within the first 60 days. $^{13}C$-qSIP results show enrichment of PLA-C in heavy DNA from *Actinobacteria*, *Proteobacteria*, and *Firmicutes* implicating a specific decomposer guild in both mineralization and stabilization of BDM-derived carbon. This study provides one of the first full soil carbon budgets for BDM-amended soil and explicitly links polymer fate to definite microbial degraders, advancing both sustainability assessment and the mechanistic understanding of polymer–microbe interactions in agricultural soils.

**ABSTRACT**

Microplastics (MPs) in soils have attracted increasing scientific attention, yet their implications for soil quality and the role of mulching duration are not fully understood. This study aimed to determine how MP accumulation in mulched agricultural soils affects soil physical, chemical, and biological quality across different mulching durations. Soil samples were collected from two depths (0–10 and 10–20 cm) at 15 agricultural sites in Adana, Türkiye, characterized by a hot-summer Mediterranean (Csa) climate, representing plastic mulching durations of approximately 5, 10, and 30 years. Microplastics were extracted using density separation and identified by ATR-FTIR spectroscopy. Soil quality was evaluated using the Soil Management Assessment Framework (SMAF), integrating physical, chemical, and biological indicators, including bulk density (BD), aggregate stability (AS), available water content (AWC), water-filled pore space (WFPS), soil pH, electrical conductivity (EC), available phosphorus (P), exchangeable potassium (K), soil organic carbon (SOC), microbial biomass carbon (MBC), and potentially mineralizable nitrogen (PMN). Clear differences in MP abundance and soil quality were observed among mulching durations. At the 0-10 cm depth, MP abundances were 69.3 ± 18.2, 64.0 ± 14.39, and 48.0 ± 9.53 particles $kg^{-1}$ for short-, medium-, and long-duration mulching, respectively, whereas at the 10-20 cm depth, MP abundances increased from 37.33 ± 6.18 and 48.0 ± 9.75 to 78.66 ± 27.76 particles $kg^{-1}$ under long-duration mulching. These patterns indicate progressive vertical redistribution of MPs with increasing mulching duration. Prolonged mulching was associated with a 10% increase in bulk density and substantial reductions in aggregate stability (48%), potentially mineralizable nitrogen (24%), and microbial biomass carbon (14%) at the soil surface. Soil physical quality declined most strongly with increasing MP accumulation, while chemical indicators showed moderate, depth-dependent responses. Integration of soil indicators revealed a consistent decline in overall soil quality, with the Soil Quality Index decreasing by approximately 9% under medium duration mulching and 17% under long-duration mulching. These findings demonstrate that continuous plastic mulching leads to cumulative MP redistribution within the soil profile and measurable degradation of soil physical structure, biological functioning, and integrated soil quality. As a field-based study conducted under real agricultural conditions, environmental and management variability should be considered when interpreting the results.

*luigipaolo.dacqui@cnr.it

**ABSTRACT**

Microplastics (MPs) in farmland soils amended with urban compost since 2005 were extracted using an elutriation device adapted from marine sediment protocols (1) for soil application.

MPs were recovered from both the entire soil and from the <2 mm fraction, then quantified (mass and counts) and characterized via FTIR-PAS. Results indicated MP concentrations and particle counts consistent with existing studies (2-7), with polystyrene, polyethylene, and polypropylene as the predominant polymers. Key methodological insights include the necessity of volume-based sampling (5), analyzing the total soil matrix rather than solely the <2 mm fraction (7), and pretreatment for breaking up soil aggregates through ultrasonication or dispersion to enhance elutriation efficiency (2, 4).

**ABSTRACT**

Wetlands, as critical transition zones between terrestrial and aquatic ecosystems, play a vital role in regulating the global carbon cycle and maintaining ecosystem services. Despite the increasing accumulation of microplastics (MPs) in wetland soils, their impacts on litter decomposition remain insufficiently understood. This study aims to systematically investigate the effects of MPs pollution on wetland litter decomposition characteristics and their driving factors.

To accomplish this, we focused on litter from dominant vegetation in the hydro-fluctuating zone in Shengjin Lake wetland. We conducted a 100-day indoor mesocosm pot experiment and a 6-month field in situ burial experiment was conducted. Ten treatments were established: a control without MPs and groups amended with 0.1%, 0.5%, or 2.5% (w/w) of polyethylene MPs (PEMPs), polyvinyl chloride MPs (PVCMPs), or polystyrene MPs (PSMPs).

The results indicated that: (1) Under laboratory conditions, MPs inhibited litter decomposition primarily by elevating the litter carbon-to-nitrogen (C:N) ratio and suppressing enzyme activities. High concentrations of PVCMPs significantly suppressed decomposition by reducing microbial diversity. In contrast, the addition of 2.5% PEMPs strongly inhibited decomposition at the early stage; however, decomposition gradually recovered at later stages, coinciding with fungal community succession toward *Mortierellomycota* and the upregulation of genes involved in chitin degradation. (2) Field experiments further demonstrated that MPs compromised soil structural stability. High concentrations of PVCMPs and PSMPs significantly reduced the contribution of soil fauna to litter decomposition to 11.49% and 16.71%, respectively, whereas soil fauna exhibited partial tolerance to low concentrations of PEMPs.

Overall, this study provides key scientific evidence regarding the processes and potential mechanisms by which MPs affect litter decomposition. The findings are of great significance for unraveling wetland carbon cycling processes, protecting wetland ecosystem services, and developing strategies for pollution control of MPs.

# Screening of microplastic-degrading bacteria and their effect on lettuce growth under pollution stress

**Qiming Lu[1*], Yueling Qi[1]**

[1] *Anhui Province Key Laboratory of Wetland Ecosystem Protection and Restoration, School of Resources and Environmental Engineering, Anhui University, Hefei 230601, China*

*E-mail Address of Presenting Author: 13966291661@163.com

**ABSTRACT**

Microplastics (MPs) have accumulated in farmland soils, posing a potential threat to crop safety and human health. Microbial degradation represents a highly promising remediation strategy; however, it currently faces challenges such as limited resources of functional strains and unclear mechanisms of their effects on crop growth. To address these gaps, this study aims to achieve two core objectives: (1) To screen for functional strains capable of efficiently degrading polyethylene microplastics (PEMPs) and polypropylene microplastics (PPMPs) from environmental samples. (2) To investigate the alleviating effects and underlying mechanisms of the PEMPs-degrading strains on lettuce growth under PEMPs-induced stress.

To enrich and screen functional strains, selective media with MPs as the sole carbon source were employed. Single colonies were isolated and purified via dilution plating and streak plating, followed by strain identification using 16S rDNA sequencing. Subsequently, the strains were inoculated into mineral salt media containing either PEMPs or PPMPs as the sole carbon source.Their microplastic-degrading capabilities were validated by determining the weight loss rates of MPs, along with observing morphological changes using scanning electron microscopy (SEM) and analyzing structural changes via Fourier transform infrared spectroscopy (FTIR). A strain, *Bacillus tropicus* SQF-1, was isolated from activated sludge. This strain achieved a PEMPs weight loss rate of up to 0.971% over a 35-day incubation period.

Furthermore, the strain *Bacillus tropicus* SQF-1 was introduced into lettuce cultivation systems supplemented with PEMPs at a concentration gradient of (0.1%, 1%, 10%). The results showed that PEMPs inhibited lettuce seed germination and seedling biomass accumulation; at high doses, they also impaired chlorophyll synthesis. However, inoculation with *Bacillus tropicus* SQF-1 effectively mitigated PEMPs-induced stress, promoted seedling growth, and significantly enhanced the richness and diversity of the rhizosphere microbial community.

The findings not only expand the resources of microplastic-degrading microbial strains, but also provide theoretical underpinnings and data support for the development of microbial remediation strategies to mitigate microplastic contamination in agricultural soils.

**ABSTRACT**

Plastics are widely used in agricultural production worldwide, and the release of plastic additives and debris has attracted increasing attention. Bio-based and/or biodegradable plastics (BPs) have been actively promoted in the market, however, their environmental fate in soil remains unclear, leaving doubts over their overall impacts to the global plastic pollution. Earthworms (EWs) can process significant amounts of soil and associated materials, the activities of which greatly impact soil fertility and structure. The encounters of microplastics (MPs) and EWs in soil are inevitable, if MPs, especially those derived from the uncontrolled disposal of BPs, are to enter and accumulate in soils. Therefore, the role of EWs in altering the properties and environmental behavior of MPs cannot be ignored.

Here, the fate of MPs during the soil-gut-cast transit mediated by EWs was explored. First, the fate of MPs during the ingestion and digestion processes of EWs was studied at mesocosm scale, where EWs were incubated for 49 days in soil spiked with 1% (w/w) MPs. Then, we studied the fate of MPs during the cast aging process after excretion at microcosm scale, where fresh casts (containing MPs) were left aging for 180 days. Low-density polyethylene (LDPE), polylactic acid (PLA), and polybutylene adipate terephthalate (PBAT) were used as model polymers, and *Lumbricus terrestris* was selected as the model species. The changes in the particle size distribution (PSD), concentration, and chemical composition of MPs were studied. The concentrations of PLA and PBAT MPs in the microcosm experiment were quantified by two methods: density separation with gravimetric analysis (DS) and Soxhlet extraction with q-NMR (SE).

Results showed that MPs could be fragmented and depolymerized by EWs, and that cast aging had a dual effect on MPs: immobilization and enhanced degradation. However, these effects were polymer type dependent. It was observed that all MPs were fragmented in EW gizzards in the mesocosm experiment but a secondary fragmentation during cast aging only occurred for PLA and PBAT. Evident depolymerization was found only for PLA in the gut (17.7% reduction in molar mass), but the concentrations did not change during gut passage, indicating that the short gut transit time only initiated a low level of depolymerization. The concentration, PSD, and chemical composition of LDPE MPs did not change during cast aging. The concentration of PBAT MPs in casts by DS decreased sharply with increasing aging, while the data by SE suggested no reduction. Such divergent trends indicated that cast aging caused immobilization of MPs, making MPs less available for the aqueous extraction. Interestingly, both methods confirmed that PLA concentration decreased significantly during cast aging (30–40% reduction) but not during soil incubation. In summary, our research indicates that EWs play an important role in regulating the fate of MPs in soil, and the underlying mechanisms require further investigation.

## ABSTRACT

The adoption of biodegradable plastics such as poly (butylene adipate-co-terephthalate) (PBAT) in agriculture is promoted as a sustainable alternative to conventional polyethylene (PE) mulch. However, concerns persist regarding their incomplete degradation into microplastics (MPs) and the subsequent effects on soil biogeochemical cycles and microbial ecosystems, posing a new “hidden pollution” from a presumed solution. This study systematically conducted a long-term (15-year PE + 8-year PBAT) field application to evaluate MP accumulation, polymer transformation, and their cascading impacts on soil carbon dynamics and microbial community structure.

Results showed that total MP abundance was higher in the PBAT plot (15-year PE + 8-year PBAT, 8507 ± 578 particles/kg) than that in a plot with 23 years of continuous PE use (6767 ± 336 particles/kg). The PBAT plot was enriched with finer MPs (<0.25 mm) and unique film-shaped fragments identified as polyester-terephthalate and polyester, tere-&iso-phthalate, which are intermediate degradation products of PBAT. Source apportionment indicated that ~57% of MPs originated from historical PE use, while ~33% derived from PBAT. While soil organic carbon (SOC) was higher in the PBAT plot (30 g C/kg) compared to the PE plot (27 g C/kg), the labile carbon pools directly associated with microbial vitality were significantly suppressed. Specifically, dissolved organic carbon and microbial biomass carbon measured only 74 mg C/kg and 246 mg C/kg in the PBAT plot, respectively, contrasting with 120 mg C/kg and 413 mg C/kg in the PE plot. Stable isotope ($\delta^{13}C$) analysis showed contrasting carbon flows: in PBAT soil, carbon shifted from micro-aggregates (<0.25 mm) to macro-aggregates (>0.25 mm), whereas in PE soil, carbon moved primarily between macro-aggregates, indicating altered carbon stabilization mechanisms.

Microbial community analysis revealed that both the PE plot and the PBAT plot significantly reduced bacterial Chao1 richness, Shannon diversity, and niche width compared to the no-mulch (NM) control. The PBAT plot exerted the strongest selective pressure, yielding the lowest diversity metrics. It consistently enriched fast-growing, copiotrophic bacterial taxa such as *Proteobacteria* (particularly *Alphaproteobacteria*) and *Bacteroidetes*, while depleting oligotrophic groups like *Acidobacteriota* and *Chloroflexi*. Despite reduced taxonomic diversity, co-occurrence network analysis demonstrated that the PBAT plot fostered a more connected and robust microbial network with higher average degree and lower modularity, indicating enhanced functional integration and cross-kingdom (bacterial-fungal) synergy, though with increased potential fragility due to reliance on keystone taxa.

This research provides a comprehensive, field-based investigation into the terrestrial fate and effects of MPs from biodegradable agricultural inputs. It contributes to understanding MP sources, transformation pathways, and their ecotoxicological effects on soil health by linking MP accumulation to suppressed microbial activity, altered carbon sequestration pathways, and reconfigured ecological networks. The findings highlight the limitations of equating "biodegradability" with environmental safety based solely on fragmentation or visual disappearance. A truly sustainable solution requires evaluating plastics across their full life cycle, assessing their complete mineralization pathways and their long-term impacts on soil ecosystem function and stability. This study directly supports the session's goal of fostering interdisciplinary exchange to assess and mitigate the environmental risks of MPs in terrestrial ecosystems.

**ABSTRACT**

This study investigates the ecological risk of microplastics (MPs) in peatland areas of Long An Province, located in Vietnam's Mekong Delta. Among the thirty sediment samples analyzed, polyvinyl chloride (60.7%), polyethylene (25.8%), and polypropylene (11.9%) were identified as the most abundant polymer types. The hazard index (HI) indicated a Level III contamination risk in Tan Thanh and Thanh Hoa districts. Both the pollution load index (PLI) and the potential ecological risk index (RI) revealed relatively high MP contamination across the studied sites. Based on PLI values, MP levels in the peatlands of Tan Thanh and Thanh Hoa were classified as high and moderate, respectively, while Duc Hue exhibited lower contamination. Overall ecological risk remained concerning, with PLI_overall at Level III, HI_overall at Level V, and RI_overall indicating extreme danger. Also, three machine learning models, Least Squares Support Vector Machines (LS-SVM), Random Forest (RF), and Long Short-Term Memory (LSTM) were trained and tested to predict composite MP quantities using physicochemical parameters and sediment characteristics as predictors. Model outputs showed that MP abundance and characteristics (e.g., color and shape) were strongly influenced by pH, total organic carbon (TOC), and salinity. All three predictive models demonstrated high accuracy on the testing dataset. These findings provide the first quantitative assessment of MP-related ecological risks in peatland ecosystems of the Mekong Delta and highlight the potential of using basic physicochemical variables to predict MP pollution in peatland sediments and other sensitive environments.

# Changes in the dispersivity of soil substrates after contamination with microplastic polystyrene

**S. Klushina[1*], A. Umarova[1], E. Ikkonen[2]**

[1] *Faculty of Soil Science, Lomonosov Moscow State University, Moscow, Russia*

[2] *Institute of Biology of the Karelian Research Centre of the Russian Academy of Sciences, Petrozavodsk, Russia*

*E-mail: Spieks70@gmail.com

**ABSTRACT**

The dispersivity of soil is a crucial characteristic that significantly determines all other soil properties and regimes. The widespread presence of microplastics (MP) in the environment poses a risk of significant alterations in the physicochemical properties of soil (Guo et al., 2024; Feng et al., 2012).

Polystyrene (PS), one of the most prevalent types of MPs found in agroecosystems, has the potential to impact the water-physical characteristics of soil (Shafea et al., 2023). These changes ultimately affect the structure of the soil and the availability of water for plants. Scientific literature suggests that PS MPs may reduce water permeability, modify pore distribution, and enhance water-repellant properties (Botyanská et al., 2022). The mechanisms of adsorption of MP in soil constituents include surface adsorption, electrostatic interactions, and hydrophobic interactions, which influence the distribution of contaminants and the mobility of elements within the soil profile. The aim of this study is to investigate the transformation of specific surface area and grain size distribution of soil substrates that have been contaminated with PS MPs.

(1) The particle size distribution was determined using laser diffraction analysis on a Malvern Mastersizer 3000E instrument with ultrasonic preparation, at an energy level of 450 J/mL and a processing time of 5 min 20 sec.

(2) Isotherms of water adsorption were obtained using the adsorption-equilibrium method, and (3) Nitrogen adsorption isotherms were measured using the low-temperature, static, volumetric technique on a 3P Sorptometer Vapor 100 automated sorption instrument (3P Instruments, Germany). The test soil comprised Terra Vita soil (NORD Pulp, Russia), mixed with sand at a volume ratio of 2:1. PS aqueous suspension, represented by particles with a diameter of 160 nm, were used to contaminate the soils with MPs. An alteration in the distribution of size fractions of the granulometric composition of the substrate was observed, indicating aggregation upon addition of a PS solution, which is supported by SEM analysis.

**Acknowledgments**

The study was carried out in the framework of a state assignment of the Ministry of Science and Higher Educa tion of the Russian Federation on the subject “Physical Basis of Ecological Functions of Soils: Technologies of Monitoring, Prediction, and Control

Nitrogen specific surface area was determined by means of the “Analytical complex for determination of texture characteristics of dispersed systems” (Vapor 100, 3P Instruments, Germany, 2021), purchased within the framework of the Development Programme of the Lomonosov Moscow State University.

SEM studies were carried out at the Shared Research Facility “Electron microscopy in life sciences” at Moscow State University (Unique Equipment “Three-dimensional electron microscopy and spectroscopy”).

**ABSTRACT**

Research on microplastics has focused heavily on aquatic environments, leaving a gap in understanding their sources and effects in terrestrial ecosystems. Woodlands, which are vital for biodiversity and many ecological functions, are particularly understudied. One overlooked source of microplastic pollution is woodland management materials such as tree guards, cable ties and outdoor clothing. This research aims to address this gap through an investigation into the impacts of microplastics derived from woodland management materials on woodland soils in the United Kingdom. To do this, a 15-month burial experiment is being conducted to assess how microplastic source, concentration, polymer type, size, and shape influences soil chemistry, microbial activity, and microbial biomass. In addition, the effects of prolonged soil exposure on the physical and chemical properties of the microplastics are being explored using Fourier Infrared Transform Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM). The findings will be shared with woodland management organisations. This communication with key stakeholders in woodland management aims to raise awareness of microplastics as a potential pollutant in woodland ecosystems to support the development of evidence-based policies and sustainable material use in woodlands.

**ABSTRACT**

Quantification of microplastics (MPs) and nanoplastics (NPs) in soils has been increasingly attempted. However, MPs are generally quantified by particle counting using micro-FTIR or micro-Raman spectroscopy, while NPs are quantified using pyrolysis–gas chromatography–mass spectrometry (Py-GC/MS), making it difficult to assess their abundance on a comparable basis. In addition, existing NPs extraction methods often rely on interactions with soil organic matter, resulting in limited applicability across different soil types. In this study, we explored a unified Py-GC/MS-based workflow that enables mass-based quantification of MPs and NPs, incorporating salt-induced aggregation and subsequent organic matter decomposition for NPs. We then applied this framework to the individual quantification of MNPs in agricultural soils.

Spike-and-recovery tests were conducted for three types of soils—washed quartz sand, a Fluvisol with 3.3% total carbon, and an Andosol with 11.3% total carbon—to evaluate quantification methods for MNPs. MPs were extracted by density separation. As low-density MPs, polyethylene particles (PE-MPs; particle size 150–180 µm, density 1.0 g/cm³) were spiked into soil samples, while polyvinyl chloride particles (PVC-MPs; particle size 106–250 µm, density 1.4 g/cm³) were used as high-density MPs. First, soil organic matter was decomposed using Fenton's reagent. Then, density separation was performed three times with NaI solution (density 1.6 g/cm³), and the supernatants were filtered to recover MPs onto glass filters. For the recovery test of NPs, polystyrene particles (PS-NPs; particle size 101–140 nm) were used. After spiking the NPs into soils, the samples were shaken with TMAH solution to release NPs from mineral particles. The mixture was centrifuged, and the supernatant was filtered through a glass filter. The filtrate was amended with nitric acid and sodium chloride to induce NP aggregation, followed by centrifugation and organic matter decomposition. The filters with MPs and the resulting NP suspension were separately analyzed by Py-GC/MS.

In the recovery experiments for MPs, PE-MPs showed high recovery rates of 81.2–99.7%, regardless of soil type. In contrast, the recovery rate of PVC-MPs decreased to 33.1% after organic matter decomposition. For NPs, 97.8% of PS-NPs were successfully separated from soils using TMAH solution, demonstrating its potential applicability. In addition, the amount of NPs remaining in the soil residue after TMAH treatment was only 1.4% of the added amount, confirming that the TMAH-based extraction effectively separated NPs from the soil matrix. However, the final recovery of NPs from the same Fluvisol showed substantial variability among replicates. This may be associated with insufficient dispersion of recovered NPs, and further methodological improvement is required.

**ABSTRACT**

Plastics are widely used due to their low manufacturing costs and ease of processing; however, microplastics (MPs; <5 mm) have increasingly accumulated in terrestrial and aquatic environment, becoming a global environmental concern. For decades, Uzbekistan's Syr Darya and Amu Darya rivers transported domestic wastewater and irrigation water into the Aral Sea. Since the 1960s, excessive water withdrawal has caused the Aral Sea to shrink, may have promoted microplastic accumulation in both surface water and exposed dried soils. In arid regions, strong ultraviolet radiation, low soil organic matter, and soil crust formation may further influence the environmental behavior of microplastics. However, information on soil microplastics contamination in Uzbekistan remains extremely limited. This study provides a preliminary assessment of the abundance, color, shape, and polymer composition of microplastics in Aral Sea surface water and surrounding dried soils. Soil samples were collected from dried lakebed areas at multiple depths to evaluate vertical distribution and potential migration of microplastics. Surface water samples were obtained from the Aral Sea. To minimize contamination, samples were stored in aluminum containers and processed under controlled conditions. After sieving, particles larger than 1 mm were removed by visual inspection. Microplastics were extracted using density fractionation with sodium iodide (NaI) as a heavy liquid and identified using Fourier-transform infrared (FTIR) spectroscopy (Katsumi et al., 2022). For particles with ambiguous spectral features, additional characterization was conducted using gas chromatography–mass spectrometry (GC–MS). Microplastics were detected in both the Aral Sea water and the surrounding soils of our research sites and indicating widespread contamination across aquatic and terrestrial environment. This study provides baseline data on microplastic contamination in Aral Sea region and contributes to understanding potential sources and environmental behavior of microplastics in Central Asia.

**ABSTRACT**

Microplastics (MPs) have been suggested to disrupt soil structure and degrade soil functions; however, the occurrence and impacts of small microplastics below 100 µm remain poorly understood. Small MPs are expected to interact strongly with soil particles and organic matter; however, their effects on soil structure have not been sufficiently clarified. In Japan, information on MP contamination in agricultural soils is still limited, and knowledge of their impacts in volcanic ash soils is especially limited. In this study, agricultural soils from Tokyo, Chiba, Ibaraki, and Okinawa were investigated to characterize MP contamination using a modified separation method capable of isolating plastic particles in the 20–100 µm size range (Katsumi et al., 2022). After separation, the size, color, shape, and polymer type of individual microplastic items were recorded. In addition, MP addition experiments were conducted to evaluate the effects of small MPs on soil aggregate structure.

Across all study sites, microplastic items smaller than 100 µm were consistently abundant, and a wide range of polymers not used as agricultural materials was detected. In particular, farms located near urban areas showed higher numbers of microplastic items and a greater proportion of fibrous MPs. These results suggest non-agricultural sources of microplastics in the studied soils. Micro-FTIR analysis identified numerous items that were difficult to distinguish from plant residues. Subsequent verification using pyrolysis GC-MS demonstrated that many of these items were not plastics, indicating that reliance on micro-FTIR alone may lead to overestimation of small MP abundance. Furthermore, MP addition experiments indicated that film-shaped MPs of approximately 200 µm can inhibit the formation of coarse soil aggregates larger than 2 mm.

Overall, these results suggest the widespread presence of small microplastics in Japanese agricultural soils, highlight methodological challenges in quantifying MPs below 100 µm, and indicate potential impacts of small MPs on soil aggregate structure.

**ABSTRACT**

The accumulation of plastic residues (PRs) and their oxidized counterparts (OPRs) in agricultural soils poses a potential influence on phosphorus (P) geochemical cycling and availability. Bioavailable P can be immobilized through its transformation into insoluble calcium phosphates (CaPs). The influence of PRs and OPRs on CaPs formation remains poorly understood. To address this issue, we selected polyethylene (PE), polypropylene (PP), and polyvinyl chloride (PVC), along with their oxidized counterparts, as representative PRs. The In situ atomic force microscopy revealed that OPRs significantly accelerated the nucleation of CaPs at the solid-solution interface. In addition, real-time confocal Raman microscopy and high-resolution transmission electron microscopy (HRTEM) showed that OPRs promoted the phase transition from amorphous calcium phosphates (ACP) to hydroxyapatite (HAP), a highly insoluble and bio-unavailable form. These changes indicate that OPRs further reduce P bioavailability in soils. This effect is attributed to enhanced binding between CaP nuclei and PR surfaces following oxidation, which lowers the interfacial free energy and reduces the energy barrier for CaPs nucleation and crystallization. Our findings reveal a previously unrecognized mechanism by which OPRs exacerbate P-immobilization in soils, emphasizing the urgent need to address plastic pollution and improve P-management in PR-contaminated agricultural systems.

# Ten years of microplastics in the soil-plant system research-what have I learned?

**Yueling Qi**[1*]

[1] *Anhui Province Key Laboratory of Wetland Ecosystem Protection and Restoration, School of Resources and Environmental Engineering, Anhui University, Hefei 230601, China*

**ABSTRACT**

Microplastics (MPs) are commonly defined as plastic particles with diameter smaller than 5 mm from one of two sources: intentionally fabricated primary MPs and unintentionally degraded secondary MPs originating from larger plastic items. With this definition, it is easy to note that MPs are not a new material at all. Rather, the term represents a categorization of small plastic particles based on a specific size threshold.

The ecological risk of plastic waste was recognized by pioneering marine researchers as early as in the 1960s. However, the upsurge of interest in MPs began in 2004, following a paper in *Science* that formally introduced the term 'microplastics' to refer to 'microscopic plastic debris'. Recognition of MPs in soil came even later; it was not until 2012 that Matthias C. Rillig first called for research on MPs in terrestrial ecosystems. To my knowledge, I conducted the first experimental investigation on the effects of MPs on plant growth in 2016, which was subsequently published in a peer-reviewed journal in 2018. Inspired by the review paper in *Science* by Richard C. Thompson et al. in 2025, which reviewed current understanding and future prospects of MPs pollution research from 2004 to 2024, it is pertinent to summarize the research about MPs in the soil-plant system from 2016 to 2026.

The soil-plant system encompasses numerous processes, which can be categorized as physical, chemical, and biological. For the past decade, my research has consistently focused on the key scientific question: how the interaction between MPs and soil microorganisms affects soil ecological functions. The deeper I delve into my research, the more strongly I recognize the need to contextualize my findings within the big picture. A comprehensive understanding of MPs in the soil-plant system calls for collective efforts among soil scientists, botanists, microbiologists, ecologists, and agronomists, given that these processes are intricately linked.

In my view, a framework for systematic analysis and synthesis of soil-plant systems is useful to identify, study and elucidate the most important processes, which may even help predict the evolutionary trend of MPs pollution. Ultimately, all the related research could not only fill our knowledge gaps, but also contribute to the greater good of society.

**ABSTRACT**

The extensive use of plastic mulch in agriculture has led to the accumulation of micro-nanoplastics (MNPs) and phthalate esters (PAEs) in soil-plant systems, posing potential threats to human health and ecosystems. Using lettuce as a model crop, this study systematically investigated plant uptake and transport of sub-microplastics (SMPs) and their associated physiological and molecular responses. Furthermore, it revealed the combined effects of co-contamination with a typical PAE—di(2-ethylhexyl) phthalate (DEHP)—and SMPs in soil-plant systems. By employing techniques such as fluorescence labeling, scanning electron microscopy, confocal laser scanning microscopy, transcriptomics, and metabolomics, this research clarified the uptake pathways, physiological toxicity, and molecular mechanisms of SMPs in lettuce, particularly under co-exposure with DEHP. The results demonstrated that: first, SMPs could be absorbed by lettuce roots and translocated to leaves, leading to downregulation of ion homeostasis-related genes, activation of the antioxidant system, and enhancement of sphingolipid metabolism. Second, compared with negatively charged SMPs, positively charged SMPs more readily entered leaves through stomata and the cuticle, causing stronger physiological toxicity and greater regulation of gene expression, particularly upregulation of circadian rhythm-related genes. Notably, in the soil-plant system, DEHP did not exhibit synergistic toxicity with SMPs. Instead, DEHP inhibited the accumulation of SMPs in plants, alleviated MP-induced oxidative stress and metabolic disorders, and mitigated the negative impact on soil bacterial community diversity. This indicates a complex antagonistic interaction between SMPs and PAEs. This study provides physiological and molecular evidence for understanding the multidimensional impacts of agricultural plastic pollution and offers a scientific basis for developing risk management strategies.

**ABSTRACT**

Agricultural soils are important sinks for plastic debris, with macro- and microplastic contamination widely reported, whereas nanoplastic (NP) remain poorly documented. Their nanoscale size, strong interactions with soil constituents, and the limited sensitivity of current analytical techniques make reliable extraction and quantification of NPs challenging. Therefore, improved and thoroughly validated methods are urgently needed to understand the occurrence, behavior, and fate of NPs in soils.

This study is among the first to develop an extraction and quantification protocol for nanoplastics, including polyethylene (PE, 68 nm), polypropylene (PP, 56 nm), polymethyl methacrylate (PMMA, 219 nm), polyvinyl chloride (PVC, 404 nm), and europium-doped polystyrene nanoparticles (Eu-PS, 198 nm), from three different References LUFA soil types (loamy sand, clay loam, and silty clay). The extraction protocol comprises dispersion using tetrasodium pyrophosphate, followed by organic matter digestion with hydrogen peroxide and nanofiltration, and subsequent identification and quantification using single-particle inductively coupled plasma mass spectrometry (sp-ICP-MS) and pyrolysis–gas chromatography–mass spectrometry (Py-GC/MS). Sp-ICP-MS enabled highly sensitive detection of the Eu-PS tracer, allowing accurate quantification of extraction recovery at each stage of the protocol. Py-GC/MS was used for overall recovery assessment by identifying and quantifying all spiked polymer types based on their characteristic pyrolysis products.

Preliminary results showed that soil type affected Eu-PS NP extraction recovery. The highest recoveries were obtained from loamy sand, followed by clay loam and silty clay, for both particle number concentration (73–80%, 56–60%, and 49–50%) and mass concentration (63–72%, 52–60%, and 46–49%). spICP-MS analysis showed that Eu mass per particle remained consistent across all samples, indicating no substantial leaching or aggregation of the metal tracer. Therefore, the extraction procedure likely did not alter particle integrity. Ongoing Py-GC/MS measurements are being conducted to further assess polymer-specific recovery.

This study serves as a stepping stone for analytical method development for nanoplastics in soils and contributes to understanding how polymer type and soil properties influence extraction efficiency, supporting improved assessment of the environmental occurrence and fate of nanoplastics.

## ABSTRACT

Fossil-derived plastics represent a global concern, due to their negative effects on the environment, such as their persistent accumulation in soils and water bodies, and their noxious bioactivity on various organisms (1). Therefore, innovative and environmentally friendly polymers have been proposed, such as polyhydroxyalkanoates (PHAs), microbial polyesters produced to store carbon and energy (2). However, despite their synthesis meet the current sustainability criteria, the knowledge about their degradation in soils and their effect on soil biochemistry is limited, especially when added in presence of vermicompost (VC). This substrate is indeed known to stimulate the activity of soil microbial community and may therefore affect PHAs degradation (3). Our work aimed at investigating the biodegradation of PHAs materials in soil, to establish a relationship between the degradation process and the soil characteristics.

The PHAs studied were synthesised by solvent casting, using 400 mg of either Polyhydroxybutyrate (PHB) (PHB-400) or the copolymer poly(3-hydroxybutyrate-co-3- hydroxyhexanoate) (PHBHHx) (COP-400). Also, 200 mg of PHB (PHB-200) were used to study how the amount of polymer casted affects its degradation. Each material was placed in *non*-degradable pouches, buried in a sandy soil added or not with VC, and kept at 25 °C under a water regime of 45% WHC. At specific time points, bioplastics were recovered and their weight loss was measured. Also, their morphological and thermal properties was evaluated via Scanning Electron Microscopy (SEM) and Differential Scanning Calorimetry (DSC). Moreover, the activity of *β*-glucosidase and acid phosphatase were assessed in the soil.

The fastest degradation occurred for COP-400, due to its amorphous nature, which made it more accessible to microorganisms, whereas PHB-400 was more resistant to biodegradation agents. Besides, a faster degradation was noted for PHB-200 compared to PHB-400, likely due to its higher surface area-to-volume ratio, which enhanced its contact with the biodegradation agents. Despite VC addition did not affect significantly the polymer weight loss, its qualitative effect on biodegradation was evident through SEM images and DSC of the dug materials. The effects of biodegradation were also reflected in soil biochemical activities, as evidenced by an increase in *β*-glucosidase activity, related to the addition of the polymeric carbon-based substrate, and a decrease in acid phosphatase enzymatic activity.

Future studies focusing on the microbial communities developed in the soil during the biodegradation, or testing different amount of biopolymer added, could provide valuable insights into the degradation events, then advancing our understanding of the degradation process and its impacts.

# Soil metabolome impacts the formation of the eco-corona and adsorption processes on microplastic surfaces

**Yang Song***

*Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*E-mail Address of Presenting Author: ysong@issas.ac.cn

**ABSTRACT**

The Eco-corona on microplastics refers to the initial layer of biomolecular compounds adsorbed to the surface after environmental exposure. The formation and composition of the eco-corona in soils has attracted relatively little attention; however, this has important implications on the fate and impacts of microplastics, and their associated chemical additives, in the terrestrial environment. To this end, black polyethylene film microplastics, white polyethylene film microplastics and pure polyethylene microplastic granules were selected as typical polyethylene (PE) microplastic, which is one of the most abundant microplastics in soil. Three types of soil, including mollisol soil, fluvo-aquic soil, and red soil, were collected to obtain different soil metabolomes. Both the non-targeted and targeted metabolomics, along with several spectroscopic techniques, were used to test the formation of eco-corona on microplastics based on soil metabolites. The sorption of dibutyl phthalate (DBP) as a proxy for a soil contaminant on the microplastics with or without eco-corona was investigated. Here we demonstrate a fast formation of eco-corona on polyethylene microplastics exposed to water-extractable soil metabolites (WESMs) via two pathways: direct adsorption of metabolites on microplastics and bridging interactions mediated by macromolecules. The main eco-corona components were identified as lipids and lipid-like molecules, phenylpropanoids and polyketides, nucleosides, nucleotides and their analogues. The WESMs were found to reduce sorption of organic contaminants on microplastics by two pathways: reduced adsorption to the eco-corona surface and co-solubilization in the surrounding water. The impact of eco-corona formation should be considered an integral part of environmental fate and risk assessments of terrestrial emissions of microplastics and associated contaminants.

**ABSTRACT**

Microplastic (MP) pollution presents potential negative effects on microbial communities and soil biogeochemistry; however, results are still contradictory. This variability increases when considering the different types of polymers that make up plastics, such as degradable and non-degradable ones, and the use of pristine MP in studies, which do not represent the actual state of these contaminants in nature. In this context, this study aims to evaluate the effect of two types of MPs, polylactic acid (PLA) and low-density polyethylene (LDPE), at different contents and degradation levels, on the biological activity of agricultural soil. LDPE and PLA were mechanically ground and sieved to obtain particles smaller than 5 mm. Subsequently, they were irradiated with 600W solar simulation lamps for one month, with a 12-hour photoperiod and periodic agitation, verifying their degradation status with FT-IR-ATR at 0, 15, and 45 days. This resulted in aged and pristine LDPE and PLA, which were applied at 0.25%, 2.5%, and 5% w/w to an agricultural soil, establishing a mesocosm experiment for 12 weeks. At the end, the following soil biological parameters were analyzed: fluorescein diacetate (FDA) hydrolysis, dehydrogenase activity (DHA), acid phosphatase (Pacid), urease (UA), arylsulfatase (ARY), and respiration induced with alpha-cyclodextrin (CLYC). Also, sequencing of the 16S rRNA and ITS genes was performed to analyze alpha and beta diversity of microbial communities. A potential prediction of microbiota functionality for bacteria and fungi was also conducted using FAPROTAX and FungalTraits, respectively. Results show that DHA activity decreased by up to 70% solely due to PLA across all doses and degradation states. Conversely, Pacid increased threefold under PP and aged PLA. FDA and UA showed no significant treatment effects. CLYC activity decreased linearly with increasing aged LDPE, with no differences among other treatments. Bacterial richness and evenness increased under 5% aged LDPE, showing a similar trend for PLA but with a clear decrease at the lowest dose (0.25%). Fungal communities showed a decrease in richness for all PLA treatments, and only for aged LDPE at 5%. This resulted in microbial community structure discrimination by dose and degradation state for both bacteria and fungi, including an effect of plastic type only for fungi. Functional prediction revealed a potential increase in pathways associated with cellulolysis, aromatic hydrocarbon degradation, denitrification, etc., due to 5% aged LDPE and PLA. Thus, the PLA presence exerts negative effects on catabolic activity but positive effects on certain microbial hydrolysis processes. In summary, the effects of MP on soil microbial communities depend on the dose: low concentrations decrease diversity due to competition for colonization surfaces, while high concentrations increase microbial richness and evenness by providing more niches. # Effects of secondary microplastics input on the mineralization of soil organic carbon

**Xiaoyun Li[1*], Mengjie Yuan[2]**

[1] *School of Geography and Tourism, Shaanxi Normal University, Xi'an 710119, China*

*E-mail Address: lxy618@snnu.edu.cn

**ABSTRACT**

Different types of secondary microplastics are widely present in the soil. This study investigated the effects of secondary microplastics (MPs) on soil organic carbon mineralization in two distinct soil types: red soil and saline soil. Using pristine, photoaged, and pyrolyzed PVC MPs at concentrations of 0.5% and 5%, incubation experiments were conducted to monitor $CO_2$ and $CH_4$ emissions, soil pH, carbon components, enzyme activities, dissolved organic matter (DOM), and microbial community structure. Results showed that secondary MPs, especially pyrolyzed MPs, significantly enhanced cumulative $CO_2$ and $CH_4$ emissions compared to pristine MPs and controls. Pyrolyzed MPs had a greater impact on $CO_2$ emissions in red soil and on $CH_4$ emissions in saline soil. MPs addition decreased pH in red soil but increased it in saline soil, promoting oxidation and reduction reactions, respectively. Soil organic carbon and dissolved organic carbon increased in both soils, along with elevated β-glucosidase activity. Microbial diversity increased in red soil, with a notable rise in Acidobacteriota, while saline soil exhibited greater fungal community shifts. The findings indicate that secondary MPs accelerate soil carbon mineralization by altering soil properties, enzyme activities, and microbial communities, with pyrolyzed MPs exhibiting the most pronounced effects.

# Interfacial Colloidal Behavior of Microplastic-Pollutant Complexes and Its Regulation by Environmental Conditions

**Jie Han*, Han Dai**

*Xi'an Jiaotong University, Xi'an, China*

*jiehan@xjtu.edu.cn

**ABSTRACT**

The environmental behavior of microplastics (MPs) is governed by their interfacial colloidal dynamics, which are complicated by co-existing pollutants. This study systematically investigates how organic pollutants (ionic/non-ionic) modulate the colloidal stability of MP composites under varying environmental conditions.

Key findings reveal that pollutant type and interaction mode critically control stability. Ionic pollutants can either stabilize or destabilize MPs depending on charge compatibility, while non-ionic pollutants generally enhance stability in solution but promote aggregation upon adsorption. pH and cation type ($Na^+$ vs. $Ca^{2+}$) further interact with adsorbed pollutant layers, leading to non-DLVO behaviors—such as charge shielding, bridging, and hydration layer alteration—that traditional models cannot predict. Natural macromolecules like humic acid (HA) and bovine serum albumin (BSA) differentially affect stability: HA enhances stability in $Na^+$ but promotes $Ca^{2+}$-bridging, whereas BSA provides stronger steric stabilization across both ionic environments.

This work advances the mechanistic understanding of MP-pollutant co-transport in complex aqueous systems, offering critical insights for environmental risk prediction.

**ABSTRACT**

Terrestrial microplastic (MP) ecotoxicology is still dominated by liquid/agar tests and single model species, limiting environmental realism and comparability. We integrated soil-based microcosms with field monitoring to identify risks from individuals, trophic interaction and micro-food web level. A conventional MPs of low-density polyethylene (LDPE) and a biodegradable MP blend of poly(lactic acid) (PLA) and poly(butylene adipate-co-terephthalate) (PBAT) were evaluated. We aim to answer four questions: 1) Determine how plastic characteristics, soil texture, and environmentally relevant aging (microbial vs. photo-oxidative) modulate LDPE and PLA/PBAT impacts on nematode *C. elegans* performance, including offspring output, growth, and fertility. 2) Compare nematode species sensitivity to LDPE and PLA/PBAT using behavioral endpoints—locomotion, foraging activity, and food selection—in common soil nematodes. 3) Quantify MP-induced shifts in soil micro-food-web structure and functioning, emphasizing nematode–microbe trophic links and changes in energy flux under LDPE and PLA/PBAT exposure. 4) Examine how MPs interact with co-occurring environmental drivers to influence microbial biomass and community composition in Yangtze River bank soils and river sediments. We found that 1) Individual nematode fitness could be influenced mainly by soil type, plastic amount and aging (Zhang et al., 2025a). 2) MPs exposure could result in nematode behavioral disorders in moving, foraging and food choice (Zhang and Ruess, 2025). 3) MP could alter food web by negatively changing nematode and microbial biomass and structure, activity and energy flux. 4) MPs could interact with other human-sourced pollutants such as antibiotics and metals to reshape microbial community (Zhang et al., 2025b). Overall, MP effects in soils are context dependent and can scale from nematode fitness/behavior to shifts in nematode–microbe interactions and micro-food-web functioning. Linking soil microcosms with Yangtze River field monitoring strengthens risk assessment by involving co-occurring pollutants.

# Before You Measure: How Sampling Strategies Shape Microplastics Quantification in Soils

**Samuel J. Cusworth[1*], Denise M. Mitrano[1]**

[1]*Department of Environmental Systems Science, ETH Zürich, Switzerland*

*samuel.cusworth@usys.ethz.ch

## ABSTRACT

Microplastics (MPs) in soils exhibit strong spatial heterogeneity driven by land use, source proximity and soil processes. The rapid pace at which terrestrial MPs research has developed outpaced the development of robust, standardized procedures along the entire analytical workflow, including sampling strategies. Without representative sampling, uncertainty introduced at the earliest stage of the analytical chain propagates through extraction, analysis and interpretation. As a result, many reported MPs distributions, including quantification, characterization and risk assessments, remain challenging to interpret, difficult to compare and lack reproducibility.

Here, we present a multi-step sampling framework designed to improve the accuracy, precision and comparability of MPs quantification in soils. Using laboratory-scale model systems representing different MPs contamination scenarios, we systematically evaluated the effects of different sampling strategies on sample representativeness (Figure 1). To enable high-throughput assessment, we used model metal-doped MPs synthesized in-house, where the metals acted as conservative tracers and were quantified by ICP-MS, circumventing the need for more lengthy traditional MPs analysis. We demonstrate that producing a representative analytical aliquot is highly dependent on the preceding homogenization and mass-reduction techniques. Post-homogenization, subsequent aliquots from experimental systems exhibited high sample-to-sample variability indicating incomplete homogenization (Figure 2). Representativeness is strongly dependent on MPs morphology (fragments vs. fibers), since fibers are likely entangled in soil and harder to homogenize. Amongst mass reduction techniques, riffle splitting was most effective, though when used alone was insufficient to ensure sample representativeness (Figure 3). This is likely due to de-mixing phenomena and segregation of the homogenized bulk, often unconsidered in sampling workflows.

While we used a specific soil and MPs combination here, these findings emphasize the need to pre-test sampling approaches, using References materials to identify and account for segregation heterogeneity and other de-mixing phenomena in the given sampling conditions. Ongoing work extends this framework to larger, more environmentally realistic systems to develop a reproducible framework for MPs sampling across different soil environments. Overall, this work provides a workflow for representative MPs sampling in soils and identifies critical bottlenecks that must be addressed to support harmonized monitoring and inter-study comparability.

## ABSTRACT

The widespread distribution of micro/nanoplastics (MNPs) in the environment poses potential threats to ecological safety and human health. To achieve low-consumption and high-efficiency removal of MNPs, this study developed magnetic hierarchical porous adsorbents using geopolymer precursors and sawdust solid waste via a reduction roasting-hydrothermal method for nanoplastics removal from water. Optimal synthesis conditions were determined as: alkali-thermal roasting at n(Na:Al:Si) = 3.2:1:1, 20% sawdust incorporation, 700°C for 2 h, followed by hydrothermal treatment at n(Na:water) = 3.2:1, 100°C for 12 h. These conditions yielded magnetic A-type zeolite-biochar hierarchical porous materials with pore sizes ranging from 1 to 110 nm. During this process, aluminosilicates (e.g., quartz, kaolinite, nepheline) in the raw materials were activated into sodium silicate and sodium aluminate, eventually forming A-type zeolite. Simultaneously, sawdust pyrolyzed into biochar, and hematite in red mud was reduced by biochar to zero-valent iron, imparting magnetic properties. The as-prepared materials exhibited high adsorption capacity for nanoplastics and excellent reusability, with facile recovery under an external magnetic field. A maximum adsorption capacity of 125.5 mg/g was achieved for polyethylene (PE) nanoplastics. Adsorption behavior varied significantly with the surface charge and natural organic matter modification of the nanoplastics. The primary adsorption mechanisms involved hydrophobic interactions, electrostatic attraction, and hydrogen bonding. Dynamic column experiments further validated the material's removal capability in simulated soil systems. Overall, this hierarchical porous material integrates low energy consumption, high capacity, rapid kinetics, reusability, and magnetic recoverability, demonstrating significant potential for micro/nanoplastics remediation in soil-groundwater treatment systems.

**ABSTRACT**

Plastic pollution has become a major environmental problem, while the products of its degradation, microplastics (MP), appear everywhere on Earth. Data on MP in primarily agricultural soils are piling in recent years, but there is a significant knowledge gap in forest soils. In Serbia, forests are often the dumping sites for municipal waste, which creates environmental problems that have been rarely documented. In alluvial plains of the three largest rivers in Serbia (Morava, Sava, and Danube), we detected locations with waste depositions and visibly plastic-non-contaminated sites within similar forest/soil types to evaluate MP in topsoil. To explore the influence of environmental factors on soil MP, samples were taken in two years, in three forest vegetational seasons. The impact of MP on soil structure, chemistry, and fungal communities was examined. Large aggregate formation, soil coarse sand content, specific mass, porosity, and available P were the parameters that were strongly affected by contamination. MP was present in all samples, but few times larger amounts were extracted from the visibly polluted soils. Geographical location and environmental factors significantly influenced the behavior of MP in forest soils. Biodiversity and the structure of soil fungal communities were influenced by pollution, as well as by location and environmental factors. Saprotrophs were the most abundant fungal guild (29%), followed by plant pathogens (6%), parasites (4.7%), and mycorrhizal species (4.6%), but only saprotrophs and pathogens were significantly affected by the pollution. All fungal guild members were significantly affected by microplastic content, $P_2O_5$, $K_2O$, CEC, and coarse sand. We conclude that the influence of plastic pollution on fungal communities in temperate alluvial forest soils depends on soil characteristics as well as on seasonal changes in the soil environment.

**ABSTRACT**

Agricultural soils have become significant sinks for nano and microplastics (NMPs), raising widespread concern regarding their potential threats to soil health and crop safety. This study investigated the transport behavior of two commonly occurring NMPs with different polymeric properties—polyethylene (PE) and polylactic acid (PLA)—in agricultural soils. The results demonstrated distinct transport mechanisms of PE and PLA microplastics within soil pore networks. PE microplastics exhibited greater transport depths, reaching deep soil layers (8–10 cm) during a single infiltration event, whereas PLA microplastics showed significantly limited transport, predominantly distributed within the surface and middle soil layers (0–5 cm). Pore structure heterogeneity, including pore volume, connectivity, and pore-throat constriction, was identified as a critical factor governing microplastic transport. The transport and spatial distribution of PE microplastics were regulated by multiple soil pore parameters: V3D, A3D, L3D, W3D, D3D, EqD, SF, φe, φA, Macro, and Meso significantly promoted PE transport, while θ, φ, Micro, and Nano exerted inhibitory effects. Similarly, the transport of PLA microplastics was influenced by several pore parameters; V3D, A3D, D3D, SF, φe, and φA significantly enhanced the transport of 0.5 μm PLA microplastics, whereas φ inhibited their transport. For 5 μm PLA microplastics, φ was the only parameter that significantly suppressed transport, while no other pore parameters showed significant correlations. Random forest modeling further revealed that V3D, D3D, φe, and Nano were the key soil pore structural parameters controlling the transport of 0.5 μm PE microplastics, whereas φ was identified as the dominant parameter regulating PLA microplastic transport.

*Rostov-on-Don, Russia*

**E-mail: rajput.vishnu@gmail.com; rvishnu@sfedu.ru*

**ABSTRACT**

The toxicity of nanoparticles (NPs) is concerning issue; especially its effects on plants cellular-subcellular organelles, biochemical and molecular traits. In recent years; nanotechnology has resulted in the widespread use of engineered NPs across various industries, from agriculture to medicine, raising concerns about their environmental and biological impacts. Therefore, the nanotoxicomics are in trending to undertand impact of NPs at various types of plants, different climatic conditions and in soil types. We have conducted series of research experiments in various modules; i.e., hydroponic, model and field experiment, testing different forms, types and sizes of NPs behaviour in the plant tissues as well as its bio-geo-transformation, and long-term impact. Our research results indicate that the plant growth indices were severely affected at high content of NPs in soil hydroponic conditions by affecting the germination rate, root (relative root length by 35%) and shoot lengths (relative shoot length by 10%), accumulation in plant tissues (by 5.7 in roots and 6.4-folds in leaves), maximal quantum yield of photosystem II, and transpiration rate, effects on stomatal aperture and root morphology, metaxylem size and changes in cellular organelles (plastids, mitochondria), as well as in plastoglobules, starch granules, protoplasm, membranes and nucleus. Low molecular weight antioxidants like restored glutathione and ascorbate have been found to increase the activity of glutathione peroxidase (GPX), glutathione-S-transferase (GSTs), and ascorbate peroxidase (APX) in plant tissues, whereas catalase (CAT) activity increased from by 50-70%. The observed disturbance in redox balance signals the upregulation of corresponding genes. Antioxidant enzyme isoform gene transcripts increased for CAT2, and APX under NPs stress. The gene transcription of the subunits of the mitochondria electron transport chain (ETC) changed mainly only under the influence of high concentration of NPs. Expression of the ATPase subunit gene, atp1, increased slightly (by 36 %) in leaf tissue under the influence of medium and high concentrations of NPs, whereas in the root tissues, the atp1 mRNA level decreased significantly (1.6-2.9 times). The formation of electron-dense materials was noted in the intercellular space of cells of NPs-treated plants. This indicates the accumulation of NPs in edible part of crops and raising concern on human health. The mechanistic insights into NPs uptake, including their entry into plant cells, interactions with organelles and biomolecules, and the generation of reactive oxygen species are crucial. This mechanistic understanding of properties of NPs (size, shape, surface charge, and concentration) and plant-specific factors (species and growth stage) significantly influence genotoxic outcomes and can be modulate for efficient input of NPs in sustainable way.

# Biological Strategy for Identification and Elimination of Organic Pollutants in Agro-Environments

**Yanzheng Gao***

*Institute of Organic Contaminant Control and Soil Remediation, College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing 311800, China.*

*E-mail: gaoyanzheng@njau.edu.cn

**ABSTRACT**

1) Identification of organic pollutants in soil. This study aimed to establish a biosensor method for detecting extractable tetracyclines in soils using whole-cell biosensors containing a reporter plasmid (pMTGFP or pMTmCherry) carrying fluorescent protein genes tightly controlled by tetracyclines-responsive control region (tetRO). This whole-cell biosensor method can simultaneously measure 96 or more samples within 6 h and is easily parallelizable, whereas a typical high-performance liquid chromatography (HPLC) method may require 7 times more of analysis time and much greater cost to achieve similar analytical throughput. The biosensor method had a detection limit for each of six tetracyclines between 5.32-10.2 μg/kg soil, which is considered adequate for detecting tetracyclines in ethylenediaminetetraacetic acid (EDTA) extracts of soils. Relative standard deviation was between 19.8%-51.2% for the biosensor Escherichia coli DH5α/pMTGFP and 2.98%-25.8% for E. coli DH5α/pMTmCherry, respectively. This new, fast, easily parallelizable, and cost-effective biosensor method has the potential for measuring extractable concentrations of tetracyclines for a large number of soil samples in large-scale monitoring studies.

2) Elimination of organic pollutants in plants. This investigation provides a novel method of endophyte-aided removal of polycyclic aromatic hydrocarbons (PAHs) from plant bodies. A phenanthrene-degrading endophytic bacterium Pseudomonas sp. Ph6 was isolated from clover (*Trifolium pratense* L.) grown in a PAH-contaminated site. After being marked with the GFP gene, the colonization and distribution of strain Ph6-gfp was directly visualized in plant roots, stems, and leaves for the first time. After ryegrass (*Lolium multiflorum* Lam.) roots inoculation, strain Ph6-gfp actively and internally colonized plant roots and transferred vertically to the shoots. Ph6-gfp had a natural capacity to cope with phenanthrene in vitro and in planta. Ph6-gfp degraded 81.1% of phenanthrene in a culture solution within 15 days. The inoculation of plants with Ph6-gfp reduced the risks associated with plant phenanthrene contamination. Our results will have important ramifications in the assessment of the environmental risks of PAHs and in finding ways to circumvent plant PAH contamination.

3) Elimination of organic pollutants in soil. Engineering natural microbiomes for biotechnological applications remains challenging, as metabolic interactions within microbiomes are largely unknown, and practical principles and tools for microbiome engineering are still lacking. Here, we present a combinatory top-down and bottom-up framework to engineer natural microbiomes for the construction of functionenhanced synthetic microbiomes. We show that application of herbicide and herbicide-degrader inoculation drives a convergent succession of different natural microbiomes toward functional microbiomes (e.g., enhanced bioremediation of herbicide-contaminated soils). We develop a metabolic modeling pipeline, SuperCC, that can be used to document metabolic interactions within microbiomes and to simulate the performances of different microbiomes. Using SuperCC, we construct bioremediation-enhanced synthetic microbiomes based on 18 keystone species identified from natural microbiomes. Our results highlight the importance of metabolic interactions in shaping microbiome functions and provide practical guidance for engineering natural microbiomes

# Boron in Soil: Linking Microbial Responses and Plant Performance

**Felipe Bastida[1*], Alfonso Vera[1], Emilio Nicolás[2] and José Luis Moreno[1]**

[1] *CEBAS-CSIC, Department of Soil and Water Conservation, Murcia, Spain*

[2] *CEBAS-CSIC, Department of Irrigation, Murcia, Spain*

*fbastida@cebas.csic.es

**ABSTRACT**

Water scarcity in Mediterranean and arid regions is driving the adoption of desalinated seawater (DSW) as an irrigation source, yet its elevated boron (B) content raises environmental and agronomic concerns. Across a series of complementary studies using soils from southeastern Spain and diverse plant models (ryegrass, tomato, onion, lemon, and apricot), we evaluated how increasing B concentrations and the use of organic amendments affect the soil–plant–microbiome system. Results consistently demonstrated that irrigation with B-enriched or DSW causes B accumulation in soil and plant tissues, modifies soil nitrogen dynamics, and alters the activity, biomass, and structure of soil microbial communities. A threshold around 1 mg B $L^{-1}$ in irrigation water emerged as critical: below this level, soil microbial functionality and crop performance were generally maintained, whereas higher concentrations induced negative effects on microbial respiration, enzyme activities, and community composition—particularly reducing fungal diversity. The magnitude and direction of microbial responses depended on both the B chemical form and the crop species, with more tolerant crops such as tomato or apricot showing limited physiological stress compared with sensitive species like onion and lemon. Organic amendments modified B mobility and bioavailability through interactions with dissolved C and N pools, sometimes enhancing plant B uptake and aggravating toxicity symptoms, despite stimulating microbial biomass. In lemon soils, the combination of DSW and organic inputs intensified B accumulation and impaired photosynthetic performance, while in apricot systems microbial biomass increased without detectable physiological stress. Collectively, these studies reveal that B exerts complex, dose-dependent effects on plant physiology and the soil microbiome, mediated by species sensitivity, soil organic matter, and irrigation water quality. Sustainable use of DSW for irrigation therefore requires careful monitoring of B concentrations, crop-specific tolerance thresholds, and soil organic management to prevent long-term degradation of soil fertility and ecosystem functioning.

# Chemical characterization, fluorescence properties, and photochemical reactivity of natural dissolved organic matter

**Davide Vione***

*University of Turin, Department of Chemistry, Via P. Giuria 5, 10125 Turin, Italy*

*davide.vione@unito.it

**ABSTRACT**

Dissolved organic matter plays a very important role in aqueous systems, including most notably: *(i)* the carbon cycle, with important implications for the $CO_2$ budget of water environments; *(ii)* the absorption of sunlight, with the ability to protect living organisms from the harmful effects of UV-B radiation, and *(iii)* the production of reactive transient species that are involved in the degradation of xenobiotics and of natural organic compounds.

Several tools can be used to characterize natural organic matter. NMR spectroscopy has allowed important discoveries about the structure of soil humic substances. Further advances were obtained more recently by use of LC-MS and of GC-MS, the latter requiring chemical modification of the sample. All these techniques, to which FT-IR can also be added, are extremely useful but require extensive sample pre-treatment and concentration, in soil extracts and *a fortiori* in the case of natural waters. For this reason, the characterization of organic matter in surface waters is most frequently carried out by use of spectroscopic techniques, namely UV-vis absorption and fluorescence spectroscopy that require virtually no sample pre-treatment. Although limited to the chromophoric fraction of dissolved organic matter (the so-called CDOM), these techniques can provide important insights into its origin and valuable information concerning structure and photochemical reactivity.

This keynote presentation will also deal with the results of recent studies into the possible fluorophores that could account for the fluorescence properties of organic matter, with the double role of the latter as both inducer (photosensitiser) and quencher (reductant) in the photodegradation of contaminants, and with the photomineralisation kinetics on a global scale.

# Enhanced Sorption of Per- and Polyfluoroalkyl Substances by Soils from Water via Cation Bridging Interaction

**Andrew Huang, Wei Zhang, Brian J. Teppen, and Hui Li***

*Department of Plant, Soil and Microbial Sciences, Michigan State University, East Lansing, Michigan, United States*

## ABSTRACT

Per- and polyfluoroalkyl substances (PFAS) are a diverse group of widespread contaminants, and their many environmental impacts are governed mainly by sorption by soils. PFAS sorption is affected by the salts present in soil and water, and the sorption could be enhanced by strengthening cation-bridging interaction between PFAS and multivalent cations on soil surfaces. In this study, sorption experiments of a series of PFAS were conducted to evaluate the effects of PFAS structures on cation-bridging interaction, including (1) hydrophilic head groups (carboxylic vs. sulfonic, e.g., PFNA and PFOS), (2) different electric charges (anionic vs. neutral, e.g., PFOS, PFOSA, and N-EtFOSA), and (3) perfluorinated chain length (e.g., PFHxA, PFOA, PFNA, PFDA, PFUnA, PFDoA, and PFTrA). To quantify the contribution of cation-bridging interaction to sorption, sorption isotherms by soil from water were measured for the soils with cation exchange sites occupied by either $K^+$ or $Ca^{2+}$ with KCl or $CaCl_2$ as background solution. All measured sorption isotherms demonstrated linear relationship between sorbed concentration vs. the aqueous concentration. The obtained distribution coefficients ($K_d$), as the slope of sorption isotherm, increased exponentially with the PFAS C-F chain length. The $K_d$ values of PFAS sorption by Ca-soil was approximately 9 to 17 times greater than that by K-soil. With the same C-F chain length, PFOS with sulfonic acid head group exhibited stronger interaction with soil than PFNA with carboxylic acid group. Sorption of anionic PFAS by Ca-soil was consistently greater than that by K-soil. Neutral PFAS showed no apparent difference in sorption by K- vs Ca-soil, indicating that neutral PFAS chemicals cannot form cation-bridging interaction that anionic PFAS interact with $Ca^{2+}$ through forming specific interaction with cations on soil surfaces. This study provides strong evidence to support the contribution of cation-bridging interaction to PFAS sorption, and offers new insights into the contribution of this mechanism to PFAS retention by soils.

**ABSTRACT**

The special attention and widespread concern caused by the presence of heavy metals in the environment are mainly due to their physicochemical properties, high toxicity and persistence, and negative effects on biological properties and soil structure, and the possibility of transfer to the human body through agricultural products. Heavy metals in soil can cause respiratory, cardiovascular, and renal diseases. Currently, more than 200 million tonnes of waste have accumulated in 13 tailings ponds in northern Tajikistan, including about 55 million tonnes of uranium waste in 10 tailings ponds. The total area of the tailings ponds is 200 hectares. It should be noted that the tailings are located in the basin of the transboundary Syr Darya River, which, along with the rest of Tajikistan, is an earthquake-prone area with a high frequency of debris flows. The tailings ponds at Taboshar have been subject to repeated erosion by mudslides throughout their existence. The industrial site at Taboshar contains rock dumps with excessive amounts of radionuclides, and the tailings contain radioactive waste from the primary hydrometallurgical processing of uranium ores.

The aim of the present work is a comprehensive assessment of heavy metal content in the soils of radioactive dumps in northern Tajikistan by determining environmental pollution indices and their transfer to plants.

Soil sampling was carried out in accordance with GOST 17.4.3.01-83 of the Interstate Standard for Nature Protection. Soils. General requirements for sampling. The method of soil keys was used for soil sampling of the investigated area. Each key of the study area consisted of five sampling points. Soil samples were taken from a depth of 10-30 cm. The soil samples were dried, crushed, and sieved through a 1 mm mesh sieve. The content of heavy metals was determined by X-ray fluorescence analysis in a Spectroscan MAKS-G spectrometer. The sampling of plants was carried out in the summer seasons of 2023 and 2024.

To study the processes of heavy metal migration and transport in plants, the dominant genus of perennial meadow grasses of the Alopecúrus family was used in the study area. Several methodological tools and complex indicators have been developed to assess the degree of soil contamination with heavy metals. Geoaccumulation index, accumulation coefficient, individual pollution index (PI), general pollution index (PLI), Nemerow pollution index (NPI), and potential ecological risk indicator (RI) allow the identification of areas according to the degree of soil contamination with heavy metals. They are also important for the development of measures to neutralize the effects of heavy metals, for the integrated assessment of soil quality and for predicting the sustainability of ecosystems for crop production under conditions of certain soil contamination with heavy metals.

The soil of the Taboshar tailings dump area belongs to different classes according to the values of the individual pollution index (PI) of heavy metals (Sr, Pb, As, Zn, Cu, Ni, Co, Cr, and V). According to the classification, the soil is considered unpolluted at values PI<1, 1<PI<2 - weak pollution, 2< PI<3 - medium, 3<PI<5 - strong, PI>5 - very strong pollution. The contents of Sr, Pb, Ni, Co, Cr, and V are in the range of 0.13 - 0.77, and according to these elements, the soil of the territory belongs to the class of unpolluted. According to the Zn, Cu content, the soil belongs to the slightly polluted class, and according to the As content, to the highly polluted class.

The values of geoaccumulation index of heavy metals Sr, Pb, As, Zn, Cu, Ni, Co, Cr, and V in the soils of Taboshar dump, from which it can be seen that the scatter of values of geoaccumulation index of metals is in a wide range and for Sr, Ni, Co, Cr and V have a negative value. According to the values of geoaccumulation index of heavy metals, as stated in soils are divided into the following classes: clean (Igeo<0), polluted from weak to medium (0<Igeo<1) from medium to strong medium degree of pollution (1 <Igeo<2). Then medium to heavily polluted (2<Igeo<3), heavily polluted (3<Igeo<4), heavily to very heavily polluted (4<Igeo<5), and very heavily polluted (5<Igeo).

Comparing the result of the heavy metal geoaccumulation index values with the above soil class values shows that the soil of the Taboshar tailings dump area corresponds to the weak to moderate contamination class for Sr, Pb, Ni, Co, Cr, and V. The Zn and Cu values are medium, and As values are from medium to high levels of contamination.

The ratio of the difference between the individual pollution index and the load index to the individual metal pollution index has positive value only for As, Zn, Cu and almost zero value for Pb and negative value for Sr, Ni, Co, Cr and V. This is an evidence that As, Zn and Cu predominate in the soils of Taboshar tailings dump area and among them As has the highest concentration.

On the way of transfer of chemical elements into the human body, and the main link in the biochemical cycle of substances are plants, which are characterised by high absorption capacity. Heavy metals, with their physical and chemical properties, toxicity, and high migration stability, cause widespread concern in terms of transfer to living organisms. This problem has become particularly relevant in recent years due to the increasing anthropogenic pollution of ecosystem components. The study of the migration and transfer of heavy metals into living organisms and the establishment of their regularities are important from a practical point of view for the development of methods of protection against their ingress into crops and further along the 'soil-plant-living organism' chain. In addition, plants can serve as indicators of a heavy metal-contaminated environment.

The Ecological Risk Index (RI) values for Sr, Pb, As, Zn, Cu, Co, Cr, and V of the soil from the Taboshar tailings area show that they are all well below 90, with an average RI value of 59.48 for the whole sampling area. Consequently, the soil of the Taboshar tailings area, namely the soil of the sampling area, is characterised by a low ecological risk indicator for the listed metals.

Thus, as a result of the conducted research, it is established that the contents of Sr, Pb, Ni, Co, Cr, and V are in the interval 0.13 - 0.77, and according to these elements, the soil of the area belongs to the class of unpolluted soils. According to Zn and Cu content, the soil belongs to the class of slightly polluted, and As to the class of heavily polluted soils. The values of the index of geoaccumulation of heavy metals Sr, Pb, As, Zn, Cu, Ni, Co, Cr, and V in the soil of the Taboshar dump are in a wide range, and for Sr, Ni, Co, Cr, and V have a negative value. The soils of the Taboshar tailings area belong to the class of weak to medium contamination in terms of Sr, Pb, Ni, Co, Cr, and V. Zn and Cu values are medium, and As values are from medium to strong contamination. The values of the biological absorption coefficients of Cu, Ni, and Cr are lower, and for the rest, more than 1. Heavy metals with a biological absorption coefficient greater than one are accumulated in plants, while metals with a biological absorption coefficient less than one are taken up by plants.

# Bioremediation of soil contaminated with boron by using biochar and barley plants

**Rubén López-Mondejar[1], Felipe Bastida[1], José Luis Moreno[1*]**

[1] *CEBAS-CSIC, Department of Soil and Water Conservation, Murcia, Spain*

*jlmoreno@cebas.csic.es

**ABSTRACT**

Soil is an essential and finite resource, and its degradation through different processes threatens its ecological functions, as well as the sustainable development of agricultural activity. In particular, in agricultural areas characterized by intensive production of irrigated crops under arid and semi-arid climate, the use of desalinated seawater results in the accumulation of boron (B) in soil and crops. Soil bioremediation technologies have emerged as a viable approach to promote the transition from conventional, intensive agrosystems to more sustainable ecological production systems. Moreover, the reuse of processed organic wastes as soil amendments has been proposed as a key strategy for the restoration of degraded soils. Biochar can act as a beneficial organic soil amendment while serving as a catalyst in the bioremediation of contaminated soils, enhancing the B adsorption, and stimulating the activity, biomass and diversity of soil microbial community. In addition, barley plants exhibit a high tolerance to B toxicity and may help mitigate its detrimental effects on soil microorganisms. This study aims to evaluate, at the laboratory scale, the bioremediation of a B-contaminated agricultural soil by integrating the application of two types of organic amendments - a common biochar (BC) and this biochar enriched with a compost (BCE) - with the cultivation of barley plants. Specifically, the study investigates the capacity of biochar, both alone and in combination with compost to reduce the B concentration in the soil solution. Furthermore, it examines whether the proposed bioremediation strategy enhances soil health and quality by assessing several soil enzyme activities, as well as the biomass and composition of the microbial community, in both B-contaminated and uncontaminated control soils. Overall, after 30 days of incubation, we observed that the BCE treatment exerted a significantly greater influence on the microbial community in B-contaminated, rendering it more comparable to that of the uncontaminated soil amended with either type of biochar.

# Evaluation of nano-PbO and macro-PbO transformation in soil-plant system based synchrotron methods

**Minkina T.*, Nevidomskaya D., Shuvaeva V., Kirichkov M., Chernikova N., Fedorenko A.G., Bauer T.V., Mandzhieva S.S.**

*Southern Federal University, Rostov-on-Don, Russia*

*E-mail tminkina@mail.ru

**ABSTRACT**

Nanotechnology is a rapidly evolving field in the 21st century. Nanomaterials, due to their ultra-small size, exhibit an extremely high surface area-to-volume ratio. These physical characteristics of nanomaterials contribute to their chemical and biological properties being significantly different from those of their macroscopic counterparts. The study employs advanced technological research methods lead oxide (PbO) nanoparticles based on synchrotron radiation (Kurchatov Synchrotron Radiation Source, Moscow). In a model experiment, the impact of macro- and nanoscale PbO particles on the processes of uptake and transformation in Haplic Chernozem soil, as well as on structural and functional alterations in the tissues and cells of spring barley (*Hordeum vulgare* L.) throughout its growth cycle, was investigated. The transformation and speciation of Pd were studied using a direct nondestructive physical method, including X-ray diffraction (XRD), X-ray absorption spectroscopy (XAS) and transmission electron microscopy (TEM). Newly formed crystalline mineral lead-containing compounds were identified in plant tissues: plumboferrite ($Pb_2(Fe_3^+, Mn_2^+, Mg)_{11}O_{19}$), litharge (PbO), galena (PbS), and pyromorphite ($Pb_5(PO_4)_3Cl$). The Pb content in plant samples was 25.4% for PbO-nano and 1.6% for PbO-macro. It was noted that in samples contaminated with PbO-nano, an incomplete phase transition from the tetragonal phase of PbO to the orthorhombic phase was observed. This supports the high transformation and penetration capacity of PbO nanoforms into barley plant tissues, followed by their accumulation and formation of new mineral phases. Molecular-structural data revealed a reduction in the coordination number to 2-3 atoms for the nearest atomic environment of Pb, a characteristic feature of soil and plant samples. High dispersion values of local interatomic distances in the nearest coordination spheres around the absorbing Pb atom were diagnosed, marked by short Pb—O distances close to 2.14 Å, typical of aqua complexes $Pb^{2+}(H_2O)n$. It was found that the toxicity of introduced PbO forms, especially nanoparticles, significantly affects the state of intracellular structures (mitochondria, plastids, and inclusions) involved in photosynthesis and energy metabolism, leading to destructive changes that reduce metabolic processes related to barley growth and development. The study demonstrates the potential of combining synchrotron methods and other instrumental techniques for characterizing and analyzing the behavior of nanoparticles in biological systems and organo-mineral polydisperse structures, such as soil.

**ABSTRACT**

Chlortetracycline (CTC) is a major tetracycline antibiotic, which has been widely used in livestock and fish husbandry. The widespread presence of CTC in the environment poses a significant threat to both ecological environment and human health. Biodegradation is considered an effective method to reduce CTC in environments. In this study, the strain BCTC-2 was obtained from an activated sludge of a pharmaceutical plant, through enrichment, domestication, and isolation screening. BCTC-2 was identified as *Bacillus paramycoides* and possessing high CTC degradation capacity and good environmental adaptability. Meanwhile, we investigated the influence of different environmental conditions, such as incubation temperature, pH, external carbon source, initial CTC concentration, and inoculum amount for the activity of bacteria and CTC removal efficiency. Results indicated that the maximum removal efficiency of CTC could reach 84.15% under optimal conditions: initial concentration of 50 mg $L^{-1}$, sodium citrate as the external carbon source, 30°C, pH=7, and 5% inoculum. Additionally, BCTC-2 demonstrated effective degradation of CTC in actual wastewater containing antibiotics. Under conditions of 30°C and pH=7, strain BCTC-2 achieved a CTC degradation rate of 75.23%. This strain can be applied to the treatment of actual antibiotic-containing wastewater, reducing environmental pollution and health hazards caused by antibiotic residues. The present study confirmed the effectiveness and feasibility of using BCTC-2 for the biodegradation of CTC in wastewater, offering a promising strategy for mitigating CTC pollution in aquatic environments.

## ABSTRACT

Smectite clays are ubiquitously present in soil with high abundances. They can retain and mediate the transformation of a variety of organic contaminants due to their large specific surface areas and high surface activities. Here, we examined the expression of tetracycline resistance gene *tet*(M) of a fluorescent *Escherichia coli* whole-cell bioreporter influenced by the phototransformation of tetracycline in the presence of smectite clays or humic substances. Despite the similar phototransformation ratios (80~90%) of the total loaded tetracycline after irradiation, the decrease ratios of cell fluorescence intensity were much higher with montmorillonite and hectorite (94% and 93%) than with Pahokee Peat humc acid and Pahokee Peat fulvic acid (44% and 69%) when compared to the respective dark controls. As illustrated by mass spectroscopic and chemical analyses, tetracycline was found to be transformed to amide (ineffective in inducing ARGs) with the presence of clays by reaction with self-photosensitized singlet oxygen ($^1O_2$), while the humic substances catalyzed the production of another two demethylated and/or deaminated compounds (still effective in inducing ARGs) in addition to the amide compound via reaction with triplet excited state dissolved organic matter ($^3$DOM*).

Additionally, we investigated photoaging processes of polystyrene and polyethylene microplastics deposited on surfaces of three representative Fe-bearing clay minerals (biotite, lizardite, and montmorillonite) under simulated sunlight and natural sunlight. We observed severe photoaging of the two microplastics catalyzed by Fe-bearing clay minerals at soil-air interfaces, manifested by intensifying morphological damage with increasing structural Fe content and 2 times more carbonyl groups than reported aqueous systems. These structural alterations, predominantly localized on microplastic surfaces, though accounting for merely 0.1% of total carbon, significantly enhanced their hydrophilicity and microbial affinity. This aggravation originated from boosted surface-bound hydroxyl radicals with prolonged half-life via light-driven Fenton-like reactions of Fe-bearing clay minerals. The direct light exposure of clay surfaces and interlayer confinement within nanosized clay interlayers facilitated *in-situ* oxidation of microplastics. Critically, photoaged microplastics possessed severe toxicity on luminescent bacteria, with maximum increase in acute toxicity units by 0.67. Enhanced microplastics photoaging and toxicity were also observed under natural sunlight within 7-day diurnal and wet-dry cycles, similar to the effects seen under 36-h continuous simulated sunlight.

The results clearly demonstrate that smectite clays can effectively mediate the phototransformation of tetracyclines and microplastics and in turn strongly affect their biologic effects.

# Biochar downsizing: From bulk to nanoscale solution in soil remediation and contaminants immobilization

**Patryk Oleszczuk[1*] and Monika Raczkiewicz[1]**

[1] *1Radiochemistry and Environmental Chemistry Department, Faculty of Chemistry, Maria Curie-Skłodowska University in Lublin, Poland*

*patryk.oleszczuk@mail.umcs.pl

**ABSTRACT**

The conversion of bulk biochar (b-BC) to nano-biochar (n-BC) via ball milling yields substantial physicochemical modifications, including enhanced specific surface area, increased pore volume, and shifts in elemental composition and surface functional chemistry, all of which depend on feedstock characteristics and pyrolysis conditions (Raczkiewicz et al., 2024a). Ball milling further reduces the concentrations and bioavailability of PAHs and heavy metals through mechanochemical degradation, defect generation, and improved adsorption efficiency (Raczkiewicz et al., 2024b).

However, nanoscale transformation is associated with elevated ecotoxicological risk; n-BC displays increased toxicity toward microbial communities, invertebrates, and plants relative to b-BC (Raczkiewicz et al., 2024c). Despite these hazards, n-BC demonstrates superior immobilization of potentially toxic elements (PTEs) and PAHs in contaminated soils, decreasing their bioavailability and plant uptake, including in lettuce (Raczkiewicz et al., 2025a). These effects arise from enhanced adsorption capacity and accelerated immobilization kinetics for metals such as Pb, Zn, and Cd (Raczkiewicz & Oleszczuk, 2025b). Optimization is achievable through targeted feedstock selection and pyrolysis under nitrogen. Overall, n-BC presents a duality of improved remediation performance and heightened ecotoxicological concern, underscoring the need for controlled production parameters to ensure environmentally responsible application.

# Risk Ranking of Antimicrobial Resistance Across One Health Sectors: Leveraging Long-Read Sequencing and Methylation Analysis

**Antti Karkman**[1*]

[1] *Department of Microbiology, University of Helsinki, Helsinki, Finland*

*antti.karkman@helsinki.fi

**ABSTRACT**

Antimicrobial resistance (AMR) represents a severe global health threat, undermining the effectiveness of treatments for infections and threatening human and animal health. Its rapid spread across humans, animals, and the environment complicates infection treatment and increases the risk of severe illness and death. The magnitude of AMR's impact demands a comprehensive, integrated approach commonly known as One Health, which recognizes the interconnected health of people, animals, and ecosystems. This framework calls for collaborative, multisectoral actions across human health, veterinary medicine, agriculture, and environmental management to address AMR sustainably and effectively.

The importance of risk ranking in AMR within a One Health framework lies in its ability to identify and prioritize the highest-risk antimicrobial resistance genes, pathogens, and transmission pathways across the human-animal-environment interface. AMR risk ranking provides a systematic approach to prioritizing antimicrobial resistance threats by integrating data on genetic context, mobility potential and host range of AMR genes. Risk ranking enables robust identification of high-risk resistance genes, pathogens, and exposure pathways for targeted surveillance and intervention strategies that are critical given the vast diversity of resistant agents and their complex transmission dynamics. By helping to assess where the greatest threats lie—whether in clinical settings, agriculture, or environmental reservoirs—risk ranking guides the implementation of policies such as antimicrobial stewardship, infection prevention and control, and environmental contamination reduction measures. These efforts are central to slowing the spread of resistance, preserving the effectiveness of antimicrobials, and ultimately protecting public health, animal welfare, and ecosystem resilience.

By using long-read metagenomics and methylation pattern analysis, we have developed a framework for predicting mobility and host range of AMR genes and determine their transmission routes across One Health sectors. Our results demonstrate the importance of non-clinical bacteria in acting as reservoirs and transmission vectors of AMR genes. The developed framework can be used to predict the latent AMR genes of greatest concern that could be the targets of future monitoring campaigns.

Recognizing AMR as a One Health threat and applying risk ranking approaches underpin the global fight against antimicrobial resistance by facilitating the design of focused, evidence-based, and sustainable interventions at local, national, and international levels.

# Global ecological and health risks of PFAS in surface soil

**Min Wei[1,2*], Zhongxing Chen[1,2,3], Kun Yang[1,2,3], Lifeng Cao[3], Chuntian Qiu[3], Lianqing Zhou[1,2], Zhou Shi[1,2], and Songchao Chen[1,2,3]**

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFAS) are highly persistent and potentially toxic, making them a growing global concern. Yet, the large-scale ecological and human health risks of PFAS contamination in soils remain poorly understood. In this study, we synthesized about 2,000 PFAS concentration data points from surface soil samples reported in 106 peer-reviewed studies to evaluate global contamination patterns and associated risks. A probabilistic approach showed that long-chain legacy PFAS, particularly perfluorooctane sulfonic acid (PFOS), were the dominant contaminants in soil (median concentration 1.03 ng $g^{-1}$), with 30.32% of the grids exceeding safety threshold. We identified geographic hotspots that include Central Europe, the northeastern United States, and southeastern China. Notably, health risks linked to perfluorohexane sulfonic acid (PFHxS) are elevated in both Europe and the U.S (exceeded global median by a factor of 26.77). Moreover, short-chain PFAS exhibit higher mobility, suggesting a greater potential for groundwater leaching. These findings highlight the urgent need to establish global soil quality standards for PFAS and offer critical insights to guide public health policy and soil management strategies.

**ABSTRACT**

Understanding plant uptake of per- and polyfluoroalkyl substances (PFAS) is crucial for assessing human exposure risks and ensuring food safety. Machine learning can be valuable in studying plant uptake of PFAS by recognizing hidden patterns in datasets and revealing new mechanistic insights. We trained four machine learning models, including eXtreme Gradient Boosting (XGBoost), Random Forest (RF), Multilayer Perceptron (MLP), and Support Vector Regression (SVR), to predict the bioconcentration factor (BCF) and concentrations (C) of 21 PFAS in plants using a newly compiled dataset composed of 11 crops, 11 plant tissues, as well as various soil properties and cultivation conditions. All models achieved satisfactory performance, and XGBoost achieved the best performance, with a coefficient of determination ($R^2$) of 0.951, mean absolute error (MAE) of 0.239, and root mean square error (RMSE) of 0.383 for Log BCF and $R^2$ of 0.943, MAE of 0.253, and RMSE of 0.386 for Log C, respectively. Soil pH and PFAS carbon chain length are identified as key predictors for Log BCF and soil PFAS concentration and growth-cycle duration for Log C. Root and leaf tissues are the primary compartments of PFAS accumulation within plants, exhibiting the highest BCF and concentration levels. Plant roots accumulate high levels of both long-chain and short-chain PFAS, whereas above-ground tissues (particularly leaves) favor the uptake and accumulation of short-chain PFAS. Notably, this chain-length selectivity was most pronounced at soil pH < 6, with BCF for long-chain PFAS in above-ground tissues dropping markedly. At soil pH > 6, the BCF range across all chain lengths narrowed among all tissues. We then retrained the XGBoost model with the 10 most influential predictor ($R^2$ > 0.95) to predict carrot root concentrations of 1051 PFAS in 11 soils. Carrot roots generally have greater Log C in alkaline soils (e.g., Alfisols) than in acidic soils (e.g., Mollisols). The number of fluorine atoms in PFAS negatively correlates with Log C, which is most pronounced in alkaline soils. These findings could help develop management and mitigation strategies to decrease PFAS accumulation in food crops and dietary exposure to humans.

## ABSTRACT

Beyond compositional changes, antibiotics may disrupt microbial interaction networks and functional capabilities that underpin plant health and soil ecosystem services. Understanding functional responses to pharmaceutical stress is critical for assessing agricultural sustainability and food security risks. This study examined how antibiotic exposure affects bacterial co-occurrence networks, functional diversity, and predicted metabolic capabilities across the plant-soil continuum. Following lettuce cultivation in sulfamethoxazole (SMX) or trimethoprim (TMP) amended soil (3 mg $kg^{-1}$), we constructed co-occurrence networks using Spearman correlations ($|\rho| > 0.6$, $P < 0.05$) and predicted functional capabilities using FAPROTAX with custom mappings for antibiotic resistance, pathogen potential, and plant-beneficial functions. Effect sizes (Cohen's d) quantified biological significance beyond statistical differences, while functional diversity metrics assessed metabolic potential across compartments and treatments. Network analysis revealed that antibiotic pressure reduced bacterial connectivity and complexity, with control communities exhibiting ~50 nodes and ~160 edges compared to ~40 nodes and ~120 edges in SMX-treated soils. Despite structural simplification, positive co-occurrences dominated across all networks (~115 positive vs ~25 negative links), indicating maintained cooperative interactions. Functional diversity showed significant compartment effects (Shannon $P = 0.0017$; richness $P = 0.0039$; evenness $P = 0.016$), with endosphere communities exhibiting 25-30% lower functional diversity than bulk soil. Critically, antibiotic treatments selectively enriched xenobiotic degradation ($P = 0.042$) and secondary metabolism pathways, particularly in bulk soil, without systematically increasing pathogen-associated functions. Effect size analysis demonstrated that while antibiotic and organic compound degradation showed large biological effects (Cohen's $d \geq 0.8$), core plant-beneficial functions, including growth promotion, biocontrol, and nitrogen cycling, remained stable with negligible to small effect sizes. Risk assessment revealed that pathogen-related functional shifts, though statistically significant, represented minimal biological changes. Plant-associated bacterial communities demonstrate remarkable functional resilience through spatial organization, maintaining critical ecosystem services despite antibiotic-induced network disruption and compositional shifts. The selective enrichment of degradation pathways suggests microbiome-assisted mitigation potential for pharmaceutical residues. These findings support the development of compartment-targeted strategies to enhance agricultural sustainability under increasing pharmaceutical pressure.

# Spatial Compartmentalization Overrides Antibiotic Effects in Shaping Plant-Associated Bacterial Communities: Insights from the Lettuce Microbiome

**Oluwaseyi S. Olanrewaju[1*], Karabo Tsholo[1], and Cornelius C. Bezuidenhout[1]**

[1] *Unit for Environmental Sciences and Management, North-West University, Potchefstroom Campus, Private Bag X6001, 2520, Potchefstroom, South Africa*

*olusam777@gmail.com

**ABSTRACT**

Agricultural antibiotic contamination threatens crop productivity through disruption of beneficial plant-microbe associations. While antibiotic impacts on the soil microbiome are documented, the extent to which spatial compartmentalization across the plant-soil continuum buffers these effects remains poorly understood. This study investigated how bacterial community assembly patterns differ across bulk soil, rhizosphere, and endosphere compartments under environmentally relevant antibiotic exposure. Lettuce seeds were planted in soil amended with sulfamethoxazole (SMX) or trimethoprim (TMP) at 3 mg $kg^{-1}$, representing realistic agricultural concentrations. Full-length 16S rRNA gene sequencing (Oxford Nanopore Technologies) was performed on bacterial communities from bulk soil, rhizosphere, and endosphere compartments (n=45 samples across five treatments). Community structure was analyzed using alpha/beta diversity metrics, differential abundance analysis (ALDEx2, ANCOM-BC), and random forest machine learning classification. Result showed spatial compartmentalization emerging as the dominant driver of bacterial community structure, significantly exceeding antibiotic treatment effects (PERMANOVA: compartment $R^2 = 0.189$, $P = 0.001$; treatment $R^2 = 0.145$, $P = 0.139$). Endosphere communities exhibited substantially reduced alpha diversity compared to bulk soil and rhizosphere (Chao1 $P = 0.0001$), with distinct taxonomic signatures. Gammaproteobacteria dominated endosphere assemblages (up to 82.9% relative abundance in controls), while Alphaproteobacteria and Actinobacteria prevailed in soil compartments. Random forest classification achieved higher accuracy for distinguishing spatial compartments than antibiotic treatments, with *Methyloceanibacter superfactus* and Rhizobiaceae species serving as key discriminatory taxa. Core microbiome analysis revealed compartment-specific enrichment patterns: *Stenotrophomonas* (endosphere, ~0.9% abundance), *Microbacterium* (bulk soil), and *Herbaspirillum* (rhizosphere), with these patterns remaining stable across antibiotic treatments. Differential abundance analysis identified 68 ASVs significantly associated with compartment identity (FDR < 0.05), while treatment comparisons yielded minimal significant differences. Plant-mediated spatial filtering represents the primary mechanism structuring bacterial communities, effectively buffering core microbiome composition against pharmaceutical pressure. These findings suggest that compartment-specific microbiome management strategies may enhance agricultural resilience to emerging antibiotic contamination while maintaining beneficial plant-microbe associations critical for sustainable crop production.

*xuzhilia@msu.edu

## ABSTRACT

Biosolids generated from municipal wastewater treatment plants (WWTPs) are a major point source of per- and polyfluoroalkyl substances (PFAS) to the agricultural environments. PFAS compounds are considered the major class of contaminants of emerging concern; the occurrence and fate of PFAS in municipal wastewater treatment processes remain inadequately studied. In this study, we collected sludge and biosolids samples from twelve WWTPs across the United States and conducted target analysis for 43 PFAS chemicals using liquid chromatography coupled to tandem mass spectrometry using the modified EPA 1633 method. The sludge samples were separated into solid and liquid fraction and analyzed PFAS in each fraction. The highly hydrophilic PFAS such as short-chain PFAS were frequently detected in the liquid fraction while the more hydrophobic PFAS compounds were predominantly presented in the solid fractions. The total PFAS concentration ranged from 93 to 297 ng/g in the sludge samples and from 135 to 491 ng/g in the biosolids samples. PFAS distribution profiles in sludge/biosolids samples showed that the precursors including polyfluoroalkyl phosphate diesters (diPAP), perfluorooctane sulfonamidoacetic acids, and fluorotelomer carboxylic acids (FTCA) contributed approximately 90% of total PFAS, whereas legacy PFAS chemicals accounted for only a small fraction. Furthermore, our results demonstrated that the conventional sludge treatment processes such as anaerobic digestion followed by dewatering processes cannot remove PFAS effectively. In most WWTPs, elevated PFAS levels were observed in the biosolids samples which could be attributed to the reductions in biomass, biotransformation of precursor compounds and the changes in sorption capacity after the treatment processes. Significant variations in PFAS composition were found in sludge samples, but such variations were less pronounced for the PFAS in biosolids samples, which could be attributed to the similar treatment processes in WWTPs selected in this study.

**ABSTRACT**

Brominated flame retardants, represented by decabromodiphenyl ether (BDE-209), are widely accumulated in soils contaminated by electronic waste; however, the microbially driven transformation processes in soil environments remain poorly understood. Although previous studies have shown that some cultivable microorganisms are capable of debrominating BDE-209 and eventually utilizing it, integrated in situ multi-omics evidence linking contaminant removal with functional gene expression of uncultured soil microorganisms is still lacking. Here, soil microcosm incubation experiments were established using electronic waste–contaminated soils collected from Taizhou and Guiyu, amended with BDE-209, and monitored over a 90-day period for BDE-209 residues and bromide release, together with 16S rRNA gene amplicon sequencing, metagenomic, and metatranscriptomic analyses to characterize microbial responses. The results showed that BDE-209 was substantially degraded in both soils, with removal efficiencies of 77% and 74%, respectively, accompanied by continuous bromide release. Throughout the incubation, microbial community richness decreased significantly, and community composition exhibited pronounced stage-dependent successional patterns. In the later stages, lower-brominated polybrominated diphenyl ether congeners accumulated, resulting in increased overall toxicity potential and concurrent declines in microbial metabolic potential and transcriptional activity. Integrated multi-omics analyses indicated the involvement of debrominating microorganisms and their syntrophic partners, supporting a community level degradation mechanism whereby BDE-209 undergoes stepwise debromination by debrominators, followed by secondary transformation of lower brominated products by cooperative heterotrophic microorganisms. Overall, this study elucidates the microbially mediated degradation processes and mechanisms of BDE-209 in contaminated soils, offering mechanistic insight relevant to the management and remediation of brominated flame retardants at impacted sites.

# Soil Biogeochemical Responses to Acid Mine Pollutants in Coal-Mined Inceptisols of Assam, India

**Lumbini Kalita[1], Dr Bhabesh Gogoi[2]**

*[1]PhD Scholar, Department of Soil Science, Assam Agricultural University, Jorhat, Assam*

*[2] Scientist, Department of Soil science, Assam Agricultural University,Jorhat, Assam*

*E-mail Address: lumbini_k27@yahoo.com

**ABSTRACT**

Open-cast coal mining generates substantial acid mine pollutants that disrupt soil biogeochemical functioning, particularly in the strongly acidic Inceptisols of Assam, India. Exposure of pyrite-bearing strata enhances Acid Mine Drainage (AMD), leading to mobilization of sulphates, sulphides, and trace metals that alter nutrient cycling, microbial processes, and soil structure. This study examined soil responses across four mining-related land-use stages namely CI (active mining), CII (5-year recovery), CIII (10-year recovery), and CIV (uncontaminated control) in paddy-growing landscapes affected by coal extraction. Soil acidity was most severe in CI, where surface soil pH averaged 3.79 and subsurface pH 3.72, gradually improving toward CIV (5.31 and 5.25, respectively). Organic carbon increased from 0.83% (CI) to 1.25% (CIV), accompanied by progressive increases in total and available Nitrogen, Phosphorus, and Potassium. Secondary nutrients also recovered, with Calcium rising from 2.20 to 4.49 mg/kg and Mg from 1.02 to 1.98 mg/kg.AMD signatures were evident in Sulphur fractions. Sulphate-S decreased from 7.13 mg/kg in CI to CIV with landscape redistribution, while sulphide-S declined sharply from 1.88 mg/kg (CI) to 0.20 mg/kg (CIV), reflecting oxidation of reduced sulphur minerals. Trace metals displayed clear pollutant gradients from CI to CIV, confirming strong metal mobilization under acidic conditions and gradual stabilization during recovery. Biological indicators revealed depressed activity near active mining areas. Soil microbial biomass carbon increased from 182.75 mg/kg (CI) to 237.50 mg/kg (CIV), with Urease and Phosphomonoesterase activities showing similar improvements. Bacterial and fungal populations recovered significantly across the sequence. Bulk density decreased from 1.66 to 1.25 g/cm³, reflecting structural regeneration and organic matter buildup. Overall, the study demonstrates that acid mine pollutants exert strong control over soil biogeochemical processes in coal-impacted Inceptisols. While natural recovery enhances chemical, biological, and physical properties, persistent acidity and metal loads remain critical constraints, highlighting the need for targeted soil remediation strategies.

**ABSTRACT**

Antimicrobial resistance (AMR) is a global health threat requiring a One Health approach across human, animal, and environmental sectors. Bacterial extracellular vesicles (BEVs) are membrane-bound particles secreted by bacteria that are capable of carrying genetic cargo. In previous research, we demonstrated the ubiquitous presence of BEVs in different environmental habitats, including dust, soil, and wastewater. Our results showed that BEVs serve as vectors for a large number of antibiotic resistance genes (ARGs), conferring resistance to diverse classes of antibiotics. In this study, we focus on agricultural soils as a direct One Health interface, investigating ARG profiles in BEVs from a long-term field experiment in which agricultural soils were managed using different fertilization regimes involving farmyard manure. Following the purification of the BEV fraction, we found the particle concentrations ranging from $1.45 \times 10^6$ to $2.23 \times 10^7$ particles/g soil. Metagenomic sequencing revealed that BEVs were predominantly released by the phyla *Pseudomonadota*, *Actinomycetota*, and *Bacteroidota*, which also represent the dominant phyla in the soils. Furthermore, these BEVs carried 12 types and 48 subtypes of ARGs, as well as mobile genetic elements and virulence factors, with profiles remaining consistent across soils treated with different fertilization regimes. These findings emphasize the importance of further investigating the role of BEVs in disseminating AMR in environmental microbiomes. Due to their ubiquitous presence and specific properties, BEVs may play a pivotal role in the dissemination of AMR across One Health sectors.

# Biotransformation of tire-derived 6PPD and 6PPD-Q and metabolism alteration in rice plants under different exposure routes

**Jinlin Jiang[1*], Li Li[2], Tao Long[1], Si Luo[2],**

[1] *Nanjing Institute of Environmental Science of the Ministry of Ecology and Environment, Nanjing, China*

[2] *Hunan Agricultural University, Changsha, China*

*jjl@nies.org

**ABSTRACT**

The tire-derived rubber antioxidant 6PPD is widely present in various environmental media, and the environmental toxicity of its oxidation product, 6PPD-Q, has attracted increasing attention. As one of the most extensively cultivated food crops, the uptake and biotransformation, of 6PPD/6PPD-Q, as well as their induced metabolism alteration in rice remains unclear. This study simulated two exposure pathways—root and foliar—along with two contaminants via hydroponic experiments to investigate the absorption, metabolism, and underlying mechanisms of 6PPD/6PPD-Q in rice. The results indicated that rice can take up 6PPD/6PPD-Q through both root and foliar pathways. After foliar uptake, reverse translocation occurred, leading to significant accumulation of 6PPD and 6PPD-Q in both roots and leaves. Under root exposure, the biotransformation of 6PPD and 6PPD-Q was dominated by quinone degradation, dealkylation, and hydroxylation, whereas foliar exposure resulted in a higher proportion of conjugated metabolites. Molecular docking further confirmed that 6PPD/6PPD-Q can stably bind to metabolic enzymes such as CYP450, UGT, GST, and CarE. Root exposure to 6PPD and 6PPD-Q significantly enhanced the activities of metabolic-related enzymes (CYP450, GST, UGT, CarE) in rice roots and up-regulated associated genes (CYP86A1, CYP72A17, GSTU6). Foliar exposure also activated defense mechanisms in rice. Untargeted metabolomics revealed that 6PPD and 6PPD-Q markedly perturbed amino acid metabolism, the TCA cycle, lipid metabolism, and nucleotide metabolism in rice. Specifically, energy supply and glutathione (GSH) synthesis were inhibited in roots, while membrane lipid and nucleic acid metabolism were impaired. In leaves, compensatory defense was achieved through enhanced TCA cycle activity, GSH synthesis, and unsaturated fatty acid production. Metabolic remodeling was more pronounced under root exposure compared to foliar exposure, and 6PPD-Q exhibited higher toxicity. This study systematically elucidates the uptake and metabolic patterns of 6PPD/6PPD-Q in rice under different exposure routes and highlights that foliar exposure represents a non-negligible risk pathway in agricultural scenarios.

**ABSTRACT**

Antibiotic resistance genes (ARGs) have been recognized as emerging contaminants that can enter the human food chain via manure-amended agricultural soils. However, the migration of manure-derived ARGs in the soil–vegetable system and effective mitigation strategies remain unclear. Here, carrot and pakchoi were used as model vegetables to a) quantify human exposure to ARGs via vegetable consumption, and b) develop soil- and leaf-based interventions to control ARG dissemination.

High-throughput qPCR showed that manure application markedly promoted ARG enrichment in the carrot rhizosphere and tubers. ARG abundance, diversity and bioaccumulation factors were higher in leaves than in tuber tissues, and manure increased the bioaccumulation of multiple ARGs and mobile genetic elements (MGEs) in tubers. Carrots grown in manured soil could deliver up to ~$10^7$ ARG copies per person per day, while peeling carrots reduced ARG and MGE intake by up to 91% and 59%, respectively.

To mitigate antibiotic and ARG burdens in soil, a biochar-based biofilm (BB) carrying antibiotic-degrading bacteria was introduced into antibiotic-contaminated soils. BB accelerated sulfadiazine and trimethoprim dissipation and, after initial fluctuations, decreased the relative abundance and diversity of soil ARGs, particularly among antibiotic-degrading microorganisms, while limiting the introduction of exogenous ARGs and reducing pathogenic taxa.

To interrupt external ARG transfer routes, a magnetic biochar/quaternary phosphonium material (MBQ) was applied as a foliar spray on pakchoi. MBQ reshaped the phyllosphere community, inactivated antibiotic-resistant bacteria and reduced the abundance of high-risk human pathogens and ARGs on leaves; subsequent water washing further removed residual ARGs.

Overall, this work reveals the enrichment and transfer of manure-derived ARGs in the soil–vegetable continuum and proposes BB- and MBQ-based strategies that jointly target soil and phyllosphere pathways, providing technical support for controlling antibiotic resistance dissemination through vegetable production.

## ABSTRACT

The combustion of biomass and fossil fuels releases vast amounts of carbon into the atmosphere, leading to global climate change. Up to 27% of these released carbon is retained as black carbon rather than emitted as greenhouse gasses. As an essential source of the natural dissolved organic matter (DOM), biochar-derived dissolved organic matter (BDOM) plays a vital role in the photodegradation of organics; however, there is rare information about the BDOM-induced photodegradation mechanism of clindamycin (CLM), one of the widely used antibiotics. CLM was shown to be degradable by a combination of zerovalent iron, $H_2O_2$ and ultrasonication, while the photodegradation mechanism of CLM by BDOM is still largely unknown.

Herein, we discovered BDOM-generated reactive oxygen species (ROS) stimulated CLM photodegradation. Hydroxy radical (•OH) could directly attack CLM by OH-addition reaction, the singlet oxygen ($^1O_2$) and superoxide ($O_2^{\bullet-}$) contributed to the CLM degradation by transforming to •OH. In addition, the binding between CLM and BDOMs inhibited the photodegradation of CLM by decreasing the concentration of freely dissolved CLM. Binding process inhibited CLM photodegradation by 0.25-1.98% at pH 7.0 and 6.1-41.77% at pH 8.5. These findings suggest that the photodegradation of CLM by BDOM is simultaneously regulated by the ROS production and binding effect between CLM and BDOM, benefiting the exact evaluation of the environmental impact of BDOMs.

**ABSTRACT**

Pesticide residues in soils are an environmental concern that requires special attention due to their potential impacts on ecosystems and public health risk, especially in agricultural and urban areas. Different studies have been conducted to understand the occurrence and persistence of pesticide residues, primarily in similar land uses. Studies conducted under varying land-use and intensity conditions are scarce. In this context, this study aimed to assess the impact of land use on pesticide occurrence and to determine whether land use intensity influences pesticide occurrence. Soil samples were collected across five European biogeographical regions and countries: Alpine (Switzerland), Atlantic (NW Spain), Boreal (Latvia), Continental (West Germany), and Mediterranean (NE Spain). Five different land use types were selected in each biogeographical region: agricultural and seminatural (all regions), mining (4 regions), wetland, urban and forest (3 regions), and industrial uses (2 regions). Within each land use and region, three intensity levels were selected, ranging from the most degraded to the least degraded condition. Ten composite soil samples (each composed of five points) were collected from the 0-20 cm soil depth using the LUCAS methodology, resulting in a total of 770 soil samples for each combination of land use and intensity. Seventy-two pesticide residues were analyzed using the QuEChERS method for the determination of pesticide residues in foods of plant origin and adapted to measure pesticide residues in soil samples. The determination of multi-pesticides residues was carried out by UPLC-MS/MS and GC-MS/MS. At least one pesticide residue was detected in 318 samples (41% of the analyzed samples), with pesticide amounts ranging from 1 to 6633.8 ng/g. By land use, pesticide residues have not been detected in industrials land uses, whereas they are frequently found in urban and agricultural uses (except in the Boreal region). At least 25 pesticide residues or their metabolites were detected, with the most common residue (>5% occurrence) being Hexachlorobenzene (19%), p,p`-DDE (11.8%), Methyl parathion (11.3%), Tebuconazole (6.62%), Boscalid (6.5%) and o,p-DDT+p,p`-TDE (DDD) (5.8%). Although DDT-related pesticides were banned several decades ago in Europe, they appear in different study areas and land uses, highlighting their persistence over time. Further assays will focus on the analysis of glyphosate-related compounds and the risk assessment analysis of the studied samples, as well as the potential risk to inhabitants.

**ABSTRACT**

Sulfamethoxazole (SMX) is a frequently detected sulfonamide antibiotic in surface and groundwater, raising environmental concerns about its fate. Oxidative treatments, such as persulfate application, are commonly used for micropollutant removal. To investigate and differentiate SMX transformation by various radicals from other SMX dissipation processes using multi-element compound specific isotope and transformation products (TP) analysis, SMX transformation experiments were conducted using heat-activated persulfate at pH 3, 7, and 10. SMX hydroxylamine (TP269a) and TP178 were identified as the dominant transformation products across all pH levels. The exclusive formation of 4-nitroso-SMX, 4-nitro-SMX, and TP518 at pH 3 highlighted the role of $SO_4^{\bullet-}$ in attacking the amino group. At pH 7 and pH 10, 3A5MI emerged as the dominant TP. Normal carbon isotope fractionation ($\Delta\delta^{13}C$ from 1.9‰ to 2.3‰), with consistent isotopic values across pH levels, was attributed to the formation of TP178, which involves C-S bond cleavage. An inverse nitrogen isotope fractionation at pH 3 ($\varepsilon_N = +0.68 \pm 0.11$‰) was linked to $SO_4^{\bullet-}$-induced single-electron transfer, leading to the formation of N-centered SMX radicals. Conversely, normal nitrogen isotope fractionation at pH 10 ($\varepsilon_N = -0.27 \pm 0.04$‰), was associated with multiple bond cleavages, including N-H bond cleavage initiated by H ABSTRACTion through HO• and N-S bond cleavage leading to the formation of 3A5MI. The inverse nitrogen isotope fractionation observed at pH 7 indicated that the dominant pathway involved $SO_4^{\bullet-}$ reactions, accounting for 76% of the overall transformation. Overall, the results highlight the potential of CSIA to elucidate SMX persulfate oxidation pathways and evaluating the natural attenuation of SMX through radical reactions in aquatic systems.

# Fluorinated Pesticides Pose Emerging Global Environmental Risks

**Yunqiao Zhou[1*], Zihao Sun[1], Yanming Li[1], Xiaoping Wang[1]**

## ABSTRACT

Ensuring food security remains one of the major global challenges. To sustain crop productivity, pesticides have become widely adopted in modern agriculture as highly effective chemical tools. Among them, fluorinated pesticides now account for more than half of newly registered pesticides worldwide, owing to the incorporation of fluorinated functional groups that enhance biological efficacy and chemical stability. However, the increasing reliance on these compounds occurs against a broader backdrop of rising chemical pollution, which has been linked to the transgression of Earth's planetary boundary associated with novel entities. Despite their extensive use, understanding of the environmental fate, transformation processes, and long-term ecological consequences of fluorinated pesticides remains limited.

Here, we synthesize current knowledge on fluorinated pesticides from a life-cycle perspective, encompassing their historical development, mechanisms of action, environmental fate, degradation pathways, and toxicological effects. Available evidence indicates that fluorinated pesticides exhibit substantial mobility across environmental compartments, including soil, freshwater, atmosphere, and biota, allowing transport beyond treated agricultural areas at regional to global scales. Environmental transformation through hydrolysis, photolysis, and biodegradation leads to the formation of diverse degradation products, some of which persist in the environment and exhibit toxicities comparable to or greater than those of the parent compounds. Toxicological studies demonstrate that fluorinated pesticides pose disproportionate risks to non-target organisms, particularly insects and aquatic species. Reported adverse effects include neurotoxicity, endocrine disruption, reproductive impairment, and immunotoxicity, indicating a potential for ecosystem-level impacts.

Special attention is highlighted to the debated formation of trifluoroacetic acid (TFA), an ultra-short-chain per- and polyfluoroalkyl substance increasingly detected in global water resources. Experimental evidence suggests that TFA formation from fluorinated pesticides is highly compound-specific and dependent on degradation pathways, indicating that current global mass-balance estimates may overestimate their contribution to environmental TFA burdens. This uncertainty highlights the need for improved mechanistic understanding and internationally harmonized monitoring strategies.

Overall, the frequent occurrence of trifluoromethyl-containing structures among highly toxic pesticides underscores a fundamental trade-off between chemical design for agricultural efficacy and long-term ecological safety. By integrating fragmented evidence into a unified global framework, this work identifies key knowledge gaps related to metabolite toxicity, chronic low-dose exposure, and cumulative multi-stressor effects across ecosystems. These findings emphasize the importance of evaluating fluorinated pesticides not only as local agricultural inputs, but also as globally relevant stressors within coupled food, environment, and health systems, thereby informing sustainable pesticide development and international risk governance.

**ABSTRACT**

Antimicrobial resistance is recognized as a major global public health challenge. In addition to antibiotics, non-antibiotic antimicrobial agents that are ubiquitous in the environment may also exert selective pressure on microbial communities; however, their environmental occurrence and resistance risks have long been underestimated. In this study, we integrated high-resolution mass spectrometry with machine learning to develop an intelligent screening framework for antimicrobial chemicals in soil matrices. An interpretable graph neural network was constructed to predict the antimicrobial activity of industrial chemicals, outperforming conventional models across multiple evaluation metrics and enabling efficient identification of potential non-antibiotic antimicrobial agents from large chemical inventories. Guided by model predictions, suspect and nontarget mass spectrometric analyses were subsequently applied, allowing high-throughput identification of diverse antimicrobial compounds in environmental samples, including antibiotics, disinfectants, and their transformation products. Overall, this data-driven approach substantially enhances the discovery efficiency of antimicrobial contaminants and provides a novel tool for systematically assessing the potential contribution of non-antibiotic antimicrobials to environmental antimicrobial resistance, thereby supporting the prioritization and risk assessment of emerging contaminants.

**ABSTRACT**

The widespread use of antibiotics in livestock poses environmental and public health risks due to their persistence in manure. This study examined the fate of Tylosin (100, 700 mg $kg^{-1}$), Enrofloxacin (29, 200 mg $kg^{-1}$), and Oxytetracycline (229, 1600 mg $kg^{-1}$) in cattle manure under aerobic incubation for 110 days, and their impacts on microbial communities and associated $CH_4$ and $N_2O$ emissions. Antibiotics were quantified by LC-MS/MS, and microbial DNA analyzed via shotgun metagenomics. All antibiotics showed biphasic degradation, with rapid loss in the first 21 days: Tylosin degraded most (99.0%), followed by Enrofloxacin (83.4%) and Oxytetracycline (73.3%). Microbial community alpha diversity was stable, but shifts were separated primarily by antibiotic class. Treatment explained ~21% of between-sample variation ($p = 0.001$). Concentration explains an additional ~3%. False Discovery Rate-corrected correlations linked functional groups to greenhouse gas fluxes: *Pseudomonadota* and *Bacteroidota* were positively associated with both gases, $CH_4$ ($\rho$=0.51) $N_2O$ ($\rho$=0.47). *Ignavibacteriota* showed the strongest positive associations, $CH_4$ ($\rho = 0.62$), $N_2O$ ($\rho = 0.61$), whereas *Planctomycetota* were negatively associated ($\rho = –0.85$), and *Verrucomicrobiota* $\rho$=-0.31. There was a temporal recomposition from *Proteobacteria* to *Bacteroidota* modulated by the treatments. Methanogens were more evident at later storage of manure. Antibiotic residues alter microbial dynamics and functional groups linked to greenhouse gas emissions, emphasizing the need for improved manure management, including longer composting, to mitigate ecological risks.

# Adsorption of antibiotics by natural clay minerals

**Leonid V. Perelomov*, Maria M. Gertsen, Ilya V. Khaidanov, Vadim I. Sychev**

*Laboratory of Biogeochemistry, Tula State Lev Tolstoy Pedagogical University (Tolstoy University), Tula, Russia*

*perelomov@rambler.ru

**ABSTRACT**

Complex interactions between antibiotics of the tetracycline (oxytetracycline), aminoglycoside (gentamicin), amphenicol (chloramphenicol), and sulfonamide (streptocide) groups and natural bilayer (kaolinite) and trilayer (bentonite, expanded (heat-treated) vermiculite) clay minerals were studied. It was shown that clay minerals of various structures and of all groups can be effective sorbents of hydrophilic antibiotics (oxytetracycline and gentamicin).

The obtained experimental data were approximated by the Langmuir, Freundlich, and Dubinin-Radushkevich adsorption models. According to the Langmuir model, the maximum adsorption of oxytetracycline increased in the order: kaolinite < bentonite < vermiculite. The maximum Langmuir constant was characteristic of bentonite, while the minimum was for vermiculite. The maximum adsorption of gentamicin by minerals was somewhat lower in comparison with oxytetracycline, with bentonite also exhibiting the maximum binding strength. According to the Freundlich equation, the 1/n values are in the range of 0.6-0.9. The adsorption energies of antibiotics calculated using the Dubinin-Radushkevich model are less than 8 kJ/mol, suggesting that physical adsorption is predominant.

The influence of sorption solution properties: pH, ionic strength, and temperature on the adsorption of antibiotics on bentonite and kaolinite was studied. The acidity of the sorption solution is key for the adsorption of hydrophilic antibiotics, as most of their molecules have more than one ionic state, and protonation of the edge functional groups of the minerals themselves is also possible under the influence of pH. Ionic strength influences the adsorption of antibiotics on natural clay minerals at relatively high ionic strengths in solution. Competitive adsorption was more pronounced for kaolinite, which has a lower adsorption capacity. Increasing temperature from 283 to 303 K leads to a steady decrease in the maximum adsorption (Langmuir equation), indicating the exothermic nature of the sorption.

The structural changes of clay minerals under the influence of antibiotics were studied using FTIR spectroscopy and X-ray diffraction. The IR spectra of the reaction products show bands with high extinction coefficients and the highest number of identical groups in the molecule ($-CH_2-$ groups in the alkyl components of antibiotic molecules). X-ray diffraction showed that oxytetracycline at a concentration of 15 mmol/L alters the structure of kaolinite (a new peak appears). Exposure of bentonite to oxytetracycline at concentrations of 0.3-15 mmol significantly increases the basal reflex $d_{001}$.

Based on these results, practical recommendations are proposed for the use of natural clay minerals to remove hydrophilic antibiotics from contaminated water and soil solutions.

*mkjin@rcees.ac.cn

**ABSTRACT**

Worldwide, pyrethroids, such as cypermethrin, are the second most applied group of insecticides, however, their effects on the soil microbiome and non-target soil fauna remain largely unknown. Herein, we assessed the change of bacterial communities and antibiotic resistance genes (ARGs) of soil and in the gut of the model soil species *Enchytraeus crypticus* using a combination of 16S rRNA gene amplicon sequencing, and high-throughput qPCR of ARGs. Results indicate that cypermethrin exposure enriches potential pathogens (e.g. *Bacillus anthracis*) in the soil and gut microbiome of *E. crypticus*, heavily disrupting the latter's microbiome structure, and even disrupts activities of the *E. crypticus* immune system. The co-occurrence of potential pathogens (e.g. *Acinetobacter baumannii*), ARGs, and mobile genetic elements (MGEs) revealed the increased risk of pathogenicity as well as antibiotic resistance in potential pathogens. Moreover, structural equation modeling demonstrated that the dissemination of ARGs was not only promoted by MGEs, but also by the ratio of the core to non-core bacterial abundance. Collectively, these results provide an in-depth view of the previously unappreciated environmental risk of cypermethrin on the dissemination of ARGs in the soil and non-target soil fauna.

# Nationwide Screening and Priority Ranking of Plastic Additives in Agricultural Soils of China

**Jiamin Zeng [1, 2], Xiaoping Wang [1, 2, 3, *], Wenyuan Su [3, *]**

[1] *State Key Laboratory of Tibetan Plateau Earth System, Resources and Environment (TPESRE), Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China.*
[2] *University of Chinese Academy of Sciences, Beijing, China.*
[3] *College of Resources and Environmental Sciences, China Agricultural University, Beijing, China.*
*E-mail Address of Dr. Xiaoping Wang: wangxp@cau.edu.cn

**ABSTRACT**

Agricultural soils act as an important sink for plastic additives released from agricultural plastics and other anthropogenic sources; however, their chemical diversity, environmental behavior, and ecological risks remain poorly characterized at large spatial scales. In this study, a nationwide survey of agricultural soils across China was conducted to systematically identify plastic additives, characterize their environmental occurrence, investigate the drivers of their spatial distribution, assess ecological risks, and establish management priorities. An integrated "all-in-one" analytical strategy combining target, suspect, and non-target screening based on high-resolution mass spectrometry (HRMS) was employed to comprehensively capture both known and previously overlooked plastic additives in agricultural soils.

In total, 196 plastic additives belonging to 14 chemical classes were identified, including 109 confidence level 1 (CL1), 29 CL2, and 56 CL3 compounds. Among these, 86 compounds were reported for the first time in agricultural soils. Organophosphate (OPs), phenols (PHs), and phthalate esters (PAEs) dominated in both detection frequency and concentration levels. The concentrations of OPs, PHs, and PAEs ranged from 316.29–5828.54 ng/g, 83.84–14904.73 ng/g, and 15.69–14544.23 ng/g, respectively, with median values of 1000.85, 681.19, and 484.78 ng/g. Tri-OPEs and di-OPEs were the predominant OP subclasses, while hindered phenolic antioxidants occurred at substantially higher concentrations than bisphenols, indicating their strong sorption affinity and accumulation potential in soils.

At the national scale, total concentrations of plastic additives exhibited a pronounced west–east gradient, with higher levels observed in western and southwestern regions compared to eastern China. Mulched farmlands showed significantly higher additive concentrations than non-mulched soils, highlighting agricultural plastic films as a major direct source of plastic additives. Correlation analysis and Mantel tests further demonstrated that, in addition to plastic film usage and socioeconomic factors, climatic variables played a key role in controlling the spatial distribution of OPs. Solar radiation, total irradiance, sunshine duration, and relative humidity were strongly associated with OP distributions, particularly for novel organophosphate esters (NOPEs). This pattern suggests that environmental transformation processes, rather than direct emissions alone, largely govern their environmental occurrence. These results support the hypothesis that phosphite antioxidants can serve as important precursors of more stable phosphate esters through oxidative transformation in soils.

Ecological risk assessment based on mixture risk quotients indicated that plastic additives in agricultural soils pose overall medium-to-high ecological risks, with higher risk levels observed in mulched farmlands in western China. Tri-OPEs and di-PAEs were the primary contributors to mixture risks, whereas bisphenols and phenolic antioxidants generally contributed less at the national scale. Notably, novel and traditional additives exhibited comparable cumulative risk levels. A ToxPi-based prioritization approach integrating persistence, bioaccumulation, mobility, toxicity, environmental concentrations, and detection frequency identified BDtBPP, AO245, AO1076, AO1024, AO4426, AO168=O, DCHP, and DDP as high-priority substances for management. Several of these compounds—particularly novel OPEs, hindered phenolic antioxidants, and their oxidation products—are currently underrepresented in existing regulatory frameworks.

Overall, this study provides the first nationwide and systematic assessment of plastic additives in agricultural soils in China, highlights the critical role of environmental transformation processes in shaping additive profiles, and underscores the need to expand regulatory attention beyond traditional plastic additives to include emerging and transformed compounds in agricultural ecosystems.

# Effects of predator-prey interactions on driving the evolution of bacterial antibiotic resistance

**Bao-Anh Thi Nguyen [1], Ji-Zheng He [1], and Hang-Wei Hu [1,*]**

[1] *School of Agriculture, Food and Ecosystem Sciences, Faculty of Science, The University of Melbourne, Parkville, Victoria 3010, Australia*

*hang-wei.hu@unimelb.edu.au

**ABSTRACT**

Biological factors, especially predator-prey interactions, are crucial drivers of ecological processes. However, their roles in driving the evolution of antibiotic resistance, a global health concern, remain poorly understood in complex natural soil ecosystems. Predatory protists and predatory bacteria are primary bacterial predators, however, mechanisms underlying the influence of their predation on the richness and abundance of bacterial antibiotic resistance within a multitrophic soil ecosystem are still poorly known. Here, we assessed effects of soil predatory protists on predatory bacteria and antibiotic resistance genes (ARGs) across a gradient of protist concentrations under the control of bacteria's competitors – fungi. Our findings reveal that high-protist predation pressure significantly amplified the relative abundance of predatory bacteria *Streptomycetales* and *Myxococcales* between days 15 and 45 of the microcosm incubation. Aligning with a rising abundance of predatory bacteria and antibiotic-producing bacteria, the relative abundance and diversity of soil ARGs significantly increased under high protist concentrations, regardless of fungal effects. Many ARGs encoding key resistance mechanisms (antibiotic deactivation and efflux pumps) were enriched in response to predatory protists within complex inter-group interactions. Moreover, these enriched ARGs were strongly associated with both predatory bacteria and predatory protists. More profound effects of predatory protists on the predatory bacteria and soil ARGs were identified in the presence of fungi. Our study provides novel evidence about crucial effects of predatory protists on shaping the predatory bacterial community and driving bacterial antibiotic resistance under complex multitrophic interactions in a natural soil. These findings pave the way for future research aimed at mitigating this global health issue and uncovering other ecological processes.

# Mitigation of antibiotic resistance genes in agricultural soil by Fe/Mn oxides functionalized biochars via suppressing horizontal gene transfer

**Yuxin Li[1*], Mei Shi[1], Cuizhu Sun[1] and Hao Zheng[1]**

*[1] Institute of Coastal Environmental Pollution Control, College of Environmental Science and Engineering, Ministry of Education Key Laboratory of Marine Environment and Ecology, Frontiers Science Center for Deep Ocean Multispheres and Earth System, Ocean University of China, Qingdao 266100, China*

*E-mail Address of Presenting Author: 1781570143@qq.com

**ABSTRACT**

The rapid spread of antibiotic resistance genes (ARGs) in agricultural soils poses a threat to global ecological security and public health under the One Health framework. The application of biochar-based functional materials is a promising strategy for controlling biological pollutants in soils. However, the impacts of Fe/Mn oxides functionalized biochars (Fe/Mn-MBCs) for controlling ARGs in agricultural soils is still unknown. Therefore, the effects and mechanisms of Fe/Mn-MBCs on the abundance of ARGs and mobile genetic elements (MGEs) in agricultural soils were investigated via a 60-day microcosm experiment, combined with plasmids-mediated conjugation and natural transformation models. The results showed that Fe/Mn-MBCs significantly reduced total ARGs abundance by 20.95–42.94%, following the order MnBC > FMBC > FeBC. MGEs abundance decreased by 10.60–40.80% and showed positive correlations with ARGs, indicating that the reduced ARG pollution was achieved by Fe/Mn-MBCs weakening MGE-mediated horizontal gene transfer (HGT). Specifically, Fe/Mn-MBCs effectively inhibited bacterial conjugation (53.26%–66.11%) by decreasing cell membrane permeability, disrupting energy metabolism, and suppressed transformation (39.08%–76.06%) by adsorbing extracellular ARGs (eARGs) to reduce bioavailability, primarily due to the presence of oxygen-containing functional groups and Fe/Mn oxides ($Fe_3O_4$, $Mn_3O_4$, $MnO_2$) on biochar surfaces. Moreover, Fe/Mn-MBCs enhanced microbial diversity and niche filtering, consequently inhibiting ARG-hosting bacteria by 23.80–50.80%. Structural equation model analysis demonstrated that MGE-mediated HGT was the primary driving factor in the mitigation of soil ARG pollution by Fe/Mn-MBCs. These results demonstrate that Fe/Mn-MBCs effectively mitigate soil ARGs by inhibiting HGT, offering insights for the practical application and rational design of functionalized biochars as an in-situ remediation strategy against soil ARG pollution.

**ABSTRACT**

Microfibre pollution is of growing global concern [1]. One of the main ways microfibres are released into the environment is from textile laundering via waste-water treatment plants (WWTP) into rivers and waterways [2]. However, microfibres are also introduced to terrestrial environments as in these WWTP, microfibres also make their way into sewage sludge, which is then applied to agricultural land as fertiliser [3]. Therefore, further work is needed into the impact of microfibres in soil environments.

In addition, microfibres are often categorised as part of the microplastic problem, however, studies have shown that cotton microfibres are the most prevalent in the environment [4]. These non-plastic microfibres often have chemical dyes and finishes applied during manufacturing so pose a potential risk to soil environments [5]. Despite this, existing research is more focussed on plastic microfibres resulting in a gap in research into impact of non-plastic microfibres such as cotton and wool.

This project aims to investigate the impact that decomposition of plastic and non-plastic microfibres, dyed and undyed, have on soil environments. A textile biodegradation experiment has been set up comparing dyed and undyed cotton and wool (examples of non-plastic textile microfibres) alongside virgin polyester, recycled polyester from polyethylene terephthalate (PET) bottles and recycled polyester from sea waste (examples of plastic textile microfibres). These textile samples (5 x 5 cm squares) and soil samples are being monitored over 18 months using Pyrolysis-GC-MS and LC-MS to trace chemical changes over time, as well as monitoring impacts to soil properties and soil function. Here we present preliminary data, focussing on the changes to textile and soil properties after 6 months.

# Ecological Risks of Antibiotic Residues and Bioremediation in Agricultural Soils

**Lixia Zhao*, Zheng Pan, Side Yang, Chenxi Lu, Chang Lu**

Agro-Environmental Protection Institute, Ministry of Agriculture and Rural Affairs, Tianjin 300191, China
*E-mail Address: zhaolixia@caas.cn

**ABSTRACT**

After nearly a decade of investigation into antibiotics in the agricultural soils of the North China Plain, tetracyclines (TCs) and quinolones were identified as the dominant antibiotics, exhibiting the highest detection frequency and concentrations, which ranged from 1.62 to 4238 μg·kg$^{-1}$. Notably, the concentrations of tetracycline metabolites (MTCs, particularly the 4-epimers of TCs) in soil were nearly equivalent to those of the parent compounds. Long-term manure application was found to contribute to the accumulation of TCs in soil, with higher antibiotic levels observed in greenhouse soils compared to open-field soils. Elevated antibiotic concentrations in soil tended to reduce microbial diversity and alter the structure and composition of soil microbial communities. An antibiotic resistome emerged in soils where antibiotic residues exceeded 300 μg·kg$^{-1}$. Based on a weighted comprehensive pollution index and risk quotient assessment, high ecological risk was identified in 9 out of 32 soil samples, while the remaining 23 samples posed a medium ecological risk. Laboratory-controlled experiments demonstrated that TCs and their 4-epimers (MTCs) are interconvertible in soil. Given their significant conversion potential to TCs, slow degradation rates, and potential impacts on soil microbes and antibiotic resistance genes (ARGs), the environmental risk posed by TC 4-epimers cannot be overlooked. Two ecologically distinct earthworm species—the epigeic *Eisenia fetida* and the endogeic *Metaphire guillelmi*—significantly accelerated the degradation of both TCs and MTCs in soil. *Eisenia fetida* notably promoted the proliferation of the degradation gene *tetX*, whereas *Metaphire guillelmi* enhanced interspecific relationships among soil microorganisms. In general, earthworm amendment improved the bioaccessibility of TCs and stimulated indigenous microbial activity, thereby facilitating TC degradation. Furthermore, earthworm addition reduced interspecific bacterial interactions and the relative abundance of mobile genetic elements (MGEs), which contributed to limiting the dissemination of ARGs. Additionally, earthworm application substantially mitigated the accumulation and transmission risk of antibiotics and ARGs from soil to lettuce. Collectively, these findings enrich the existing database, provide a scientific References for controlling antibiotic contamination in agricultural soils, and offer a cost-effective bioremediation strategy to address antibiotic and ARG pollution, thereby helping to ensure vegetable safety and human health.

## ABSTRACT

Pharmaceutical pollution has always been a grave concern in global hydro-geosphere regions especially in emerging economies like India, China, Brazil, and Russia where there is a mismatch between the application and development of pharmaceuticals coupled with their effective removal strategies using advanced technologies.[1] Sulfamethoxazole (SMX), a sulfonamide antibiotic and ciprofloxacin (CIX), a fluoroquinolone group antibiotic have been recognized to exert negative effects on soil and water due to its mobility and widespread usages globally but particularly in India.[2] This current study investigated the removal of SMX and CIX with biochar (pine needle derived) material (0.05g, 0.125 g and 0.25 g) mixed with 5g soil. The Brunauer-Emmett-Teller (BET) method and surface morphological analysis, using a field emission scanning electron microscope (FE-SEM), revealed a porous biochar surface whereas energy-dispersive X-ray spectroscopy (EDS) analysis showed the co-existence of different minerals (i.e. Ca, S, K, Fe and Si) indicating the suitability of biochar materials as antibiotic sequestration agents from the soil solution. Changes in peaks were observed after SMX and CIX adsorption through Fourier transform infrared (FT-IR) and Raman spectroscopic measurements suggesting the involvement of chemisorptions for the removal mechanism. Batch sorption studies were performed to optimize experimental parameters for maximum removal of SMX and CIX. The shaking time was about 24 hrs with the equilibrium attained at 600 min. The samples were taken at time intervals of 0, 30, 60, 120, 240, 360, 480, 600 and 1440 minutes. Maximum removal (>65%) of SMX and CIX was observed for pine needle biochar and soil mixture at 50 µg $L^{-1}$ initial concentration of antibiotics, 25±2°C temperature, and 600 min contact time. Among the different adsorbent dosages, 0.25g for biochar was selected as an optimum dosage (maximum adsorption capacity ≈ 188 µg $g^{-1}$). The Langmuir isotherm ($R^2$>0.97) and pseudo-second order kinetic model ($R^2$>0.92) supported the data of SMX and CIX adsorption onto biochar. The adsorption with adsorbent concentration of 0.05g and 0.125g were <40% of maximum adsorption capacity. The SMX and CIX removal can be facilitated through different mechanisms like charge/ion-dipole interaction, pore-filling, Vander Waals interaction, electrostatic interaction and pi-pi interactions.

## ABSTRACT

Antimicrobial resistance (AMR) has emerged as one of the most pressing global public health and environmental challenges, particularly in low- and middle-income countries where antibiotic use in human medicine and livestock production is intensive and poorly regulated. A substantial proportion of administered antimicrobials is excreted unchanged or as active metabolites and subsequently released into soils and aquatic environments through manure application, wastewater discharge, and irrigation practices. Once introduced into the environment, antibiotics may persist, undergo transformation, or be remobilized, while simultaneously exerting selective pressure on microbial communities that promotes the emergence and dissemination of antibiotic-resistant bacteria (ARB) and antimicrobial resistance genes (ARGs). These processes are especially dynamic in tropical agroecosystems, where high temperatures, strong seasonal rainfall, and fluctuating soil moisture strongly influence soil biogeochemical processes.

Vietnam represents a regional hotspot for environmental AMR due to high antibiotic consumption, dense human and animal populations, and limited wastewater treatment infrastructure. In peri-urban areas of Hanoi, agricultural production systems are closely connected to polluted rivers receiving untreated domestic, hospital, and livestock effluents. Thanh Tri district, located along major river systems, was selected as a pilot site to assess both the prevalence of environmental AMR and the underlying environmental behavior of antibiotics. Household surveys indicated that approximately 38% of households had used antibiotics for human treatment and 44% for animal production, suggesting continuous and diffuse antibiotic inputs into surrounding soils and water bodies.

To characterize environmental reservoirs of AMR, a total of 180 samples from household and geographic environments (including soil, sediment, groundwater, wastewater, and river water) were collected and analyzed for indicator bacteria listed under the Global Antimicrobial Resistance and Use Surveillance System (GLASS). Escherichia coli, Salmonella spp., and Staphylococcus aureus were detected at prevalences of 33.3% (95% CI: 23.9–44.1), 15.6% (95% CI: 9.1–25.0), and 12.2% (95% CI: 6.6–21.2), respectively. Molecular analysis revealed widespread resistance determinants, with sulfonamide resistance genes (sul1–sul3) present in approximately 14.52% of isolates. Resistance genes associated with aminoglycosides (20.13%), beta-lactams (16.17%), tetracyclines (13.2%), chloramphenicols (12.28%), and colistin (0.99%) were also detected. Antibiotic-resistant E. coli was the most prevalent, followed by Salmonella spp. and S. aureus, highlighting the role of river-connected agricultural landscapes as environmental reservoirs of AMR with potential implications for human and animal health.

To mechanistically link antibiotic residues with environmental AMR, a lysimeter-based field experiment was conducted to investigate the fate of sulfamethoxazole (SMX), a widely used sulfonamide antibiotic frequently detected in Vietnamese environments. The experiment was carried out using a tropical soil and lettuce (Lactuca sativa) as a representative leafy vegetable. SMX concentrations were monitored in soil and plant tissues over a 56-day cultivation period, while air temperature, relative humidity, and rainfall were continuously recorded.

SMX exhibited a pronounced biphasic dissipation pattern in soil. During the initial phase (0–7 days), more than 95% of extractable SMX was lost, with estimated half-lives of approximately 1.3–1.5 days. This rapid decline is attributed to strong sorption to soil constituents, rapid microbial or abiotic transformation, and redistribution from the readily extractable pool. In the intermediate phase, non-monotonic behavior was observed, with temporary rebounds in SMX concentrations following rainfall and periods of high humidity. These fluctuations indicate climate-driven desorption and remobilization processes that can temporarily increase SMX bioavailability. During the late phase, SMX concentrations declined again, reaching less than 1–2% of the initial input by the end of the experiment.

Compound-specific stable carbon isotope analysis (CSIA, $\delta^{13}C$) was applied to distinguish microbial transformation from physical redistribution processes. Trace levels of SMX were detected in lettuce roots and edible tissues throughout the cultivation period. Although concentrations in plants were low, $\delta^{13}C$ signatures confirmed soil to water transfer of SMX or its transformation products, highlighting a potential pathway for chronic low-level human exposure. Isotopic fractionation observed in soil samples further indicated ongoing microbial transformation and partial incorporation of SMX-derived carbon into soil organic matter.

By integrating environmental surveillance of ARB and ARGs with field-scale investigations of antibiotic fate, this study demonstrates that tropical soil–water–crop systems function as dynamic interfaces linking antibiotic inputs, climate-driven soil processes, and environmental AMR. Climatic variability modulates antibiotic persistence and remobilization, thereby influencing selective pressure on environmental microbial communities. These findings underscore the importance of coupling antibiotic fate studies with resistance monitoring within a One Health framework to improve risk assessment and inform sustainable management strategies for agricultural and river-connected systems in tropical regions.

**ABSTRACT**

South Korean agriculture has an extreme phosphorus (P) imbalance, with much greater amounts of phosphate fertilizer added to the land than is removed in crops. This imbalance has caused P to accumulate in soils to high concentrations throughout the nation. Reservoirs and rivers across South Korea are eutrophic and suffer from annually from toxic algal blooms, while dead zones are increasingly common in coastal areas around the country. South Korea uses a unique soil P test method – a modification of the Lancaster P test – which complicates comparison with other world regions. However, conversion of thousands of Lancaster P values from the Korean national soil inventory to Olsen P indicates that South Korean soils contain on average the highest soil test P levels in the world. As a result, most soils in the national inventory exceed recommended P levels for optimum crop growth, particularly for upland soils under plastic-film house agriculture. Estimation of the risk of P loss to water using break point analysis indicates that available P in most upland soils exceeds the point at which P leaching increases strongly. This value is comparable to the recommended soil test P levels for most crops, limiting opportunities to reduce environmental risk by drawing down legacy P. However, assessment by sequential fractionation, $^{31}$P NMR spectroscopy, and XANES spectroscopy indicates that the chemical nature of the accumulated P varies depending on soil pH and land use, offering opportunities for developing targeted drawdown strategies. Given the extremely high national P imbalance, widespread accumulation of legacy P, and pervasive eutrophication, South Korea must urgently develop novel long-term strategies to reduce agricultural P inputs and reduce legacy P while simultaneously maintaining crop productivity and improving soil and environmental health.

# Ligand-to-Metal Charge Transfer Driven Transformation of Ferrihydrite and its Effect on Arsenic Repartitioning

**ABSTRACT**

Ferrihydrite, a poorly ordered metastable iron oxide, is closely associated with dissolved organic matter (DOM) in soils and sediments. Although sunlight-induced photoreductive dissolution of ferrihydrite via ligand-to-metal charge transfer (LMCT) process has been extensively studied, its potential impacts on mineralogical transformation and environmental behaviors of coexisting contaminants remain largely unknown. Here, we systematically investigated effects of environmental parameters (e.g., solution pH, $pO_2$ level, arsenic speciation and content) on ferrihydrite transformation with the representative DOM-oxalate under simulated solar irradiation. Results showed that oxalate-mediated LMCT process synchronously initiated Fe(II) production and solution deprotonation, the latter of which facilitated interfacial electron transfer-atom exchange (IET-$AE_{Fh\text{-}Fe2+}$) process among ferrihydrite and newly formed Fe(II). At pH 5.0-8.0, ferrihydrite was prone to transform into goethite due to appropriate degree of both $LMCT_{oxa}$ and IET-$AE_{Fh\text{-}Fe2+}$ processes, while it only underwent reductive dissolution at pH 3.0-5.0 or kept a steady state over pH 8.0. Increasing $pO_2$ level and arsenic content hampered the recrystallization of ferrihydrite, whereas the presence of As(III/V) also led to the formation of lepidocrocite with As(V) being more prominent. Additionally, chemical extraction and As *K*-edge EXAFS spectroscopy revealed that As was consecutively incorporated into the structures of goethite and lepidocrocite in the form of As(V) regardless of primary As speciation. These findings shed novel insights into low-crystalline iron oxide transformation and element migration driven by sunlight in natural environments.

[3] *University of Chinese Academy of Science, Beijing 100049, China*
*f.wang@iaea.org

**ABSTRACT**

Microplastics are pervasive contaminants across environmental and food systems, threatening ecosystem integrity and human health. This talk outlines the Joint FAO/IAEA Centre of Nuclear Techniques in Food and Agriculture of International Atomic Energy Agency's (IAEA) coordinated response, which mobilizes nuclear and isotopic techniques, capacity building, and international collaboration to generate actionable evidence and practical solutions. The IAEA employs unique nuclear tools—such as isotope tracing, neutron activation, and radiation-assisted sample preparation—to advance source-to-sink understanding and harmonize measurements alongside conventional analytical workflows. Through its global networks, the IAEA supports method development, proficiency testing, and integrated monitoring that links microplastics surveillance with nutrient, contaminant, and antimicrobial resistance tracking. Beyond detection, the IAEA promotes radiation processing (gamma/electron beam) to enhance plastic circularity and reduce microplastic loads in wastewater and sludge. The presentation also highlights a case study, investigating micro-nanoplastics (MNPs) and phthalate esters (PAEs) in agricultural systems. Using lettuce as a model, the research combined fluorescence labeling, microscopy, transcriptomics, and metabolomics to examine uptake pathways and molecular responses to sub-microplastics (SMPs) and co-contamination with di(2-ethylhexyl) phthalate (DEHP). Key findings show that SMPs are absorbed and translocated within plants, altering gene expression and metabolism. Positively charged SMPs caused greater toxicity than negatively charged ones. Notably, DEHP exhibited antagonistic—not synergistic—effects, reducing SMP accumulation and alleviating oxidative stress and soil microbial disruption. The talk presents new evidence on microplastic fluxes in food webs, results from harmonization efforts and Member State case studies, and a forward agenda linking nuclear science, standardized monitoring, and circular economy solutions to measurable risk reduction. By integrating rigorous analytics with deployable technologies, the IAEA assists countries in translating science into effective policy and practice.

**ABSTRACT**

The fate of antimicrobials in farm ecosystems and the related risks of antimicrobial resistance (AMR) have attracted global attention. In our study, sulfamethoxazole (SMX) was selected as a model to systematically study its migration, transformation mechanisms, and AMR characteristics using various stable isotope techniques. First, Compound-Specific Isotope Analysis (CSIA) was used to determine the dual-element fractionation of 13C and 15N during degradation. This approach clarified the variations in natural degradation pathways and reaction mechanisms of SMX across different soils. Subsequently, a specifically synthesized 13C10-SMX was utilized as a tracer. Through isotope tracing, we measured the transfer and distribution of SMX in the soil-lettuce system, while also revealing its driving effects on the propagation of AMR. Furthermore, using Stable Isotope-Assisted Untargeted Metabolomics (SIAM), we tracked the 13C-label to identify both endogenous and exogenous metabolites of SMX within the complex plant matrix. Finally, using DNA-Stable Isotope Probing (DNA-SIP), we identified specific soil microbes and antibiotic resistance genes (ARG) stimulated by organic fertilizer that actively assimilate 13C-SMX. By linking environmental fate with microscopic metabolic mechanisms, this study constructs a comprehensive “Pollutant-Metabolite-Functional Microbe” network. These findings provide a robust scientific basis for the monitor, control, and risk assessment of antimicrobials and AMR in agricultural environments.

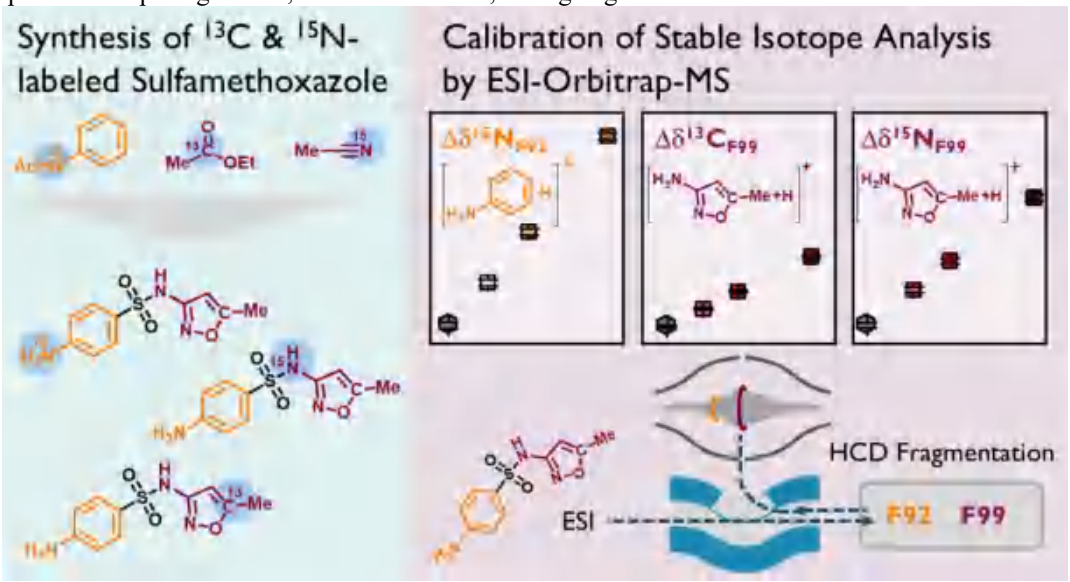
# Synthesis and isotope analysis of labelled sulfamethoxazole to trace persistence and natural degradation in the field

**Aoife Canavan[1], Christopher Dirr[1], and Martin Elsner[1*]**



[1] *Chair of Analytical and Water Chemistry, Technical University of Munich, Garching, Germany*

*m.elsner@tum.de

## ABSTRACT

The widespread presence of pharmaceuticals, including the widespread antimicrobial sulfamethoxazole (SMX), in our aquatic environment raises important societal concerns. Stable isotope techniques offer two powerful avenues to study their fate and degradation. **First, isotope-labeled antimicrobials** can be applied in realistic field settings. This enables the distinction between previous contamination of the target antimicrobial and the freshly introduced label, and can trace the flux of stable isotopes into the biomass of actively degrading microorganisms. **Second, stable isotope analysis at natural abundance** offers unique insight into source fingerprinting. Changes in these isotope values are further an indicator of natural degradation, as they are the result of degradation-associated kinetic isotope effects. Both approaches can, therefore, deconvolve changes in concentrations that are caused by degradation from those changes that are brought about by repetitive application or remobilization.

**To support the first approach**, we synthesized fully $^{13}C$-labelled sulfamethoxazole (SMX) for a concerted effort within the CRP D15022_AMR of the International Atomic Energy Agency (IAEA), to study the fate of this antimicrobial in actual field experiments. In parallel, **in support of the second approach** we synthesized compound-specific References standards to enable electrospray ionization (ESI) Orbitrap mass spectrometry as novel approach for fragment-specific carbon and nitrogen isotope analysis ($Dd^{13}C$ and $Dd^{15}N$) of SMX at natural isotopic abundance. Fragment-specific isotope analysis relied on fragmentation of SMX ions in the collision cell, forming two fragment ions representing the aniline part (m/z = 92, F92) and the 3-amino-5-methylisoxazole ring (m/z = 99, F99) of SMX. References materials were prepared (i) through total synthesis of SMX from labelled precursors that resulted in specific positions labeled with $^{13}C$ and $^{15}N$, (ii) followed by the mixing of labeled SMX with SMX at natural abundance. The bulk isotope values of these in-house standards were determined by elemental analysis isotope ratio mass spectrometry and used for calibration of the ESI-Orbitrap method. Injecting standards directly into the Orbitrap resulted in 95% confidence intervals (CIs) 0.7‰ and 3.4‰ for $Dd^{13}C$ and $Dd^{15}N$ in F92, respectively, and 1.3‰ and 2.9‰ for $Dd^{13}C$ and $Dd^{15}N$ in F99 for quintuplicate measurement of standards. A proof-of-principle demonstration shows that this approach could indeed successfully quantify changes in fragment-specific isotopic signatures, $Dd^{13}C$ and $Dd^{15}N$, during degradation of SMX.

## ABSTRACT

Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants of increasing global concern. However, PFAS contamination data for Northwest China remain limited, and ecotoxicological effects of emerging alternatives on soil organisms are largely unknown. This study addresses these gaps through systematic PFAS characterization across industrial parks in Shaanxi Province, China, combined with the first comprehensive toxicity assessment of the PFOS alternative F-53B (Cl-PFESA) in *Eisenia fetida*.

**Environmental Survey:** Soil sampling across three industrial sectors revealed distinct contamination profiles. Fluorosilicone manufacturing exhibited PFOA-dominated pollution (11.9–65.9 ng/g; >90% PFOA), textile finishing showed moderate short-chain perfluorocarboxylic acid contamination (<1–26.1 ng/g), and electroplating sites displayed the highest levels (6.2–412.6 ng/g), with PFOS and F-53B collectively accounting for >60% of total PFAS. F-53B was detected at all electroplating sites (10–70% composition), reflecting its widespread use as chromium mist suppressant.

**Toxicity Assessment:** Acute exposure (14 d) induced dose-dependent mortality with $LC_{50}$ of 465.4 mg/kg. Sublethal exposure caused significant histopathological alterations and oxidative stress. Molecular docking revealed stable F-53B binding to SOD (−7.7 kcal/mol) and AChE (−11.0 kcal/mol), corroborating observed enzyme inhibition.

Chronic exposure at environmentally relevant concentrations (10–5000 ng/g; 28 d) revealed non-monotonic reproductive toxicity. Cocoon production declined by 50% at 100 ng/g but recovered to 120% of controls at 5000 ng/g. Transcriptomic profiling identified concentration-dependent mode switching: "active defense" at 100 ng/g with detoxification upregulation (GST↑, TPMT↑) but reproductive suppression (HSD3B↓), versus "metabolic reprogramming" at 5000 ng/g featuring suppressed lipid catabolism (CPT1A↓, ACADVL↓), enhanced amino acid metabolism (GLS↑), and upregulated cytoskeletal proteins (ACTB↑, TUBB↑). Reproductive recovery may be associated with metabolic shifts favoring biosynthetic capacity.

**Ecological Significance:** The concentration eliciting maximum toxicity (100 ng/g) falls within ranges detected at electroplating sites, indicating current environmental F-53B levels may pose risks to soil invertebrates. This study establishes the first F-53B toxicity benchmarks for earthworms and reveals novel non-monotonic mechanisms challenging conventional dose-response assumptions.

## ABSTRACT

In the context of intensifying agricultural production and escalating environmental challenges, soil degradation has emerged as a critical global issue threatening food security and ecosystem sustainability. China, as a major agricultural nation, relies significantly on chemical inputs including pesticides to maintain crop productivity. Among these, herbicides constitute the largest segment of the global pesticide market, with triazine herbicides like prometryn being widely adopted due to their broad-spectrum weed control, cost-effectiveness, and relatively low mammalian toxicity [1-2]. However, the persistent nature of prometryn in soil ecosystems poses substantial risks to non-target organisms and soil health. As a systemic and translocative herbicide, prometryn primarily functions by disrupting photosynthetic electron transport in plants, thereby inhibiting ATP synthesis and ultimately impairing cellular functions [3-4]. Beyond its intended phytotoxic effects, prometryn residues can accumulate in soils, leading to reduced microbial diversity, altered nutrient cycling processes, and long-term degradation of soil quality.

To address these challenges, this study investigates an integrated remediation approach combining microbial augmentation with phytoremediation—a strategy that holds particular promise for sustainable soil reclamation. We focused on the interaction between *Bacillus proteolyticus* strain 4-7, a plant-growth-promoting rhizobacterium with demonstrated biofertilizer potential [5], and alfalfa (*Medicago sativa L.*), a perennial leguminous forage renowned as the "King of Forages" for its exceptional soil-improving capabilities [6]. Alfalfa exhibits remarkable adaptability to stressed environments, with documented abilities to modify soil pH, enhance microbial activity, and facilitate contaminant immobilization [7-9]. The synergistic potential of combining these biological agents for remediating herbicide-contaminated soils represents an innovative approach to soil restoration that merits systematic investigation.

The experimental design employed soil artificially contaminated with prometryn at three environmentally relevant concentration gradients 0mg/kg,0.25mg/kg,and0.5mg/kg, reflecting both background and moderately contaminated agricultural scenarios. Three primary treatments were established: (1) prometryn-contaminated soil with alfalfa monoculture, (2) contaminated soil with both alfalfa and Bacillus 4-7 inoculant application, and (3) contaminated control soils without plants or microbial amendment. A comprehensive assessment protocol was implemented, analyzing changes in soil physicochemical properties (including pH, organic matter, total and available nitrogen, phosphorus, and potassium), key enzyme activities (catalase, urease, and sucrase) as indicators of microbial metabolic function, and microbial community structure through high-throughput sequencing approaches. This multi-faceted analytical framework enabled a holistic evaluation of remediation efficacy across chemical, biochemical, and biological dimensions of soil health.

The investigation yielded several significant findings that elucidate the mechanisms and effectiveness of this integrated bioremediation strategy:

(1) Soil Nutrient Dynamics and Fertility Enhancement: The combined Bacillus-alfalfa treatment exerted pronounced effects on soil nutrient status under prometryn stress. While organic matter content exhibited a gradual decline with increasing herbicide concentration—likely reflecting initial microbial stress—specific nutrients demonstrated optimized accumulation patterns at different contamination levels. Total phosphorus 0.35g/kg, total nitrogen 1.35g/kg, and nitrate nitrogen reached maximal concentrations at 0.25 mg/kg prometryn, suggesting that low-level contamination may initially stimulate certain nutrient mobilization processes. At 0.5 mg/kg prometryn, total potassium and ammonium nitrogen peaked, indicating the system's capacity to maintain potassium cycling and ammonium retention even under moderate stress. Notably, available phosphorus achieved its highest level at 1.0 mg/kg prometryn, revealing a potentially hormetic response where moderate contamination stimulates phosphorus solubilization mechanisms. Comparative analysis against control soils revealed statistically significant improvements: total potassium increased substantially ($P < 0.01$), ammonium nitrogen rose by 89.61%, and organic matter content enhanced by 55.62%. Simultaneously, soil pH decreased by 5.66% ($P < 0.01$), shifting toward more neutral conditions favorable for nutrient availability and microbial activity. When compared to alfalfa monoculture, the interactive treatment further boosted total potassium by 102.99% and organic matter by 22.79%, with total nitrogen increasing up to 164.86% in specific treatments. These findings collectively demonstrate that the plant-microbe partnership not only counteracts herbicide-induced nutrient depletion but actively enhances soil fertility parameters beyond what either component achieves independently.

(2) Soil Enzyme Activity and Biochemical Functionality: Enzymatic assays provided insights into the treatment effects on soil biochemical processes. During alfalfa germination, catalase activity—which decreased progressively with rising prometryn concentration in control soils—was effectively maintained in the interaction treatment, indicating improved oxidative stress mitigation. Urease activity, relatively stable in contaminated controls, showed significant enhancement following combined remediation, suggesting stimulated nitrogen transformation pathways. Most remarkably, sucrase activity not only increased substantially in treated soils but exhibited a positive correlation with prometryn concentration, implying that the remediation system may upregulate carbon cycling processes in response to contaminant challenge. These enzymatic responses collectively indicate that the Bacillus-alfalfa system preserves and even enhances the metabolic capacity of soil microbiota under herbicide stress, maintaining critical nutrient cycling functions that are often impaired in degraded soils.

(3) Microbial Community Restructuring and Functional Recovery: Microbial diversity analysis revealed temporal dynamics in community responses. Initial contamination stages maintained relatively high diversity, but prolonged prometryn exposure under natural attenuation reduced diversity and compromised ecosystem functions. Alfalfa planting alone significantly reversed this trend, restoring microbial richness and evenness compared to natural attenuation controls. The addition of Bacillus 4-7 introduced further modulation, increasing community variability but also enhancing the relative abundance of key functional taxa. Proteobacteria and Sphingomonas emerged as consistently dominant groups across treatments, with the latter—known for its aromatic compound degradation potential—showing particular enrichment in remediation groups. Statistical analysis revealed significant positive correlations between Sphingomonas abundance and soil $NO_3^-$-N and available potassium $r=0.69, P<0.05$, suggesting functional coupling between this bacterial group and nutrient mobilization processes. Venn diagram analysis indicated that phytoremediation treatments reduced the number of unique operational taxonomic units (OTUs) while increasing shared community members, promoting a more homogeneous and functionally integrated microbial assemblage. This community restructuring appears driven by altered rhizosphere chemistry, with remediation treatments creating nutrient conditions that selectively enrich beneficial bacterial lineages while suppressing non-functional or stress-sensitive taxa.

The implications of these findings extend beyond prometryn remediation to broader applications in soil reclamation practice. The demonstrated capacity of this plant-microbe system to simultaneously address multiple aspects of soil degradation—contaminant stress, nutrient imbalance, pH extremes, and microbial dysfunction—aligns with the integrated approach needed for effective soil restoration. Specifically, the treatment's ability to enhance potassium and nitrogen retention while reducing pH addresses common limitations in degraded agricultural soils. The stimulation of enzyme activities and functional microbial taxa suggests restored biochemical cycling capacity. Perhaps most significantly, the promotion of a more homogeneous, functionally coherent microbial community represents a shift toward more resilient soil ecosystems capable of maintaining functions under stress.

In conclusion, this study provides compelling evidence that the synergistic interaction between *Bacillus proteolyticus* 4-7 and alfalfa constitutes an effective, ecologically sound strategy for remediating prometryn-contaminated soils and mitigating associated degradation processes. The approach enhances soil fertility parameters, preserves critical enzymatic functions, and restores functional microbial community structure through targeted enrichment of beneficial taxa. These findings advance our understanding of plant-microbe partnerships in contaminated environments and offer a practical, sustainable methodology for soil reclamation that aligns with contemporary priorities in sustainable agriculture and environmental management. Future research should explore field-scale applications, long-term stability of observed improvements, and potential extensions to other herbicide classes and degradation scenarios to further validate and expand the utility of this promising bioremediation strategy.

## ABSTRACT

Antibiotic resistance is currently an unfolding global crisis threatening human health worldwide. While antibiotic resistance genes (ARGs) are known to be pervasive in environmental media, the occurrence of antibiotic resistance at interfaces between two or more adjacent media is largely unknown. Here, we designed a microcosm study to simulate plastic pollution in paddy soil and used a novel method, stimulated Raman scattering coupled with deuterium oxide ($D_2O$) labelling, to compare the antibiotic resistance in a single medium with that at the interface of multiple environmental media (plastic, soil, water). Results revealed that the involvement of more types of environmental media at interfaces led to a higher proportion of active resistant bacteria. Genotypic analysis showed that ARGs (especially high-risk ARGs) and mobile genetic elements (MGEs) were all highly enriched at the interfaces. This enrichment was further enhanced by the co-stress of heavy metal (arsenic) and antibiotic (ciprofloxacin). Our study is the first to apply stimulated Raman scattering to elucidate antibiotic resistance at environmental interfaces and reveals novel pathway of antibiotic resistance dissemination in the environment and overlooked risks to human health.

# Pollution characteristics, sources and risk assessment of per- and polyfluoroalkyl substances (PFASs) in river water, sediments, soils of the Inner Mongolia Section of the Yellow River

**Mao Wang[1,2], Xuehui Xu[1,2*]**

*[1] College of Resources and Environmental Sciences, Inner Mongolia Agricultural University, Inner Mongolia Key Laboratory of Soil Quality and Nutrient Resource, Hohhot 010018, China*

*[2] Key Laboratory of Agricultural Ecological Security and Green Development at Universities of Inner Mongolia Autonomous Region, Hohhot 010018, China*

*E-mail address: xhxu@imau.edu.cn

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFASs) are persistent contaminants that can accumulate in aquatic and terrestrial compartments, yet integrated evidence across water–sediment–soil continua remains limited for major river basins. This study investigated 17 PFASs in surface water, riverine sediments and riparian soils along the Inner Mongolia reach of the Yellow River during wet and dry seasons, aiming to characterize multi-media occurrence, seasonal patterns and potential sources, and to evaluate ecological and human health risks. PFASs were ubiquitous in all media and exhibited pronounced spatial and seasonal heterogeneity. In surface water, $\Sigma_{17}$PFASs ranged from 11.0–68.5 ng/L in the wet season and 9.5–95.3 ng/L in the dry season, indicating higher overall contamination during low-flow conditions; perfluorooctanoic acid (PFOA) and perfluorobutyric acid (PFBA) were dominant compounds. Sediments contained 185.9–723.3 pg/g dry weight (dw) $\Sigma_{17}$PFASs, with PFOA contributing 23.6–35.6%. Riparian soils showed 94.6–1071.6 pg/g dw $\Sigma_{17}$PFASs, dominated by long-chain PFASs (40.44–45.88%). The relative contribution of PFAS precursors in soils was higher in the wet season (28.39%) than in the dry season (17.01%), implying enhanced terrestrial inputs and transformation potential under rainy conditions. Source apportionment indicated mixed anthropogenic influences, with major contributions linked to aqueous film-forming foams (AFFF), metal plating, product manufacturing and other urban–industrial activities, alongside inputs associated with agricultural practices and consumer products. Risk assessment revealed that sedimentary PFOA posed the highest ecological concern (risk quotient, RQ=0.225, medium risk), whereas human health risks via drinking water and grain intake were low (hazard quotient, HQ<0.2). These findings indicate that PFASs in sediments from certain sections of the Yellow River in Inner Mongolia pose ecological risks to the environment. It is recommended that industrial source control and process barrier measures be prioritized in hotspot areas within the Yellow River basin.

*E-mail Address of Yanyan Wang: sxauwyy0811@163.com
Keywords: phenanthrene, persulfate, Schwertmannite, *Brassica parachinensis*

## ABSTRACT

**Introduction**

Phenanthrene contamination in soil poses a serious threat to agroecosystems and food safety. While persulfate-based advanced oxidation processes have garnered significant attention for efficiently degrading organic pollutants—particularly with iron-based catalysts like zero-valent iron and $Fe^{2+}$—this study innovatively employs a Schwertmannite-activated persulfate system. The research aims to: (1) systematically evaluate the degradation efficiency of phenanthrene in soil, and (2) investigate the mechanism by which this system inhibits phenanthrene uptake in crops, using *Brassica parachinensis* as a model. This work is expected to provide a novel strategy for remediating phenanthrene-contaminated farmland, one that simultaneously removes pollutants and mitigates food safety risks.

**Methods**

Schwertmannite was synthesized according to the method of Liu et al.[2]. A pot experiment was conducted, in which the concentrations of Schwertmannite, persulfate, and phenanthrene were set at 1 g/kg, 200 mg/kg, and 20 mg/kg, respectively. Soil samples were collected every five days. The contents of phenanthrene in the soil extracts were analyzed by gas chromatography-mass spectrometry.

**Results**

In this study, we explored the degradation efficiency of phenanthrene in soil using a Schwertmannite-activated persulfate system and evaluated the ability of the treatment to limit phenanthrene uptake and accumulation in *Brassica parachinensis*. As shown in Fig.1, the system which added schwertmannite and persulfate together achieved a phenanthrene removal rate of 86.2% after 5 days, while all other treatments were lower than 31.9%. The concentration of phenanthrene in *Brassica parachinensis* exhibited notable variations across different treatments (Fig.2). The lowest phenanthrene accumulation across all plant tissues was consistently observed in the treatment where both persulfate and Schwertmannite were applied together.

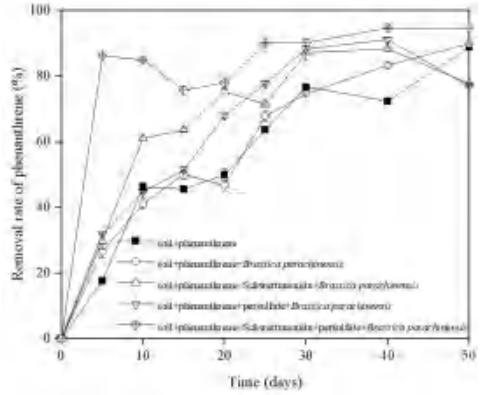

Fig.1. Dynamics of Phe under different treatments

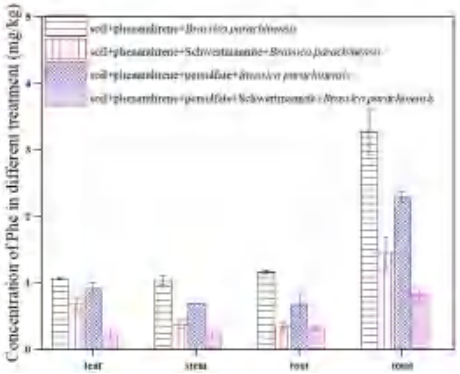

Fig.2. Migration of Phe in leaf, stem, and root of Bok choy

**Conclusion**

The combined application of Schwertmannite and persulfate rapidly degraded phenanthrene in the contaminated soil, thereby effectively preventing its uptake and accumulation by *Brassica parachinensis*.

## ABSTRACT

The extensive use of agricultural plastic films has led to increasing contamination of farmland soils with emerging pollutants such as microplastics (MPs) and plasticizers. However, the environmental behavior of these co-occurring pollutants and their interactions remain poorly understood. In this study, we investigated the environmental behavior of the plasticizer Di(2-ethylhexyl) phthalate (DEHP) in two typical Chinese agricultural soils (Chao soil and red soil), along with the effects and potential mechanisms of environmentally relevant polyethylene microplastics (PE-MPs) on the fate of DEHP. Using $^{14}$C-isotope tracing techniques, we first examined the mineralization, extractable residues, and non-extractable residues (NERs) of DEHP in aerobic farmland soils. Our results demonstrate that DEHP's environmental behavior is governed by soil properties (e.g., pH, organic matter, and clay content) and its inherent characteristics. In active soils, DEHP showed high mineralization and extractable residues, with relatively stable non-extractable residues (NERs), indicating significant short-term environmental risk. Over time, however, the locked NERs showed instability, suggesting potential long-term environmental risks. Compared to chao soil, red soil exhibited lower mineralization and higher extractable residues of DEHP, indicating higher bioavailability and persistence of DEHP in red soil, which may pose greater environmental risks. Furthermore, we explored the impact of PE-MPs on the environmental fate of DEHP and the possible mechanisms involved. Critically, the presence of PE-MPs significantly altered DEHP's fate. Sorption-desorption experiments revealed that PE-MPs have a higher affinity for DEHP (log Kd: PE-MPs > red soil > chao soil). In soil, PE-MPs reduced DEHP mineralization and NER formation while increasing its extractable residues, thereby enhancing bioavailability and immediate environmental risk. Notably, PE-MPs influenced DEHP fate primarily in sterilized soils and delayed the formation of stable, locked NERs. This study provides novel insights into the co-fate of MPs and plasticizers, revealing that MPs can remobilize aged organic pollutants and increase their bioavailability. These findings are crucial for developing scientifically sound risk assessment frameworks and effective pollution control strategies for composite pollution in agricultural ecosystems.

**ABSTRACT**

An in-depth understanding of the sorption behaviors of per- and polyfluoroalkyl substances (PFAS) in soil is essential to assess their environmental risks accurately. Due to chemical industry production and waste treatment, co-contamination soil of heavy metals (HMs)-PFAS has become a public concern worldwide. This study investigated soil sorption and transport behaviors of PFAS including perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), and perfluorohexanesulfonic acid (PFHxS) under coexisting As5+/Cd2+.

Combining batch experiments, column tests, and Hydrus-1D modeling, the sorption isotherms and transport dynamics of PFAS were examined. PFAS sorption affinity followed the order: PFOS > PFOA > PFHxS, while the opposite order was observed for desorption and transport rates. A multiple linear regression (MLR) model was developed to predict the soil sorption of PFOS. Validation results demonstrated that this model could effectively predict the distribution coefficients ($K_d$) of PFOS based on soil organic carbon (OC), silt, clay, and Fe oxide contents, exhibiting a strong predictive ability ($r^2 = 0.942$, $p < 0.001$). In raw soils, $As^{5+}$ and $Cd^{2+}$ influence three anionic PFAS sorption primarily by altering the electrostatic and hydrophobic interactions between soil components and PFAS. The $K_d$ values of PFOS tend to rise with increasing $Cd^{2+}$ concentration but decline with increasing $As^{5+}$ concentration. In contrast, HMs have a relatively minor influence on the sorption of PFOA and PFHxS. Subsequently, a nonlinear model was constructed for the first time to quantify the impact of HMs on PFAS sorption, achieving exceptional prediction accuracy when applied to both experimental data from this study and literature data. In column tests, the breakthrough curves (BTC) of PFOA and PFHxS are generally symmetric, but the BTC of PFOS displays a nonideal transport. Critically, $As^{5+}$ accelerated PFOS transport by 9.4-34.9% through pH-induced repulsion and site competition, while $Cd^{2+}$ enhanced PFOS retention by 61.6-86.8% through electrostatic attraction and cation bridging. Furthermore, multiple PFAS transport datasets were used to validate a mathematical model incorporating advection-dispersion and chemical nonequilibrium sorption, and the model was applied for the first time to simulate the PFAS transport in the saturated zone affected by HMs. Long-term simulation (50 years) showed that $As^{5+}$ accelerates PFOS migration to groundwater (5 m), whereas $Cd^{2+}$ restricts its penetration to a depth of 0.2 m. Given weak sorption, PFOA and PFHxS quickly leach downward and threaten groundwater safety within 10 years. This study developed predictive frameworks for PFAS sorption, transport, and risk assessment in industrial sites, enhancing priority management and remediation strategies based on the characteristics of co-contaminants to protect the soil environment and groundwater sources.

**ABSTRACT**

Ex-situ thermal desorption (ESTD) has been widely applied in the remediation of organically contaminated sites in China due to its high treatment efficiency. However, this technology relies on continuous heating and is therefore highly energy-intensive, attracting increasing attention to its carbon emissions. To identify the key environmental burden of soil remediation and support green and sustainable remediation, this study developed a full-process carbon accounting framework for ESTD based on engineering practices in China. Based on data from 210 ESTD cases from 2011 to 2025 in China, the primary sources, spatiotemporal patterns, and future mitigation potential of carbon emissions from ESTD were systematically analyzed. Results showed that ESTD consumed 2200–4300 MJ per cubic meter of soil treated, and the thermal treatment stage accounted for 83.77% of total carbon emissions. Over the past 15 years, ESTD in China generated a total of 1.98 Mt $CO_2$. Temporally, national carbon emissions of ESTD experienced four stages: initial development, rapid expansion, high-level fluctuation, and gradual stabilization. Spatially, high-emission areas were concentrated along the Yangtze River Economic Belt and expanded from the middle and lower reaches to the upper reaches. Mitigation potential analysis further indicated marked interprovincial differences in optimal pathways. Under the combined province-specific optimal pathways, the maximum national mitigation rate of ESTD could reach 16.86% by 2035. These findings suggest that the low-carbon transition of ESTD can be better realized through region-specific strategies that consider provincial energy structures and technology suitability. This study provides important support for ensuring the safe use of soil resources and promoting the green and sustainable soil remediation.

**ABSTRACT**

Bromophenols are among the most common naturally synthesized compounds in the marine environment. Deep-sea cold seeps are potential reservoirs of microorganisms capable of degrading halogenated organic pollutants, such as 2,4,6-tribromophenol (TBP). This study investigated the microbial communities and their functional potential for TBP reductive debromination in cold seep sediments from the South China Sea. Anaerobic enrichments with TBP as the sole electron acceptor were established from sediment samples at different depths (0-150 cm). All enrichments showed debromination activity, with the 150 cm-depth culture exhibiting the highest efficiency, completely converting TBP to phenol. Metagenomic analysis revealed Pseudomonadota and Bacillota as the dominant phyla. A total of 23 high-quality metagenome-assembled genomes (MAGs) carrying reductive dehalogenase (*rdhA*) genes were recovered, all belonging to the phylum Bacillota. The most active culture also had the highest *rdhA* gene abundance and diversity. Genomic context analysis revealed structurally complete *rdh* gene clusters in several MAGs. Metabolic profiling of high-quality MAGs indicated a universal dependence on the cobalamin salvage pathway, employing BtuBFCD transporters and adenosylcobinamide-phosphate synthase, as they lack a complete *de novo* biosynthesis route. Complementary research demonstrated that nutrient optimization (e.g., lactate with yeast extract) significantly enhanced TBP degradation and enriched a key novel dehalogenator, Bin3 (Peptococcaceae), which harbored multiple, expressed *rdhA* genes. Our findings confirm the presence of diverse and novel dehalogenating microorganisms in cold seeps, highlighting their ecological role and potential application in bioremediation.

# Microbial reductive dehalogenation of emerging organohalides and its application in bioremediation

**Qihong Lu[1], Shanquan Wang[1*]**

[1] *School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, China*

*E-mail: wangshanquan@mail.sysu.edu.cn

**ABSTRACT**

Emerging organohalides, due to their persistence and lipophilic-hydrophobic characteristics, have become a significant challenge for site remediation in China. Traditional physicochemical remediation methods face limitations in terms of efficiency and sustainability, especially at industrial sites, where less disruptive and long-term stable remediation strategies are needed. Based on this, the present study developed an *in situ* microbial reductive dehalogenating remediation method and conducted a systematic investigation from three aspects: (1) Organohalide-respiring bacteria (OHRB) collection; (2) functional enhancement, and (3) engineering applications. Firstly, a dehalogenating respiratory strain collection was established by screening various environmental sources, including black-odor water bodies, landfills, salt lakes, and nearshore sediments, revealing the distribution characteristics of organohalides and their *in situ* transformation patterns in contaminated environments. Secondly, to enhance microbial activity, strategies such as growth promoters, interspecies interactions regulation, and habitat optimization were explored, effectively improving the efficiency of microbial reductive dehalogenating remediation. Finally, this technology was applied at typical polluted sites in Suzhou, Taizhou, and Shaoguan, demonstrating excellent remediation performance. This study provides a theoretical basis and technical pathway for the efficient bioremediation of emerging organohalides.

**ABSTRACT**

Soil visible and near–infrared reflectance spectroscopy is an effective tool for the rapid esti- mation of soil organic carbon (SOC). The development of spectroscopic technology has increased the application of spectral libraries for SOC research. However, the direct application of spectral libraries for SOC prediction remains challenging due to the high variability in soil types and soil–forming factors. This study aims to address this challenge by improving SOC prediction accuracy through spectral classification. We utilized the European Land Use and Cover Area frame Survey (LUCAS) large–scale spectral library and employed a geographically weighted principal component analy- sis (GWPCA) combined with a fuzzy c–means (FCM) clustering algorithm to classify the spectra. Subsequently, we used partial least squares regression (PLSR) and the Cubist model for SOC predic- tion. Additionally, we classified the soil data by land cover types and compared the classification prediction results with those obtained from spectral classification. The results showed that (1) the GWPCA–FCM–Cubist model yielded the best predictions, with an average accuracy of R2 = 0.83 and RPIQ = 2.95, representing improvements of 10.33% and 18.00% in R2 and RPIQ, respectively, compared to unclassified full sample modeling. (2) The accuracy of spectral classification modeling based on GWPCA–FCM was significantly superior to that of land cover type classification modeling. Specifically, there was a 7.64% and 14.22% improvement in R2 and RPIQ, respectively, under PLSR, and a 13.36% and 29.10% improvement in R2 and RPIQ, respectively, under Cubist. (3) Overall, the prediction accuracy of Cubist models was better than that of PLSR models. These findings indicate that the application of GWPCA and FCM clustering in conjunction with the Cubist modeling technique can significantly enhance the prediction accuracy of SOC from large–scale spectral libraries.

**ABSTRACT**

Soil organic carbon (SOC) is a critical indicator of soil health and carbon cycling, essential for sustainable agricultural development and climate change mitigation. Visible near-infrared reflectance spectroscopy (vis-NIR) technology combined with machine learning models has shown potential for rapid and accurate SOC prediction. However, due to significant spatial heterogeneity in SOC distribution across different regions, global models based on soil spectral libraries (SSLs) often lack sufficient generalization capability for local applications. To address this challenge, we propose an innovative sample selection framework for instance-based transfer learning, KNN-FRSS, a forward recursive sample selection method combined with K-nearest neighbor algorithm. This framework identifies the most representative samples from the SSL for the target region using a two-step process: step 1: preliminary selection by local similarity metric, and step 2: precise selection by forward recursive sample selection mechanism, thereby enhancing the adaptability of cross-regional SOC modeling. We employed three predictive models (1D-CNN, Cubist, and PLSR) to evaluate the transferability of the KNN-FRSS strategy in cross-region modeling. In addition, we compared the performance of KNN-FRSS with another sample selection method (RS-LOCAL-v2.0) and feature-based transfer learning approach. These transfer learning methods were evaluated across four distinct regions. The results indicate that all transfer learning methods improved model predictive accuracy in four study regions. Notably, the combination of KNN-FRSS with the 1D-CNN model consistently outperformed the others. Compared to the best-performing models built using local data, this combined approach achieved an improvement in $R^2$ranging from 3% to 26%, and a reduction in RMSE by 12.82% to 43.4%. Finally, this study provides a feasible path to enhance the effectiveness of transfer learning in soil spectral modeling, and provides methodological support for rapid and high-accuracy SOC prediction across diverse geographic regions.

# Design of effective materials to collaborate with microorganisms in reductive remediation of chlorinated organic pollutants

**Jingchun Tang**[1*]

[1] *Nankai University (College of Environmental Science and Engineering, Tianjin, China)*

*tangjch@nankai.edu.cn

**ABSTRACT**

Chlorinated Organic Pollutants (COPs), due to their strong persistence, bioaccumulation, and carcinogenicity, have become a major challenge in global pollution control. Traditional chemical reduction techniques and microbial dechlorination methods, each with their own limitations, struggle to achieve efficient remediation of COPs alone. In recent years, the bio-abiotic synergistic dechlorination strategy, by integrating the advantages of abiotic catalysis and microbial metabolism, has demonstrated groundbreaking application potential. Current research primarily focuses on empirical optimization of material synthesis and its enhancement of microbial communities, lacking in-depth exploration of rational material design. Nature contains materials that promote biological dechlorination, including humus, protein-containing organic materials, and iron minerals. These naturally evolved systems over millions of years provide "natural wisdom" insights for the field of pollution remediation. Currently, nano-zero-valent iron materials are widely used in reductive dechlorination. CMC were used to enhance the stability of nZVI materials; then novel CMC-FeS@biochar was developed using biochar as carrier of iron materials to enhance the electron transfer and protect the stability of the iron materials; Furthermore, ball milling method was applied to both micro iron and pyrite to enhance their reductive ability by reducing the particle size and improving the surface activity at the same time. For improving the selectivity of the iron materials, sulfidation and nitridation were applied to change the surface properties of the iron materials, furthermore, biochar was also added as carrier to enhance the selectivity and reactivity at the same time. Finally, CMC-FeS@biochar was used for a bio-chem dechlorination process; nZVI, S-nZVI, nFe/Ni and ball milled Fe0/FeS2 was compared on their ability to enhance the microbial dechlorination; and Synergetic effect of nZVI@BMPC and sodium lactate as an external nutrient was proved to be able to achieve complete 2,4,6-trichlorophenol degradation by anaerobic sludge acclimated culture.

**ABSTRACT**

Many halogenated aromatics have been detected as contaminations in soil and groundwater, including halogenated alkenes, alkanes, aromatics and polyaromatics, some of which are highly persistent and toxic. Several organisms have been described to transform halogenated contaminants via different dehalogenation pathways. Such pathways can lead to different dehalogenation extents depending on the dominating microorganisms. In this talk I summarize our work on the biochemistry in Dehalococcoides, Dehalogenimonas, Dehalobacterium and Dehalobacter species, all able to reductively dehalogenate halogenated compounds but with important differences in the pathways and kinetics. We explore the underlying biochemistry that leads to such differential behavior to understand the processes and to be able to design a rational remediation strategy. This led to the identification of respiratory chain architectures, subunit compositions of respiratory complexes, cofactor compositions, and membrane-soluble mediators. However, we still see proteins within such dehalogenating systems which we cannot functionally describe. We now have indications that different electronic properties in the different respiratory chains lead to different enzyme mechanisms and eventually to different catalytic properties. This has major implications for the selection of treatment and enrichment conditions in situ.

# The Marine Environment as a Rich Source of Diverse Anaerobic Organohalide-Respiring Bacteria

**Max M. Häggblom**

*Department of Biochemistry and Microbiology, Rutgers University – New Brunswick, New Jersey, USA*

* haggblom@rutgers.edu

**ABSTRACT**

Organohalogen compounds are widely distributed in the marine environment as a source of both anthropogenic pollution and natural production.: polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins (PCDDs) and brominated flame retardants are common anthropogenic contaminants of aquatic sediments, while a great variety of natural organobromine compounds are produced by sponges and other organisms. Cleavage of the carbon-halogen bond is a critical step in degradation of organohalides and the natural organohalogen cycle. Organohalide-respiring bacteria, which utilize organohalides as electron acceptors for energy conservation, play an important role in the global halogen cycle. They have been identified from bacteria phyla with a wide range of halogenated substrates and can be classified as obligate or facultative depending on whether organohalide respiration is their sole energy gaining metabolism. We have enriched and isolated diverse organobromide-respiring bacteria from different marine habitats, including organohalide-contaminated sediments, pristine sites, as well as marine sponges. These bacteria utilize both organohalides and sulfate as electron acceptors for energy conservation. Reductive dehalogenase (RDase) genes and the capacity for organohalide respiration were widely distributed in members of marine *Pseudomonadota*. Novel debrominating members of the *Desulfovibrionaceae* and *Desulfuromonadaceae* families were isolated from different estuarine and marine sediments. In contrast, organobromine-rich sponges appear to provide a specialized habitat for organohalide-respiring microbes with different *Desulfobacteraceae* species responsible for reductive dehalogenation in geographically widely distributed sponge species (Atlantic, Pacific and Indian Oceans and the Mediterranean) indicating a cosmopolitan distribution. The physiology and dehalogenation range of these two bacteria were investigated, and genomes are sequenced and analyzed for their metabolic potential. The genes relevant to reductive dehalogenation were further studied to extend our knowledge on the diversity of organohalide respiration. The identification of diverse bacteria capable of organohalide respiration through functional assays and dehalogenase gene analysis extends our knowledge of their extensive distribution and diversity in the marine environment. The prevalence and diversity of *rdhA* genes in various isolates and metagenomes indicates that organohalide respiring potential is widely distributed in marine habitats. Dehalogenating members of the *Desulfovibrionaceae*, *Desulfuromonadaceae* and *Desulfobacteraceae* bacteria appear to play an important role in natural organobromide cycling with major impact on the fate of organohalide pollutants in the marine environment.

*xsong@issas.ac.cn

## ABSTRACT

This study investigated the biodegradation and defluorination potentials poly- and perfluoroalkyl substances (PFASs) by microbial communities enriched from soils collected at industrial sites contaminated with PFASs compounds. Specifically, the aerobic biodegradation of 6:2 FTS and subsequent anaerobic biotransformation of representative perfluorinated compounds, including TFA, PFOA, and HFPO-DA, were evaluated.

In the aerobic biodegradation of 6:2 FTS, an enriched microbial culture (SXC01) achieved ≥99.5% degradation of 6:2 FTS removal at initial concentrations of 0.5–5 mg/L within 14 days under sulfur-limiting aerobic conditions. The dominant strain, *Brucella anthropi* SX009, isolated from SXC01, degraded >99% of 6:2 FTS within 60 h by utilizing it as an alternative sulfur source and achieving 13% defluorination. Metabolite profiling identified 11 transformation products, including 6:2 FTCA, 6:2 FTUCA, 5:3 FTUCA, 5:3 FTCA, and terminal products PFHxA and PFHpA, indicating a stepwise oxidative chain-shortening pathway. The accumulation of 6:2 FTUCA suggests its further degradation may be rate-limiting, while the higher yield of PFHxA compared to PFBA supports the dominance of the 5:2 sFTOH degradation route. Integrated metatranscriptomic and transcriptomic analyses revealed significant upregulation of genes involved in desulfonation (e.g., *ssuEADCB*, *cysI*, *sbp*, *iscS*), defluorination (e.g., *ladA*, *dehH*, *crcB*, *dhaA*), and Fe–S cluster assembly (*suf* operon), together with increased expression of α/β-hydrolases, dehydrogenases, and oxidoreductases. Molecular docking further confirmed favorable binding of 6:2 FTS within hydrophobic or semi-polar active pockets, supporting their catalytic roles in fluorotelomer transformation.

In the anaerobic microcosm study, the defluorination of TFA, PFOA, and HFPO-DA were evaluated in 10 months of incubation experiments. The defluorination ratios of TFA, PFOA, and HFPO-DA reached 3.32%, 3.46%, and 2.15%, with their corresponding removal efficiencies of 8.03 ± 3.03%, 13.52 ± 4.96%, and 2.38 ± 0.49%, respectively. Microbial biotransformation intermediates, including TFA and PFA, were verified, and PFOA-derived metabolites PFHxA and PFHpA accumulated to 0.21 and 4.14 μg/L. Co-occurrence network analysis based on full-length PacBio amplicon sequencing showed that microbial functional modules were mainly composed of *Bacteroidetes*, *Nitrospirae*, *Acidobacteria*, and *Chloroflexi*, suggesting their involvement in anaerobic PFAS transformation.

Collectively, these findings demonstrate that indigenous microbial consortia from PFASs co-contaminated sites possess condition-dependent metabolic networks that enable highly efficient fluorotelomer degradation under sulfur limiting conditions. They also reveal that these consortia can mediate measurable anaerobic defluorination of fully perfluorinated compounds, providing a mechanistic basis for potential *in situ* bioremediation of PFASs in groundwater and soil.

# Mapping the Co-Occurrence of Organohalides and Microbial Dehalogenation: A Microbial Biochemistry Framework for One Health

**Yan He[1,2*], Shuyao Li, Meng Liu, Yifan Song**

*1 State Key Laboratory of Soil Pollution Control and Safety, Zhejiang University, Hangzhou, China*

*2 College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, China*

*E-mail Address of Presenting Author: yhe2006@zju.edu.cn

**ABSTRACT**

Organohalides are ubiquitous and persistent contaminants. Despite their widespread presence, our understanding of their global distribution, the microbial capacity for their degradation across diverse habitats, and the true associated risks—particularly from mixtures and in specific environmental contexts—remains fragmented.

We first characterized the actual contamination status of 32 COPs across diverse habitats in China, revealing their widespread occurrence with hotspots linked to anthropogenic activities. Simultaneously, using global soil metagenomes and a curated dehalogenase database, we mapped the biogeography of microbial dehalogenation traits and taxa, demonstrating that the potential for microbial dehalogenation is also widespread, reflecting the global distribution of these compounds. As the organohalide-degrading bacteria was usually hard to isolate and culture, we established a new method which integrates anaerobic culture and single-cell Raman sorting under environmental stress, enabling the efficient isolation and cultivation of functional anaerobes. Mechanistic insights from our work highlight how microbial reductive dehalogenation, a key anaerobic pathway, is intricately coupled with other biogeochemical cycles (e.g., methanogenesis), driven by complex interspecies interactions (e.g. metabolic exchange, electron transfer). Conventional single-pollutant assessments significantly underestimate the ecotoxicological risk posed by COP mixtures. This synergistic risk is particularly pronounced in anaerobic/flooded habitats (like wetlands and paddy fields), where combined COP toxicity presents moderate to high threats to sediment-dwelling organisms, potentially disrupting vital biogeochemical processes including carbon cycling.

Collectively, our findings underscore the complex interplay between pollution, microbial ecology, and environmental conditions in shaping the impact of organohalides. This integrated perspective is vital for developing monitoring, refined risk assessment frameworks, and targeted microbial bioremediation strategies under the ‘One Health’ concept.

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFAS) are persistent and bioaccumulative contaminants widely used in industrial and consumer products, posing substantial risks to ecosystems and human health. Feammox, the anaerobic oxidation of ammonium ($NH_4^+$) coupled with ferric iron (Fe(III)) reduction, is a microbial process that occurs naturally in acidic and iron-rich soils and sediments. Microorganisms associated with Feammox have recently been recognized for their potential involvement in the transformation of perfluoroalkyl acids (PFAAs).

This study evaluates the feasibility of stimulating Feammox reactions and enhancing the activity of Feammox-associated bacterial groups through the addition of $NH_4^+$ and Fe(III) to sediments collected from acidic, iron-rich sites impacted by aqueous film-forming foams (AFFF). Both batch incubations and column experiments were conducted to assess microbial and geochemical responses under static and flow-through conditions that reflect environmental processes more realistically. Quantitative PCR was used to quantify Feammox-related microorganisms and to monitor dehalogenase and fluoride-ion transporter genes. Microbial community dynamics were characterized through 16S rRNA gene sequencing.

The results indicate that supplying Fe(III) and $NH_4^+$ promoted Feammox activity and stimulated the growth of Feammox-associated bacteria. This stimulation was accompanied by enhanced transformation of perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS) in both batch and column systems. Gene-level analyses further revealed substantial presence and activity of dehalogenation and fluoride-transport markers. The findings demonstrate the potential for leveraging Feammox processes as a bioremediation strategy for PFAS-contaminated environments, particularly in geochemical settings that support Feammox metabolism.

# N-enriched biochar-iron cobalt mineral system for biomimetic reductive dehalogenation

**Weizhao Yin[1*], Yin Zhong[2], Xiaoen Li[3]**

[1] *College of Environment and Climate, Jinan University, Guangzhou 510632, China*

[2] *Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China*

*weizhaoyin@jnu.edu.cn

**ABSTRACT**

Bioreductive dehalogenation by organohalide-respiring bacteria is often limited by electron transfer efficiency and cofactor stability. We constructed a biomimetic system comprising bone char (N-enriched biochar), green rust (GR, Fe(II)-Fe(III) hydroxide), and cobalt hydroxide ($Co(OH)_2$) that outperforms microbial dehalogenation. GR serves as an Fe-S cluster mimic providing superior electron supply, while $Co(OH)_2$ forms Co-N active centers with biochar's nitrogen defects, analogous to vitamin $B_{12}$ cofactors. The layered morphology of GR and $Co(OH)_2$ enables self-assembly into heterojunctions, optimizing interfacial electron transfer. This Co-N center exhibits enhanced electron transfer compared to $B_{12}$, as confirmed by electrochemical analysis. The system not only dechlorinates trichloroethylene to acetylene but further hydrogenates it to ethylene/ethane. Quenching experiments and electrochemical tests reveal that reactive hydrogen species are not the dominant hydrogenation pathway. Instead, an electron-proton coupled transfer (EPCT) process drives both reductive dechlorination and subsequent hydrogenation. This biomimetic approach offers a robust platform for treating halogenated persistent organic pollutants.

# Demonstration Verification of Characterization Technology for DNAPLs in Typical Chemical Sites

## ABSTRACT

Dense non-aqueous phase liquids (DNAPLs), which are composed of toxic organic contaminants like chlorinated solvents, are pervasive in soil and groundwater at industrial sites worldwide. To design efficient remediation strategies, precise characterization of DNAPLs is required. Since the traditional survey methods, such as invasive borehole-based investigations suffer from limited spatial coverage, a combined approach using non-intrusive geophysical methods alongside invasive techniques has been applied to image the DNAPLs distribution. However, this integrated strategy for DNAPLs imaging is limited since there is no unified technical specification for fine characterization. Moreover, the inaccurate fusion of multi-source data introduced by invasive and non-invasive approaches cannot preserve physically realistic patterns. To address these challenges, this study demonstrates and validates a characterization technology for DNAPLs at a typical chemical site, exploring a precision investigation method for DNAPL-contaminated sites based on multi-source data fusion. In this paper, the Electrical resistivity tomography (ERT) technique is combined with Membrane interface probe (MIP) to provide reliable DNAPLs characterization in a contaminated legacy chemical site in Jiangyin. Specifically, the ERT data is used to generate conductivity tomograms that delineate the abnormal area. The MIP data provides tomograms of pollutant concentration and soil lithology. The geophysical and MIP tomograms are then integrated with borehole measurements in a deep learning-based joint inversion framework to accurately characterize the highly irregular source zone architecture and provide a refined DNAPL image. Results demonstrate the standalone conventional sampling, geophysical methods, or hydrogeochemical surveys method fail to infer the DNAPLs in typical chemical sites. In contrast, the combined geophysical methods and hydrogeochemical surveys provide the necessary information to reconstruct the large-scale features of conductivity and concentration fields, while integrating geophysical data with sparse but accurate borehole data results in a high-resolution characterization of the source zone architecture.

# Microbially mediated organohalide cycling in soil

**Shanquan WANG[1*], Qihao LI[1]**

[1] *School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, 510006*

*wangshanquan@mail.sysu.edu.cn

ABSTRACT

Microbially mediated organohalide cycling in soil have profound implications for global element cycles and climate, but the phylogeny, coding potential and distribution of the halogenation-dehalogenation cycling microorganisms remain unknown. To explore the global-scale microbially-mediated halogenation and dehalogenation cycling of organohalides in soil, we first developed an organohalide-cycling gene database (HaloCycDB) to support organohalide-cycling metagenomics analyses; then, we collected 3000 metagenomes to reveal geographic distribution of organohalide-cycling microorganisms and functional genes at the global scale; the microorganisms and genes for halogenation and dehalogenation cycling of organohalides were further catalogued to explore novel taxonomic and genetic resources; last, the 'microorganism-enzyme-organohalide' patterns for reductive dehalogenation were analyzed and confirmed with protein structure prediction, molecular docking and laboratory cultivation experiments. To the best ofour knowledge, this study provides the first insight into the halogenation and dehalogenation cycling of organohalides in soil at the global scale, which provides a roadmap for exploring global organohalide-associated bioresources.

# Organic Carbon Availability for Sulfate-Reducing Bacteria Governs the Dechlorination Reactivity of Biogenic Sulfidated Nanoscale Zero-Valent Iron

**Binbin Wang[1*], Wenbo Dong[1], and Feng He[2]**

[1] *College of Environment, Zhejiang University of Technology, Hangzhou 310014, China*

[2] *Institute of Environmental Processes and Pollution control and School of Environment and Civil Engineering, Jiangnan University, Wuxi 214122, China*

*bbwang@zjut.edu.cn

## ABSTRACT

Sulfidated nanoscale zero-valent iron (S-nZVI) has been extensively studied for remediating soil and groundwater contaminated with chlorinated solvents. Among various sulfidation methods, biogenic sulfidation mediated by sulfate-reducing bacteria (SRB) has attracted attention due to its cost-effectiveness and sustainability. However, most existing studies assume idealized conditions with high-organic-carbon availability for SRB, which do not accurately represent the low-organic-carbon environments typically encountered in subsurface aquifers. In this study, *Desulfovibrio ferrophilus* IS5 was employed as a model SRB to biogenically sulfidate nZVI under varying levels of organic carbon. Our findings demonstrate that organic carbon availability critically influences both sulfidation pathways and dechlorination reactivity of biogenic sulfidated nZVI (Bio-S-nZVI). *D. ferrophilus*-mediated sulfidation significantly increased the abundance of $S^{2-}$ and $S_n^{2-}$ species, facilitated the replacement of iron oxides by iron sulfides, and enhanced $Fe^0$ exposure on the surface of iron nanoparticles. Although organic carbon limitation suppressed the apparent sulfate-reducing activity of *D. ferrophilus*, it did not substantially alter the elemental composition and speciation characteristics of the resulting Bio-S-nZVI particles. Under low-organic-carbon conditions, hydrogen generated from nZVI corrosion served as an alternative electron donor for *D. ferrophilus*, promoting the expression of its hydrogen metabolism gene (*hdyA*) and sulfate reduction gene (*dsrB*). Furthermore, in response to organic carbon limitation, *D. ferrophilus* appeared to adapt metabolically by enhancing electron transfer at the surface of Bio-S-nZVI particles. This facilitated electron extraction from internal $Fe^0$, intensified $Fe^0$ corrosion, and enhanced the particles' dechlorination reactivity toward chlorinated solvents. However, this process also promoted hydrogen evolution between Bio-S-nZVI and water, thereby reducing the electron efficiency for dechlorination relative to that of Bio-S-nZVI formed under high-organic-carbon conditions. This study provides new insights into tailoring biogenic sulfidation strategies of nZVI to enhance chlorinated solvents remediation under low-organic-carbon conditions.

**ABSTRACT**

Halogenated organic pollutants (e.g., chlorinated ethenes) are prevalent in the environment, causing severe harms to ecosystem function and public health. After decades of investigation, organohalide-respiring bacteria (OHRB) have been well recognized as the key microorganisms capable of degrading and detoxifying these toxic pollutants. Although bioremediation employing OHRB has been applied in the field, unsuccessful bioremediation cases are not uncommon due to failed colonization of the augmented OHRB (e.g., *Dehalococcoides*). Most prior studies focused on investigating the roles of abiotic factors (e.g., redox potential, pH) in affecting OHRB colonization, but it remains unknown how biotic properties of bioinoculants change colonization and performance of dechlorinating communities.

Here we manipulated the diversity and biomass of both bioinoculants to unveil the roles of community diversity in OHRB colonization. We found a notable influence of bioinoculant biodiversity on OHRB colonization and activity. Namely, bioinoculants with a moderate diversity exhibited the highest trichloroethene dechlorination rate, least accumulation of toxic intermediates (vinyl chloride), and the fastest OHRB growth. Moreover, higher augmentation biomass of bioinoculant resulted in more robust colonization of OHRB, accompanying with faster pollutant detoxification. Our findings demonstrate the important roles of bioinoculant diversity in affecting bioremediation performance.

# Hotspots for Microbial Dehalogenation of Persistent Organohalide Pollutants

**ABSTRACT**

Persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) pose serious ecological and public health risks due to their persistence, toxicity, and bioaccumulation. Landfills, once viewed as passive sinks for municipal, industrial, and agricultural waste, are now recognized as complex biogeochemical hotspots hosting diverse microbiomes, yet their role in transforming halogenated contaminants remains poorly resolved. In tropical landfill sediments, POPs commonly occur at microgram-per-kilogram levels. To assess their biotransformation potential, long-term sediment microcosms were established and amended with representative contaminants, including Aroclor 1260, Penta-BDEs, and Deca-BDE. The landfill microbiomes achieved complete debromination of both Penta- and Deca-BDEs, generating over 30 previously unreported congeners and revealing diverse, novel transformation pathways. PCBs also underwent extensive dechlorination, underscoring the broad metabolic versatility of landfill-associated consortia. Quantitative molecular analyses showed that dehalogenation activity scaled with pollutant concentrations and was mediated by organohalide-respiring bacteria (e.g., Dehalogenimonas, Dehalobacter, and uncultivated Dehalococcoidia) harbouring known reductive dehalogenase genes. The consistently high abundance of sulfate-reducing bacteria suggests a key syntrophic role in supplying reducing equivalents that enable complete debromination and sustain long-term dehalogenation. Collectively, these findings position tropical landfills as natural hotspots for microbial detoxification of halogenated pollutants and highlight the ecological importance and nature-based remediation potential of landfill microbiomes for legacy and emerging contaminants.

## ABSTRACT

Zero-valent iron (ZVI) has been widely used in the remediation of groundwater contaminated by hydrocarbons in the past few decades. However, the influence of environmental components in groundwater, such as soil particles, sulfides (S(II)), and microorganisms, on the geochemical evolution and dechlorination performance of ZVI has not yet been systematically studied. Our research investigates the interactions between ZVI and groundwater components, specifically focusing on the following three aspects:

(1) **Interactions between ZVI and typical soil minerals**. We found that metal oxides and clay minerals primarily promote the corrosion of ZVI by water through adsorbing corrosion-resultant $Fe^{2+}$, rather than directly consuming $Fe^0$, while the quinone groups in humic acid as a typical of soil organic matter can directly consume $Fe^0$. These interactions enhance the reactivity of ZVI toward carbon tetrachloride in the short term, but shorten the service life of ZVI.

(2) **Interactions between ZVI and sulfide.** The sulfidation of ZVI by S(II) involves both indirect and direct sulfidation pathways, and ferrous ions can enhance the sulfidation efficiency. Biological sulfidation mediated by sulfate-reducing bacteria (SRB) affects the speciation of sulfur minerals on ZVI particle surface. Sulfidation can significantly enhance the reactivity and electron efficiency of ZVI towards trichloroethylene.

(3) **Interaction between ZVI and microorganisms.** We found that vitamin $B_{12}$, which could be secreted by environmental microorganisms, can broaden the reduction boundary of ZVI, enabling ZVI to efficiently reduce 1,2-dichloroethane. In addition, sulfidation can reduce the biotoxicity of nanoscale ZVI, thereby enhancing the synergistic dehalogenation of ZVI and dechlorinating microorganisms.

These findings are expected to offer important theoretical guideline for application of ZVI in practical remediation engineering.

**ABSTRACT**

Chloromethane (CM) is the most abundant naturally-occurring halocarbon compound on Earth, with an estimated annual global emission of approximately 4,000 Gg and an atmospheric mixing ratio of about 600 ppt. Terrestrial vegetation, soils, biomass burning, and both biotic and abiotic processes in marine environments constitute the major natural sources of CM. CM acts not only as a greenhouse gas, with a 100-year global warming potential approximately 14 times that of $CO_2$, but also as an ozone-depleting substance, contributing an estimated 12–20% to stratospheric ozone loss. Moreover, CM poses significant risks to human health, as long-term or repeated exposure can impair reproductive capacity as well as the nervous system and liver and kidney functions. Therefore, elucidating the degradation and transformation pathways of CM is of great importance for understanding global climate change and ensuring ecological and environmental safety. Despite its significance, current knowledge of the biogeochemical cycling of CM, particularly its transformation behavior and driving factors in anaerobic ecosystems, remains extremely limited. This knowledge gap hampers our understanding of CM source–sink dynamics, key controlling factors, and its role in carbon cycling in soils and aquatic environments. In this study, anaerobic enrichment cultures were established using marine sediments as the inoculum and CM as the sole energy substrate, leading to the development of an anaerobic microbial consortium capable of completely degrading CM. By integrating high-throughput sequencing, anaerobic cultivation, isotope labeling, and multi-omics approaches, the core CM-degrading microorganisms within the enrichment culture were isolated and identified. Furthermore, the degradation pathways and transformation products of CM under anaerobic conditions were elucidated, and the associated metabolic pathways, key genes, and molecular regulatory mechanisms were characterized. These findings advance our understanding of the environmental fate of CM and the underlying microbial transformation mechanisms, providing a theoretical basis for more accurate assessments of the impacts of CM on global climate change.

## ABSTRACT

The widespread use of 2,4-dichlorophenoxyacetic acid (2,4-D), a common herbicide, has led to its ubiquitous presence in subsurface environments, where anoxic conditions prevail. However, the mechanisms and pathways driving the complete breakdown of 2,4-D remain poorly understood. In this study, we investigated the microbial processes involved in the anaerobic degradation of 2,4-D. We demonstrated that 2,4-D is transformed through a stepwise process: initial ether bond cleavage to form 2,4-dichlorophenol, followed by reductive dechlorination to 4-chlorophenol and phenol, and eventual degraded to $CH_4$ and $CO_2$, as confirmed by $^{13}C$ isotope tracing. Key microbial population in this process is a novel *Dehalobacter* sp. strain, whose growth is coupled with the dechlorination of 4-chlorophenol to phenol, a metabolic bottleneck. Metagenomic analyses further revealed a syntrophic phenol-oxidizing community that enables the complete mineralization of 2,4-D. These findings provide new insights into the degradation and environmental fate of phenoxy herbicides.

## ABSTRACT

**Introduction**
Per- and polyfluoroalkyl substances (PFASs) are persistent organic pollutants in which hydrogen atoms in the carbon chain are wholly or partially replaced by fluorine atoms. Due to their surface activity, hydrophobicity, acid and alkali resistance, thermal stability, and antioxidant properties, PFASs have been widely applied in various fields. With the gradual elimination of long-chained PFASs, the introduction of some short-chained substitutes in the environment can be expected to increase, a trend that is already observed. Compared to long-chained PFASs, these short-chained PFASs exhibit better solubility and are more difficult to degrade, making them more likely to penetrate natural and anthropogenic barriers and ultimately reach drinking water sources. 2-(Trifluoromethyl)-acrylic acid (TFMAA), as a fluorinated raw material/intermediate, has been proven to undergo biotransformation in natural environments
Electrochemical technology has gained increasing attention among degradation and removal of various micropollutants from water including recently also for PFASs degradation. Compared to oxidation, electrochemical reduction is more effective for PFASs degradation due to the strong electronegativity of fluorine atoms. However, the degradation efficiency of anionic PFASs using a cathode is often limited by the electrostatic repulsion between the cathode and PFASs molecules. Therefore, finding a material capable of simultaneously adsorbing PFASs molecules and catalyzing the generation of free radicals is likely to further improve the defluorination performance in the electrochemical reduction system.
Metal-organic frameworks (MOFs) have emerged as a research hotspot in recent years for PFASs adsorption in groundwater due to their developed pore structure, huge specific surface area, and the ease of adjusting surface chemical properties. A study has compared the adsorption effects of three MOFs (NU-1000, UiO-66, and ZIF-8) with different metal node compositions, nature of organic linker, pore sizes, and pore topologies on short-chained PFASs in groundwater. The results indicate that NU-1000 exhibits the best adsorption performance, UiO-66 demonstrates a relatively good adsorption effect on non-ionic PFASs, while ZIF-8 performs poorly in adsorbing short-chained PFASs. Recent studies have increasingly highlighted cobalt's potential to catalyze dehalogenation. Cobalt demonstrates a strong affinity with halogen atoms, as evidenced in cobalamin, the core of microbial reductive dehalogenation. Moreover, cobalt-containing chemical bonds, such as Co−P and Co−N bonds, can catalyze the production of H*. from water molecules or hydrogen ions, thereby promoting indirect reductive dehalogenation. Therefore, the electrochemical reduction system modified with ZIF-67, which contains Co−N structures, is likely to enrich PFASs on the electrode surface and catalyze PFASs reduction and defluorination by promoting the production of H*. However, the catalytic defluorination of short-chained PFASs using MOF-modified cathode has not yet been investigated, and the catalytic reduction mechanism remains unclear. In this study, a cobalt-containing MOF material, ZIF-67, was selected to modify the cathode and construct an electrochemical reduction system. Subsequently, ZIF-67 was carbonized to investigate its degradation performance and defluorination mechanism on the branched unsaturated PFAS, 2-(trifluoromethyl) acrylic acid.
**1.1 Characterizations**
Figure 1a-b display the SEM images of the cathode before and after modification. As shown in Figure 1a, the surface of the fiber, which is the skeleton of the carbon paper, is smooth in the bare carbon paper. After modification, crystals with regular dodecahedral structures are uniformly distributed on the surface of the carbon fiber (Figure 1b). Energy-dispersive X-ray spectroscopy (EDS) elemental mapping confirmed that C, N, and Co are evenly distributed over the surface of the fiber after modification (Figure 1c). XRD patterns of ZIF-67, carbon black, CP, and ZIF-67/C@CP are shown in Figure 1d. The 26.1° diffraction peak of carbon black and the 26.4° diffraction peak of blank carbon paper and modified carbon paper correspond to the graphitized crystal form of carbon. The diffraction peaks of ZIF-67/C@CP at 7.3°, 10.4°, and 12.7° correspond to the (011), (002), and (112) crystal planes, respectively, indicating the existence of ordered microporous structures. Additionally, ZIF-67/C@CP exhibited the main strong characteristic peak of ZIF-67 at 18.0° (Figure 1d), demonstrating the successful loading of ZIF-67.

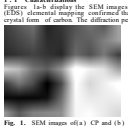

**Fig. 1.** SEM images of(a) CP and (b) ZIF-67/C@CP; (c) Elemental mapping ofZIF-67/C@CP. (d) XRD characterization ofZIF-67, carbon black, CP and ZIF-67/C@CP.
The composition and chemical states of the cathode surface after ZIF-67/C modification are shown in Figure 2. The XPS full spectrum illustrates the existence of N, $F^{2+}$and Co after ZIF-67/C modification (Figure 2a). The high-resolution N 1s spectra display characteristic peaks at 400.12 and 398.52 eV (Figure 2b), corresponding to pyrrolic N and pyridinic N. Additionally, the spin-orbit coupling of Co leads to the double peak Co $2p_{1/2}$ and Co $2p_{3/2}$, with characteristic peaks at 781.55 eV and 797.36 eV, 783.61 eV, 789.14 eV, and 802.68 eV corresponding to Co⁰, Co−N, and the satellite peak (Figure 2c). Regarding the high-resolution O 1s spectra in Figure 2d, the characteristic peaks at 533.43 eV and 534.30 eV correspond to the oxygen adsorbed on the surface of carbon paper and water molecules/hydroxyl radicals adsorbed on the surface of carbon paper, respectively. The above analysis further confirms the successful loading of ZIF-67 and carbon black on carbon paper.

**Fig. 2.** XPS characterization for (a) XPS spectra (b) N 1s (c) Co 2p and (d) O 1s ofZIF-67/C@CP.
**1.2 Adsorption and degradation ofTFMAA on ZIF-67 modified cathodes**
As shown in Figure 3a, the removal ratios of bare carbon paper (CP), carbon black-modified carbon paper (C@CP), ZIF-67-modified carbon paper (ZIF-67@CP), and ZIF-67/carbon black-modified carbon paper (ZIF-67/C@CP) after 48 hours were 6%, 8.97%, 4.63%, and 10.46%, respectively. The results show that ZIF-67 modification significantly improves the adsorption effect of the electrode on pollutants.
The degradation of TFMAA on CP, C@CP, ZIF-67@CP and ZIF-67/C@CP were studied at −1.2 V vs. Ag/AgCl. The removal efficiencies were 18.98% on CP, 92.31% on C@CP, 99.97% on ZIF-67@CP and 99.66% on ZIF-67/C@CP within 48 h (Figure 3b). The rate constant for ZIF-67/C@CP was 0.2356 $h^{-1}$, which is 1.24, 4.76 and 58.90 times higher than that for ZIF-67@CP (0.1896 $h^{-1}$), C@CP (0.0495 $h^{-1}$) and CP (0.0040 $h^{-1}$), as shown in Figure 3c. These results indicate that the addition of carbon black is indeed beneficial for ZIF-67 to further catalyze the degradation of TFMAA.
As shown in Figure 3d, the defluorination percentage of ZIF-67/C@CP, ZIF-67@CP, C@CP, and CP cathodes were 97.16%, 86.42%, 26.55%, and 9.43%, respectively. The ZIF-67 modified electrodes show a better defluorination performance than the other two electrodes, indicating that ZIF-67 has the potential to catalyze reductive defluorination. ZIF-67 coupled with carbon black shows the best degradation performance of the pollutant; this phenomenon may be due to the high conductivity and surface area of carbon black which is beneficial for providing more active sites

**Fig. 3.** Adsorption effect, degradation effect ofCP, C@CP, ZIF-67@CP, ZIF-67/C@CP. (a) Adsorption effect; (b) Removal effect (the error bars represent thestandard deviation ofduplicates); (c) Pseudo-first-order kinetic model; (d) Defluorination effect
**1.3 Electrochemical characterization**
Figure 4a-d presents the electrochemical characterization of different modified cathodes. The cyclic voltammetry curve shows that C@CP exhibits a better current response than the CP cathode due to the conductivity of carbon black (Figure 4a). Electrochemical impedance spectroscopy (EIS) can reflect the magnitude of interfacial transfer resistance near the surface of the electrode. As shown in Figure 4b, the smallest arc radius for ZIF-67/C@CP in EIS demonstrates the fastest interfacial transfer rate on the surface of ZIF-67/C@CP compared with other cathodes. The doping of carbon black in this study further enhances the catalytic effect of the modified cathode by increasing the specific surface area, improving the adsorption performance of the cathode surface, and enhancing the stability of ZIF-67 material.
The ZIF-67/C@CP cathode exhibits the strongest current density ($-2.29 \times 10^{-2}$ mA·$cm^{-2}$) at −1.2 V vs. Ag/AgCl, which is 3.09 times higher than that of the bare carbon paper cathode, demonstrating that the ZIF-67/C@CP cathode possesses a higher H* generation rate. This may be beneficial for the reduction and degradation of the pollutants (Figure 4c). Furthermore, we calculated the electrochemical double-layer capacitance (Cdl) of different electrodes (Figure 4d). C@CP shows the largest Cdl compared to the others, which is attributed to the large specific surface area of carbon black. ZIF-67@CP possessing a Cdl similar to CP, indicates that there may be a reunion in ZIF-67, which reduces the electrochemically active surface area. Due to the doping of carbon black, ZIF-67/C@CP shows a larger electrochemically active surface area than CP and ZIF-67@CP, which is beneficial for the degradation of TFMAA.

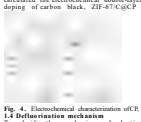

**Fig. 4.** Electrochemical characterization ofCP, C@CP, ZIF-67@CP, ZIF-67/C@CP (a) Cyclic voltammetry curve; (b) Electrochemical impedance spectroscopy; (c) Linear sweep voltammetry curve; (d) Corresponding double-layer capacitance (Cdl).
**1.4 Defluorination mechanism**
To clarify the mechanism of reductive defluorination catalyzed by the ZIF-67/C@CP cathode, different concentrations of TBA to quench radical were used in this work. Figure 5a shows that with the concentration of TBA increased from 0 to 10 mM, the pollution removal rate decreased from 99.66% to 88.17%. To analyze what free radicals play a catalytic role, we used 100 mM DMPO as the radical scavenger and employed EPR technology to detect the radical after applying voltage for 20 min. As shown in Figure 5b, nine characteristic peaks of DMPO-H were observed at ZIF-67/C@CP and ZIF-67/C@CP, while C@CP and CP cathodes did not exhibit characteristic peaks of DMPO-H. These results, in conjunction with the previous degradation capability (Figure 3b, 3d), indicate that H* catalyzed by ZIF-67 can promote the degradation of pollutants and improve the reductive defluorination performance upon TFMAA. Due to the fact that hydrated electrons are only generated under ultraviolet irradiation, and the interference of oxygen is excluded in this study, oxygen-containing free radicals will not be generated. Therefore, the only radical responsible for catalyzing defluorination through indirect electron transfer in this study is H*. The weak H* signal in the cathodyte may be due to the adsorption of most of the H* on the cathode surface.

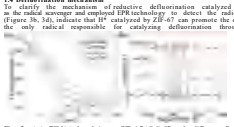

**Fig. 5.** (a) TFMAA degradation on ZIF-67/C@CP under different t-BuOH concentrations (the error bars represent thestandard deviation ofduplicates); (b) DMPO spin trapping ESR spectra ofCP, C@CP, ZIF-67@CP and ZIF-67/C@CP.
**1.5 Potential Degradation Pathways of TFMAA.**
To further elucidate the reductive defluorination pathway of TFMAA, high-performance liquid chromatography coupled with quadrupole time-of-flight mass spectrometry (HPLC-QTOF-MS/MS) was employed to analyze the intermediate products of TFMAA degradation. Figure S7 illustrates the changes in peak area of the detected degradation intermediates over 24 h, represented by TP 141.01, TP 91.00, TP 157.00, and TP 122. Initially, the C-C bond in the TFMAA molecule is hydrogenated and reduced to form a saturated branched structure. Some TFMAA molecules undergo direct C-F bond cleavage, followed by H-F exchange, resulting in the removal of one fluorine atom. Subsequently, the hydrogenated saturated structure, TP 141, undergoes a H-F elimination reaction, releasing one fluorine, while generating a C=C bond to form the TP 121.00 structure. TP 137.00 is hypothesized to be a product of an addition reaction occurring on TP 122. The intermediate product with one fluorine removed undergoes carbon chain shortening and continues defluorination to form TP 91.02, which contains only one C-F bond. The generated intermediate products continue to undergo reductive reactions with constant supply of electrons at the cathode, further removing fluorine atoms and ultimately achieving complete defluorination of the parent contaminant.

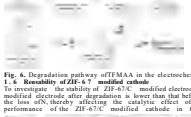

**Fig. 6.** Degradation pathway ofTFMAA in the electrochemical reductive system
**1.6 Reusability of ZIF-67 modified cathode**
To investigate the stability of ZIF-67/C modified electrodes, this section compared the changes in the element content of ZIF-67/C modified electrodes before and after degradation. Additionally, cyclic experiments were conducted to explore the recyclability and catalytic stability of ZIF-67 modified electrodes. As shown in Figure 7a, the percentage of C, N, and Co elements in the modified electrode after degradation is lower than that before degradation. It can be observed that the content of the Co element does not change significantly, while the content of the N element decreases significantly, indicating partial detachment of Co−N structures. This suggests that the saturated structure of Co−N4 may transform into an unsaturated structure due to the loss of N, thereby affecting the catalytic effect of ZIF-67. The reaction time was reduced to 24 hours, and the modified cathode was recycled and used four times at a voltage of −1.2 V. The results showed that the degradation rate of the same electrode material on TFMAA gradually increased with the increase of usage cycle (Figure 7b). It can be inferred that the improved performance of the ZIF-67/C modified cathode in the catalytic degradation of TFMAA in cycle experiments may be caused by the transition of Co−N bonds from the saturated to unsaturated state during the degradation process.

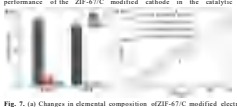

**Fig. 7.** (a) Changes in elemental composition ofZIF-67/C modified electrodes before and after degradation at −1.2 V; (b) Degradation rate ofTFMAA after four cycles.
**1.7 Degradation ofTFMAA on cathodes modified with ZIF-67 derived materials**
The Co−N2 structure formed by nitrogen loss caused by high temperature, exhibits better catalytic effects compared to the Co−N4 structure. Due to the loss of N in the ZIF-67 structure caused by 500-600 °C, this study chose a carbonization temperature of 550°C to optimize the catalytic performance of ZIF-67. In addition, when the temperature exceeds 750°C, a graphene layer will form on the surface of Co nanoparticles as a new active site, which also has catalytic activity. As a result, ZIF-67 materials carbonized at 550°C and 900 °C were prepared and loaded onto cathodes for reductive defluorination in this section. Figure 8 shows the catalytic effect of 550 °C-ZIF-67@CP and 900 °C-ZIF-67@CP on TFMAA reductive defluorination under −1.2 V. The 550 °C-ZIF-67@CP achieved a TFMAA removal rate of 98.33% and a defluorination rate of 97.99% within 24 h. The 900 °C-ZIF-67@CP slightly reduced the degradation performance upon TFMAA, with removal and defluorination rates of 88.65% and 78.73%, respectively. Observing the degradation rate and defluorination rate after 12 h of reaction, it can be seen that the carbonization of ZIF-67 at 550 °C has a better effect, and within 12 h, the degradation rate and defluorination rate have increased by 52.0% and 56.9%, respectively. This indicates that compared with high-temperature pyrolysis of ZIF-67 materials, low-temperature carbonization is more conducive to improving the catalytic activity of ZIF-67. From this result, it can be preliminarily inferred that the nitrogen loss caused by low-temperature carbonization is beneficial for improving the catalytic defluorination ability of ZIF-67, while the formation of cobalt nanoparticles surrounded by graphene by high-temperature carbonization does not significantly improve the catalytic effect of ZIF-67. Carbonization of ZIF-67 at 900°C did not further improve the catalytic performance of ZIF-67, which may be due to further nitrogen loss and thicker graphite layer wrapping, leading to a decrease in active sites.

**Fig.8.** Degradation effect of 550 °C-ZIF-67@CP and 900 °C-ZIF-67@CP compare to ZIF-67/C@CP. (a) Removal effect; (b) Defluorination percentage (the error bars represent thestandard deviation ofduplicates).
To further analyze the changes in elemental composition of carbon paper modified with ZIF-67-based materials, XPS characterization was performed on 550 °C-ZIF-67@CP and 900 °C-ZIF-67@CP. The peaks at 398.34 eV, 400.12 eV, and 402.77 eV correspond to pyridine nitrogen, pyrrole nitrogen, and graphite nitrogen, respectively (Figure 9a). During the carbonization process, the microstructure of the material underwent significant changes, and new graphite nitrogen peaks were observed. Compared with Figure 2b, it can be observed that as the carbonization temperature increases, the peaks of pyridine nitrogen and pyrrole nitrogen gradually decrease, and pyridine nitrogen is almost not observed on 900 °C-ZIF-67@CP.

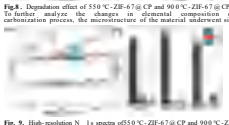

**Fig. 9.** High-resolution N 1s spectra of550 °C-ZIF-67@CP and 900 °C-ZIF-67@CP. (a) Removal effect (C/C0) (b) Changes in elemental composition after carbonization.
**1.8 DFT Calculation and Analysis**
To further analyze the catalytic mechanism of ZIF-67 and its carbonized material modified cathode, density functional theory (DFT) was employed in this section to calculate the catalytic production and adsorption capacity of different Co−N structures for H*. Figure 10 shows the calculated results of the free energies for H* generation and the energy for H* adsorption $E_{ads}$(H*) by the four constructed structures. As shown in Figure 10a, ΔGiH* of Co−N1, Co−N2, Co−N3, and Co−N4 are 0.02 eV, 0.02 eV, 0.06 eV, and 0.16 eV, respectively. Typically, research suggests that catalytic materials with ΔGiH* < 0.2 eV exhibit hydrogen evolution activity, indicating that all four structures can catalyze the production of H*. The DFT calculation results of Co−N structures connected to different numbers of N show that the lower the N content, the smaller the ΔGiH*. Among them, Co−N1 and Co−N2 structures exhibit the smallest ΔGiH*, indicating that a certain degree of N loss is conducive to improving the ability of cobalt nitrogen structures to produce H*, and Co−N1 and Co−N2 structures are most favorable to catalyzing the production of H*. Therefore, the significant improvement of the catalytic defluorination performance on the electrode 330 °C-ZIF-67@CP significantly was caused by the loss of N leading to an increase in the proportion of Co−N1 and Co−N2 structures in the ZIF-67 material.
Figure 10b shows the adsorption energies of four different structures for H*. The four Co−N structures with different cobalt nitrogen ratios have negative adsorption energies for H*, indicating that these structures can stably adsorb H*. Among them, the Co−N1 and Co−N2 structures have the lowest adsorption energies, suggesting that these two structures have the strongest ability to adsorb H*. The above calculation results indicate that all four Co−N structures are conducive to catalyzing the production of H* and stabilizing the adsorption of H* on the cathode surface. Among them, the Co−N1 and Co−N2 structures have the strongest ability to produce and adsorb H*. Furthermore, by analyzing this calculation result together with Figure 5b above, it can be confirmed that the low H* signal in the cathodyte is indeed a result of H* adsorption on the cathode surface.

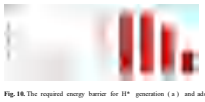

**Fig. 10.** The required energy barrier for H* generation (a) and adsorption energy diagram ofH* (b) on different Co−N structures.

# Applying Compound Specific Stable Isotope Analysis for Characterizing the Biotransformation of Hexachlorocyclohexane Isomers by Different Methanogens

**Xiaxia Zhang[1], Yaqing Liu[1*]**

[1] *School of Light Industry and Food Engineering, Guangxi University, Nanning, PR China.*

*E-mail Address of Presenting Author:yaqing.liu@gxu.edu.cn

**ABSTRACT**

The environmental persistence and toxicity of hexachlorocyclohexane (HCH) isomers continue to pose significant global remediation challenges. While the reductive dechlorination of HCH isomers by organohalide-respiring bacteria (OHRBs) has been extensively studied, forming the mechanistic basis for many bioremediation approaches, the potential for transformation by ubiquitous methanogenic archaea remains poorly characterized. This knowledge gap limits our ability to predict HCH fate in complex anoxic environments, such as contaminated aquifers and sediments, where methanogens are often abundant, especially after the depletion of preferred terminal electron acceptors. To address this, we applied compound-specific stable carbon isotope analysis (CSIA) to systematically quantify and characterize the biotransformation of α-, β-, γ-, and δ-HCH isomers by three distinct methanogens: *Methanobacterium* sp. strain KD21, *Methanosarcina mazei* WH, and *Methanospirillum hungatei*. Through high-resolution monitoring of isotopic composition ($\delta^{13}C$) in residual substrates, we derived precise carbon isotope enrichment factors ($\varepsilon_C$) for each organism-isomer pair. These $\varepsilon_C$ values, which serve as intrinsic fingerprints of the enzymatic reaction mechanism, revealed distinct patterns of substrate selectivity and transformation kinetics among the methanogens, suggesting pronounced differences in both transformation rates and apparent pathways among the methanogens, highlighting unique substrate specificities. Crucially, a systematic comparison of these novel $\varepsilon_C$ data with the well-established isotope fractionation patterns for HCH transformation by pure cultures of OHRBs (e.g., *Dehalococcoides* and *Dehalobacter*) uncovered statistically significant and fundamentally divergent isotopic fractionation patterns. For key isomers, the magnitude and even the direction of carbon isotope fractionation observed for methanogens contrasted sharply with those characteristic of reductive dehalogenases from bacteria like *Dehalococcoides*. This divergence strongly suggests that methanogens employ co-metabolic or alternative enzymatic mechanisms for HCH transformation that are isotopically distinguishable from the dedicated reductive dehalogenases used in organohalide respiration. The study yields a new, comprehensive set of enzymatic isotope effect (EIE) data for assessing HCH fate in anoxic environments.

The implications of this work are twofold. First, it fundamentally expands the conceptual model of anaerobic HCH degradation by quantitatively demonstrating that methanogenic archaea can contribute to contaminant transformation through pathways isotopically separable from OHRB activity. Second, it delivers a crucial new set of isotopic benchmarks ($\varepsilon_C$ values). These data significantly advance the application of CSIA as a powerful diagnostic tool in the field. By enabling the differentiation between OHRB-mediated dechlorination and methanogenic co-metabolism in situ, our results provide environmental scientists and remediation engineers with a refined capacity to attribute degradation activity, assess the contribution of diverse microbial guilds, and accurately evaluate the progression and endpoint of natural attenuation at complex HCH-contaminated sites. This mechanistic understanding is essential for developing next-generation bioremediation strategies that account for and potentially harness the full metabolic potential of anaerobic microbial communities.

**ABSTRACT**

Nitrate and chlorinated solvents, such as tetrachloroethene (PCE) and trichloroethene (TCE), frequently co-exist as widespread contaminants in subsurface environments such as soil and groundwater, due to agricultural and industrial activities. This study investigated the impact of nitrate-associated biotransformation on microbial reductive dehalogenation which is the most dominant natural process for detoxifying chlorinated solvents. Anaerobic microcosms were established with river sediment, amended with PCE and varying nitrate concentrations (0, 0.5, 1, 5, 10 mM) to stimulate both reductive dehalogenation and denitrification process. In nitrate-free microcosms, 86.03 ± 2.99 μmol PCE was completely dehalogenated to stoichiometric amounts of non-toxic ethene within 35 days at a total rate of 98.32 ± 3.42 μM $Cl^-$ released per day. The dehalogenation process could be separated into two stages, PCE to *cis*-dichloroethene (*c*DCE) via TCE was the first stage, which was accomplished in less than 9 days with a rate of 252.89 ± 15.88μM $Cl^-$ released per day, and *c*DCE to ethene through vinyl chloride (VC) was the second stage, which took more than 20 days at a rate of 71.11 ± 9.99 μM $Cl^-$ released per day. In contrast, the presence of denitrification (nitrate reduction to $N_2$) strongly inhibited dehalogenation, leading to slower rates and incomplete dehalogenation, with *c*DCE as the major accumulation product. High-throughput sequencing of the 16S rRNA gene revealed that the sequential dehalogenation of PCE to non-toxic ethene were contributed by a consortium containing *Sulfurospirillum*, *Tirchlorobacter*, *Dehalobacter* and *Dehalococcoides*. Under nitrate-amended conditions, the community shifted markedly: *Sulfurospirillum* (capable of PCE-to-*c*DCE dehalogenation) became dominant, while *Dehalococcoides* was strongly suppressed. Then, we investigate the effects of nitrate and nitrite on dehalogenation driven by *Sulfurospirillum multivorans* strain DSM 12446 (capable of PCE-to-*c*DCE dehalogenation) and *Dehalococcoides mccartyi* strain BAV1 (capable of *c*DCE-to-ethene dehalogenation). We demonstrated that whereas nitrate (at concentration up to 10 mM) did not inhibit reductive dechlorination, its reduction product-nitrite, was an inhibitor at much lower concentrations (e.g., 5 μM for strain BAV1). We further investigated the effects of nitrite on two enzymes essential for electron transfers and carbon-halogen bonds cleavage in OHRB: hydrogenase ($H_2$ase) and reductive dehalogenase (RDase). Nitrite inhibited both enzymes, and enzyme kinetic analysis of $H_2$ase from strain BAV1 revealed that 50 μM nitrite reduced the $V_{max}$ from 8.32 to 6.58 μmol/min/mg, while the $K_m$ remained constant (~0.3 mM). This pattern identifies nitrite as an irreversible inhibitor of $H_2$ase. These findings provide a mechanistic understanding of how nitrate and nitrite inhibit reductive dehalogenation, offering important insights for optimizing bioremediation strategies at sites co-contaminated with chlorinated compounds.

**ABSTRACT**

Chemical reduction by sulfidated nanoscale zero-valent iron (S-nZVI) and biodegradation by organohalide-respiring bacteria (OHRB) are two key technologies for remediating chlorinated hydrocarbons (CHCs) in soil and groundwater. In actual contaminated sites, however, CHCs often coexist as mixtures, making complete degradation difficult with a single treatment approach:neither S-nZVI cannot degrade certain chlorinated hydrocarbons such as 1,2-dichloroethane (1,2-DCA), nor the activity of OHRB is susceptible to electron donor limitation and inhibition by high contaminant concentrations. This study investigated the synergistic degradation mechanisms of S-nZVI and Dehalococcoides mccartyi strain 195 (Dhc 195) on a mixture of trichloroethene (TCE) and 1,2-DCA under simulated source zone (high-concentration) and plume zone (low-concentration) conditions. The introduction of quartz sand was used as a natural porous medium, aiming to imulate the porous media conditions of actual subsurface aquifers. A staged remediation strategy is proposed: microbial remediation can be applied in low-concentration zones, whereas in high-concentration zones, S-nZVI can first be introduced for chemical pretreatment. This step addresses the lag phase often associated with biological reductive dechlorination and reduces pollutant concentrations to levels that do not inhibit microbial activity. Subsequent bioaugmentation with Dhc 195 enables effective and complete removal of CHCs. Under low contamination levels, direct addition of S-nZVI inhibited the dechlorination activity of Dhc 195, leading to reduced TCE degradation rates and accumulation of intermediates. In high-concentration conditions, due to the inhibitory effect on microbial activity the abiotic pathway dominated by S-nZVI converted TCE to ethene, acetylene, and other products, but 1,2-DCA remained persistent. Notably, the introduction of quartz sand as a porous medium significantly alleviated the contact toxicity of S-nZVI toward Dhc 195, especially in low-concentration systems, the TCE degradation rate was nearly doubled compared to that of the microbial-only system, and the system maintained the ability to degrade 1,2-DCA and intermediates such as cis-DCE. These results indicate that porous media not only reduce the inhibitory effect of S-nZVI but also promote synergy between biological and abiotic processes. This study provides theoretical and technical support for the remediation of CHCs mixtures in actual soil and subsurface aquifers. By combining material injection strategies with the natural effects of porous media, a more efficient and stable bio-abiotic collaborative remediation system can be established.

**ABSTRACT**

Trichloroethylene (TCE) is a typical recalcitrant mixed contaminant at industrial decommissioned sites. The coupled system of nano zero-valent iron (nZVI) and reductive dechlorinating bacteria theoretically possesses the potential for synergistic TCE degradation; however, antagonistic effects are often observed in laboratory liquid systems, contradicting the synergistic behavior demonstrated in actual field scenarios. This discrepancy may be related to the modulating role of porous media commonly present in actual aquifers. This study selected quartz sand and three typical clay minerals (Illite, Kaolinite, and Montmorillonite) to systematically investigate the regulatory mechanisms of porous media on the coupled degradation of TCE by nZVI and its sulfidated particles (S-nZVI) with *Dehalococcoides mccartyi* strain 195 (Dhc 195) under simulated groundwater conditions. The results revealed that porous media, especially clay minerals, are key environmental factors that shift the chemical-biological coupled remediation of TCE from a "potential antagonism" in the laboratory to an "actual synergy" in the field. In media-free systems, the coupling of nZVI and Dhc showed distinct antagonism, whereas the introduction of clay minerals significantly enhanced TCE degradation efficiency and even achieved complete dechlorination. Meanwhile, porous media notably modulated the hydrogen evolution behavior of nZVI: clay minerals promoted hydrogen evolution of nZVI but inhibited it from S-nZVI. In the coupled system, the concentration of dissolved hydrogen in the liquid phase was significantly reduced, indicating an improvement in the utilization of hydrogen by Dhc 195. It was confirmed that the addition of clay minerals optimized the electron transfer efficiency of iron to bacteria. On the other hand, owing to their high specific surface area and strong adsorption capacity, clay minerals could adsorb and sequester nanoparticles, mitigating direct contact between nZVI and bacteria and effectively alleviating the biological inhibition of Dhc 195 by nanomaterials. Moreover, the metabolic activity and extracellular polymeric substance (EPS) attachment of Dhc 195 drove the structural evolution of nanoparticles toward porosity and fragmentation, exposing more active sites ($Fe^0$). Combined with the effects of mineral loading and sulfidation modification, this process facilitated dynamic evolution of the nano- iron interfacial morphology. This study provides new insights for enhancing chemical-biological coupling in the in situ remediation of TCE and promoting stable, efficient field applications.

# Rare Chlorinated Pesticide-Degrading Microorganisms from Aral Sea Sediments

**V. Tikhonov**

*Lomonosov Moscow State University, Faculty of Soil Science, Department of Soil Biology, Russia*

vvt1985@gmail.com

**ABSTRACT**

The Aral Sea represents an extreme hypersaline lake with exceptionally high concentrations of dissolved salts. Over many decades, it has been exposed to intense anthropogenic pressure — primarily from chlorinated organic pesticides — leading to the formation of a unique microbial community adapted to harsh environmental conditions.

Soils and bottom sediments serve as major reservoirs of microbial diversity, harboring the largest number of prokaryotic cells on Earth (Flemming and Wuertz, 2019). It is widely acknowledged that a substantial proportion of bacteria remain uncultivable — a phenomenon described as the *great plate anomaly* as early as the beginning of the 20th century. Estimates of cultivability remain debated, ranging from 0.01 to 1% (Staley and Konopka, 1985). The prevailing view in the scientific community holds that the majority of bacterial taxa fail to grow on standard laboratory media due to unsuitable growth conditions, such as the absence of essential microelements, nutrients, or proper environmental parameters. A cultivation approach based on soil microaggregate enrichment has previously been demonstrated as an effective strategy for isolating rare bacterial species (Yin et al., unpublished).

In this study, we applied a similar approach to cultivate microaggregate fractions of the Aral Sea sediments on nutrient media to isolate rare microbial taxa capable of degrading DDT and lindane. Previously uncultured *Acidimicrobiia* bacteria possessing linE, linG, linH, and linJ genes were isolated, along with *Trichoderma* spp. strains grown on lindane-containing media. Moreover, previously uncultured halophilic archaea of the family *Haloferacaceae* were identified as capable of tolerating and growing at high concentrations of DDT and lindane in enrichment cultures.

Metagenomic analysis coupled with microbiological isolation revealed that both microbial diversity and total abundance were substantially higher in sediments than in the water column. Pesticide-degrading strains were isolated exclusively from the sediment samples and not from the overlying water of the Aral Sea.

**Acknowledgments**

The isolation and characterization of uncultured bacteria were carried out under the state assignment of Lomonosov Moscow State University. The analysis of pesticide residues was supported by the Russian Science Foundation, project No. 25-14-00073

# A Field Study to Examine Applicability of a Novel Groundwater in-situ Bioremediation Method to Co-optimize Dechlorination of Chlorinated Ethenes and Subsurface Ecological Stability

**Hyunsoo Lim[1]*, Minjoo Lee[1], Jeongmin Yoon[1], and Joonhong Park[3]**

## ABSTRACT

Groundwater contamination by chlorinated ethenes, including tetrachloroethene (PCE) and trichloroethene (TCE), remains a persistent environmental challenge due to their widespread historical use and the limited effectiveness of conventional remediation techniques. In situ bioremediation has been increasingly applied as a cost-effective and environmentally sustainable alternative; however, existing remediation designs have primarily focused on maximizing contaminant removal, with limited consideration of subsurface ecological impacts induced by substrate addition or microbial bioaugmentation.

In a previous study, we developed a novel microcosm-based in situ bioremediation design framework that determines the injection concentrations of a primary substrate (lactate) and an exogenous microbial consortium (JL-1) to co-optimize reductive dechlorination performance and subsurface ecological stability. Because this framework was derived solely from laboratory microcosm experiments, its applicability under field conditions remained uncertain.

In this study, we evaluated the field applicability of the proposed design framework by comparing field observations with model simulations parameterized using microcosm-derived results at a PCE- and TCE-contaminated groundwater site in South Korea. Following the injection of lactate and the JL-1 consortium at concentrations determined by the optimization framework, chlorinated ethenes and their biodegradation products (DCE, VC, ethene, and chloride) were monitored alongside functional genes and target microbial populations using high-throughput qPCR. Subsurface ecological responses were assessed using ATP activity measurements and flow-cytometric analyses, including cell fingerprinting, live cell density, and microbial diversity.

Field-scale concentrations of PCE, TCE, and DCE were well reproduced by reactive transport model simulations, while a higher-than-predicted VC-to-ethene conversion was observed under field conditions. Ecological disturbance quantified by flow-cytometric fingerprinting distances showed strong consistency between laboratory and field observations, whereas ATP activity and other flow-cytometric indicators exhibited discrepancies. Overall, the results demonstrate the field applicability of the proposed in situ bioremediation design framework for co-optimizing contaminant removal and subsurface ecological stability, while highlighting the need for further investigation into enhanced VC-to-ethene conversion processes under field conditions.

**ABSTRACT**

The use of aqueous film-forming foam (AFFF) containing perfluoroalkyl acids (PFAAs) and polyfluoroalkyl substances (aka precursors) as fire suppressants has led to widespread soil and groundwater contamination with per- and polyfluoroalkyl substances (PFASs). While PFAAs are highly resistant to biodegradation, many precursors can undergo biotransformation, as demonstrated in the laboratory and at contaminated sites. Little is known about the specific processes, microorganisms, and enzymes involved in precursor transformation and defluorination, limiting our ability to predict, and potentially manage (i.e., control), precursor fate and transport at PFAS-impacted sites.

The soil isolate *Pseudomonas* sp. strain 273 grows aerobically on terminally fluorinated alkanes, including decanes with poly- or perfluorinated carbons. Catabolic products include inorganic fluoride and poly-/ perfluorinated short-chain fatty acids. Strain 273 also desulfonates 4:2, 6:2, and 8:2 fluorotelomer sulfonates to acquire sulfur as a nutrient for growth, generating fluorotelomer carboxylic acids (FTCAs) as intermediates. Batch incubation experiments revealed that this bacterium transforms and defluorinates FTCAs containing even numbers of non-fluorinated carbon atoms (e.g., n:2 and n:4 FTCAs), but not FTCAs with odd numbers of non-fluorinated carbon atoms (e.g., n:3 or n:5 FTCAs). Transformation of n:2 FTCAs primarily yields inorganic fluoride, the corresponding [n-1]:3 FTCAs, perfluorocarboxylic acids (PFCAs) with one less perfluorinated carbon (i.e., [n-1] PFCAs), and trace amounts of shorter-chain (i.e., [n-2], [n-3]) PFCAs.

Although strain 273 does not defluorinate n:3 FTCAs, lipidomic analysis revealed the covalent incorporation of intact n:3 FTCAs (e.g., 5:3, 7:3, 8:3, and 9:3 FTCA) into fatty acid acyl tails of glycerophospholipids when strain 273 cultures were exposed to n:3 FTCAs during growth. Semi-quantitative lipidomic analysis estimated that a substantial fraction of the bacterium's phospholipid pool contains n:3 FTCA when grown under laboratory conditions. Notably, this incorporation process also occurs at environmentally relevant concentrations of n:3 FTCAs. Incorporation of n:3 FTCAs into the phospholipid pool was not limited to strain 273 and was observed in other axenic bacterial cultures. The process of covalent incorporation into phospholipids (i.e., the formation of bacterial fluoromembranes) represents an unrecognized sink for n:3 FTCAs. Considering that n:3 FTCAs are intermediates in the biotransformation of various precursor classes, bacterial incorporation of n:3 FTCAs can potentially impact precursor fate, longevity, bioaccumulation, and biomagnification. This research exemplifies how pure culture laboratory studies can unravel processes that likely impact PFAS fate and transport under *in situ* conditions.

**ABSTRACT**

Nitrogen (N) cycling is fundamental to all microbiomes. Microbial, abiotic, and coupled biotic-abiotic processes turn over fixed N and produce nitrous oxide ($N_2O$) in both pristine and disturbed environments. The atmospheric $N_2O$ concentration (currently ~338 parts per billion) would give rise to aqueous phase (e.g., groundwater, soil moisture) $N_2O$ concentration in the low nanomolar range; however, orders of magnitude higher $N_2O$ concentrations exceeding 100 micromolar are observed in groundwaters. Similar observations have been made in soils, where $N_2O$ formation is highly dynamic over spatial and temporal scales, with rainfall, fertilization, and freeze-thaw demonstrated to cause hot spots and hot moments of exceptionally high soil $N_2O$.

$N_2O$ serves as a respiratory electron acceptor for bacteria possessing $N_2O$ reductase (NosZ), but otherwise has been considered biologically inert with no impact on microbial community dynamics and functions. Recent work, however, rejects this premise, highlighting that $N_2O$ is a potent inhibitor of corrinoid-dependent enzymatic reactions impacting methionine biosynthesis, methanogenesis, and organohalide respiration. Batch culture incubations demonstrated that acetoclastic methanogenesis, estimated to account for two-thirds of the annual 1 billion metric tons of biogenic methane ($CH_4$), was very sensitive to $N_2O$, with inhibitory constants ($K_I$ values) in the range of 18–25 micromolar, followed by hydrogenotrophic ($K_I$, 60–90 µM) and methylotrophic ($K_I$, 110–130 µM) methanogenesis. The analyses show that micromolar concentrations of $N_2O$ decrease or abolish $CH_4$ production, reduce methanogen growth yields, and exhibit progressively negative feedback on microbial $CH_4$ production. Organohalide respiration, a key process for the biogeochemical cycling of chlorine and bioremediation of environments impacted with anthropogenic chlorinated organic compounds, hinges on the activity of corrinoid-dependent reductive dehalogenases. Laboratory cultivation experiments demonstrated that $N_2O$ concentrations in the low micromolar range decreased dechlorination rates and resulted in incomplete dechlorination of tetrachloroethene (PCE) in *Geobacter lovleyi* and of *cis*-1,2-dichloroethene (cDCE) and vinyl chloride (VC) in *Dehalococcoides mccartyi* axenic cultures. $N_2O$ did not inhibit corrinoid-independent fumarate-to-succinate reduction in *Geobacter lovleyi*, supporting that $N_2O$ interferes with reductive dechlorination by reacting with super-reduced Co(I)-corrinoids of reductive dehalogenases. Kinetic analyses revealed a best fit to the noncompetitive Michaelis-Menten inhibition model and determined $N_2O$ inhibitory constants, $K_I$, for PCE and cDCE reductive dechlorination of 40.8 ± 3.8 and 21.2 ± 3.5 micromolar in *Geobacter lovleyi* and *Dehalococcoides mccartyi*, respectively. The lowest $K_I$ value of 9.6 ± 0.4 micromolar was determined for the VC to ethene reductive dechlorination step. Considering that soil and groundwater $N_2O$ concentrations often exceed the measured $K_I$ values, especially in watersheds impacted by nitrate runoff from agricultural sources, $N_2O$ is an underappreciated modulator of organohalide respiration and other corrinoid-dependent processes.

* michal.gasiorek@urk.edu.pl

**ABSTRACT**

Soil pollution with heavy metals represents one of the most serious environmental threats in urban areas, as these metals readily accumulate and can persist for hundreds or even thousands of years, posing risks to human health through the food chain. Urban soils, including those in Krakow, exhibit significantly elevated concentrations of heavy metals due to anthropogenic activities such as industrial emissions, traffic, and coal combustion. In Krakow, the highest levels of pollution are observed in the city center and industrial zones, underscoring the strong human impact, and continuous monitoring of heavy metal concentrations is crucial for public health protection. Investigating the distribution and sources of these metals also provides insights into the historical influence of human activity on the urban environment.

The novelty of this study lies in its comprehensive assessment of heavy metal pollution across the entire central area of Krakow, integrating multiple pollution indices with advanced geostatistical and machine learning approaches. The aim of the study is to evaluate topsoil contamination by heavy metals, explore their relationships with soil properties, and compare traditional and modern analytical methods to elucidate spatial patterns and environmental risks.

In this study, the concentrations of six heavy metals (Cd, Cr, Cu, Ni, Pb, and Zn) were measured in over 50 topsoil samples from the city center of Krakow, alongside key soil properties including texture, pH, $CaCO_3$, and total organic carbon. Heavy metal contamination was assessed using multiple pollution indices, such as $I_{geo}$, *CSI*, and *PLI* (Kowalska et al., 2018), while geostatistical and machine learning methods were employed to map spatial distribution and identify pollution hotspots. Elevated concentrations of Pb, Cd, and Cu were particularly observed near the Wisła River, the main railway station, and other high-traffic areas. A comparative meta-analysis contextualized these results within Europe, highlighting spatial and temporal trends in soil pollution across the continent.

## ABSTRACT

Neurotoxic methylmercury (MeHg) accumulation in rice grain primarily originates from paddy soils, where inorganic mercury (Hg) is converted into MeHg by microorganisms harboring the *hgcAB* gene pair. Although paddy soils represent important reservoirs of Hg-methylating microorganisms, their large-scale biogeographic distribution, phylogenetic diversity, and metabolic potential remain insufficiently understood. Here, we integrated *hgcA* gene amplicon sequencing with deep metagenomic analyses to investigate Hg-methylating communities across major rice-producing regions of China, spanning approximately 3600 km in latitude and 1300 m in altitude.

Amplicon sequencing revealed pronounced spatial variation in Hg-methylating communities, with significantly higher *hgcA*$^+$ microbial community richness in tropical and subtropical paddy soils than in temperate regions. *Geobacteraceae*, *Smithellaceae*, and *Methanoregulaceae* were identified as dominant *hgcA*$^+$ families associated with MeHg production, collectively accounting for up to 77% of total *hgcA* sequences. Hierarchical partitioning analyses indicated that soil pH was the primary environmental factor shaping *hgcA* distribution in *Geobacteraceae* (14.8%) and *Methanoregulaceae* (16.3%), whereas altitude explained a substantial proportion of variation in *Smithellaceae* (21.4%), suggesting distinct environmental niche pReferences among major Hg-methylating lineages. Machine-learning-based spatial prediction further revealed heterogeneous distributions of dominant methylators across Chinese paddy ecosystems, enabling improved regional prediction of MeHg production potential.

Metagenomic sequencing of the representative paddy soils substantially expanded the known diversity of Hg-methylating microorganisms, identifying 6,057 *hgcA* genes spanning 27 microbial phyla. We reconstructed 152 high-quality metagenome-assembled genomes (MAGs) carrying conserved *hgcAB* domains, predominantly affiliated with Nitrospirota, Desulfobacterota, and Acidobacteriota. Importantly, several previously uncharacterized putative Hg-methylating lineages were recovered, including one candidate phylum and two candidate classes. Metabolic reconstruction revealed that putative Hg-methylators possess diverse functional capacities extending beyond Hg transformation, including nitrogen fixation, sulfate reduction, arsenic methylation, antibiotic resistance, and heavy-metal stress response pathways, indicating strong coupling between Hg methylation and broader biogeochemical processes.

Collectively, our results reveal extensive phylogenetic and metabolic diversity of Hg-methylating microorganisms and demonstrate that their distribution across paddy soils is governed by environmental filtering and ecological niche differentiation at large spatial scales. These findings provide new ecological and genomic insights into microbial determinants of MeHg production and establish a framework for improving prediction of MeHg accumulation risk in rice paddy ecosystems.

**ABSTRACT**

Dark-colored organomineral supraglacial sediments, known as cryoconites, constitute a primary source of elements on glacier surfaces, which are subsequently transferred to adjacent alpine soils via fluvioglacial mechanisms. Accumulation and translocation of trace elements may pose risks not only for ecosystems but also for local agriculture and water quality, especially in case of anthropogenic load nearby. Therefore, the aim of this research is to study features of trace elements accumulation in cryoconites and local alpine soils in two different areas, both with anthropogenic load and background. The first study area is represented by surroundings of the Elbrus Mt, Central Caucasus, where samples of cryoconites were taken from glaciers Skhelda, Garabashi and Maly Azau. Soils sampling included two Leptosols at the Baksan Gorge and Umbric Leptosol, Eutric Histosol and Leptic Umbrisol, according to WRB, at the Terskol Gorge. The second study area is located at the Ile Alatau Mt, Northern Tian Shan, where samples were taken from Morenny and Bogdanovicha. Sampled soils were defined as Lithic Leptosol and Skeletic Regosol at the Big Almaty Valley and Leptic Umbrisol at the Left Talgar Gorge. Content of Cu, Zn, Ni, Pb and Cd was defined by atomic absorption spectrometry according to ISO 11047, following Kruskal-Wallis ANOVA analysis and calculation of pollution indices. Results showed that cryoconites of the Skhelda and Maly Azau glaciers were the least polluted with all studied trace elements due to their remoteness from the touristic and mining sites with all pollution indices indicating absence of pollution. On the other hand, Garabashi and Bogdanovicha glaciers were the most polluted with almost all trace elements. The highest pollution was observed with Zn (max. 125 mg·kg$^{-1}$) due to both elevated natural background and local touristic activities. For the most of trace elements we observed significant difference in their content between anthropogenically loaded and background glaciers of 2 sites, indicating human role in pollution. Interestingly, background Morenny Glacier was in between and did not differ significantly from other glaciers, that is probably connected with long-distance transfer of industrial pollutants. Translocation of polluted cryoconites together with local human activities led to accumulation of trace elements in soils of Baksan and Left Talgar Gorges. Content of almost all of them was significantly higher in these gorges than in background Big Almaty Valley and Terskol Gorge, especially for Zn (max. 120 mg·kg$^{-1}$) and Ni (max. 40 mg·kg$^{-1}$). In general, cryoconites efficiently accumulated all trace elements, similarly to local soils and more. Ecological index PERI showed high risk load of sites with human activities, indicating necessity of alpine areas monitoring to preserve quality of local ecosystem services.

## ABSTRACT

Arsenic (As) contamination from mine tailings is a global environmental concern, yet most studies have focused on acidic systems where Fe(hydr)oxides dominate and arsenate binding is relatively well understood. In contrast, neutral to carbonate-rich environments remain poorly studied, despite their global relevance. These settings, including carbonate-buffered tailings and karst soils, are often assumed to limit As solubility; however, colloids can maintain As mobility under such conditions.

We investigated colloid-mediated As transport in the Cobalt–Gowganda mining district (Ontario, Canada), which was once the largest silver mining camp in the world. Pedons developed on the tailings are composed of both Fe-rich, organic-poor soils dominated by scorodite, and organic-rich, Fe-poor soils where calcium (Ca) and organic matter (OM) stabilize colloids. Size-resolved fractionation reveals that As is strongly enriched in fine colloids (20 nm–0.45 µm) in soil leachates, whereas surface waters contain colloids of both the fine and coarse fractions (0.45–5 µm). Fine colloidal As showed strong positive correlations with OC ($r = 0.70$, $p < 0.01$) and ζ-potential ($r = 0.68$, $p < 0.01$), indicating that organic coatings and electrostatic stability promote the persistence of nanoparticulate As. In contrast, coarse colloidal As correlated with higher pH ($r = 0.43$, $p < 0.01$) and less negative ζ-potentials, consistent with Ca-bridging and pH-driven charge neutralization that promote aggregation into larger flocs.

TEM–EDS indicates two types of colloids: Fe-rich colloids with As concentrated in mineral–organic matter associations (MOA), and OM-rich colloids with As and Ca co-distributed in organic shells. EELS analyses indicate that the polarity of organic-functional groups (i.e., the proportion of C=O and C–O groups) increases from the organic matrix depleted Fe and As to interfaces with Ca-As-rich areas and to interfaces with Fe-As-rich areas. Arsenic K-edge EXAFS shows the predominant occurrence of Fe-arsenate bonding environments in Fe-rich colloids and mixed arsenate–carbon/arsenite-carbon bonding environments in OM-rich colloids. The latter two observations suggest that an increase in polarity towards Fe-arsenate and Ca-arsenite-rich areas leads to the stabilization of carbon, As(V) and As(III) species. In summary, these results establish a dual pathway for As transport under near-neutral conditions: Fe-rich colloids of low zeta potential sequester and thus immobilize As(V), whereas Ca–OM colloids of high zeta potential form nanoparticulate, mobile carriers of As(III) and As(V). This helps us understand how nanometric MOAs control colloid stability and As mobility. It also explains why neutral and carbonate-buffered environments can sustain high As mobility despite low bulk solubility. The findings have broad implications for predicting and managing As risks in mining-impacted catchments and karst systems worldwide.

# Phytoremediation of Cd-Contaminated Soil: Role of Tropical Grasses in Modulating Cadmium Speciation

**Flávio Henrique Silveira Rabêlo[1*], Deivisson Ferreira da Silva[2], Jessica Caroline Albano[2], Olívia Bibiana Souza Dias[2], Everton Gerado de Morais[2], Guilherme Lopes[2] and Luiz Roberto Guimarães Guilherme[2]**

**ABSTRACT**

Understanding the mechanisms regulating cadmium (Cd) availability in the soil–plant system has become increasingly relevant, especially in agricultural environments where Cd accumulation threatens food safety and soil health. As phytoremediation is a potential alternative to remove Cd from the soil it is important to understand the factors driving soil Cd availability to potentialize phytoremediation efficiency. Soil Cd availability depends largely on its chemical speciation, which is influenced by soil pH, redox potential, organic and inorganic ligands, competition with other cations and plant species cultivated in the polluted area. This research investigated the chemical speciation of Cd in soil solutions extracted from Cd-enriched soils cultivated with various grass species for phytoremediation purposes. Samples of a Cd-contaminated dystrophic Oxisol (7.5 mg Cd $kg^{-1}$ soil) were maintained at field capacity, and the resulting soil solutions were collected and analyzed for their chemical composition. Cadmium speciation was modeled using the Visual MINTEQ 4.0 software. The simulations revealed that Cd in the soil solution occurred predominantly as free $Cd^{2+}$ ions, followed by complexes associated with fulvic acids (FACd(aq) and $FA_2Cd^{+}G(aq)$) and chloride species ($CdCl^{+}$). Grasses with greater biomass production significantly influenced both the total Cd concentration and the distribution of its chemical forms in solution. The highest concentrations of $Cd^{2+}$ were observed in soils planted with *Andropogon gayanus* cv. Planaltina and *Brachiaria brizantha* cv. Piatã. In contrast, soils cultivated with *Brachiaria* species generally exhibited higher proportions of Cd complexed with fulvic acids, whereas inorganic Cd species were more prevalent in soil solutions from treatments with *A. gayanus* cv. Planaltina and *Sorghum sudanense*. Variations in pH and ionic composition of the soil solution induced by different grass species were key factors affecting Cd speciation and plant uptake, ultimately influencing biomass yield. Consequently, *Brachiaria* species are suggested as effective candidates for reducing Cd availability in soils through complexation with humic substances, while *A. gayanus* cv. Planaltina and *S. sudanense* may increase Cd mobility, making them less suitable for remediation of contaminated sites.

**ABSTRACT**

With the development of technology, environmental functional materials for heavy metal pollution remediation are emerging one after another, and the main direction of development is nanotechnology. The application of nanotechnology in water environments has been well supported by extensive data, but its performance in other environmental media (such as soil and sediment) is often limited by its own properties. As a result, large-scale macroscopic materials are gradually emerging and showing impressive effects. This report will discuss the applicable scenarios, application points, and application examples of three large-scale polymer materials in the remediation of soil chromium (Cr) pollution. By preparing millimeter-sized polyaniline/polyvinyl alcohol/sodium alginate composite materials (PPS) for soil remediation, a single application of this material can achieve a significant effect of removing 24.2% and 52.5% of total Cr and hexavalent chromium (Cr(VI)) from the soil, respectively. Additionally, the material exhibited excellent performance, maintaining over 95% removal efficiency of Cr in solution even after four cycles of use [1]. We further prepared porous large-scale functional polymer materials PAP by combining amyloid fibrils with polyethyleneimine (diameter approximately 5~6 mm). The obtained materials can simultaneously remove multi-heavy metals, and the adsorption capacity for Cr(VI) was as high as 121.4 mg/g, being comparable to or superior to the adsorption effect of many nanomaterials [2]. Lately, we developed an ascorbic acid-based polymer material APP, and the material not only exhibited excellent Cr removal over wide pH ranges (pH 2-11) [3], but also transformed the residual Cr to the reducible fraction and continuously transferred it to the material for fixation. These results deepen our understanding of the applicability and sustainability of large-scale functional materials in environmental remediation.

*E-mail Address of Presenting Author:qnguo@sina.com

**ABSTRACT**

The application of phosphogypsum to saline soils has been recognized as an effective strategy to enhance crop productivity and alleviate salt-induced stress. However, it remains unclear whether repeated phosphogypsum application may lead to the accumulation of heavy metals in soil and maize grains, thereby posing a potential risk to human health. This study aimed to assess the health risks associated with heavy metals in a soil–maize (Zea mays L.) production system that received continuous phosphogypsum application for five years at varying rates (0, 1500, 3000, 4500, and 6000 kg·hm$^{-2}$). The total concentrations of As, Cd, Pb, Cr, and Hg were analyzed in phosphogypsum, soil, maize stalks, and grains. Results indicated that phosphogypsum application at rates up to 6000 kg·hm$^{-2}$ did not cause significant heavy metal contamination in soil, stalks, or maize kernels. phosphogypsum application also reduced soil pH, promoted the formation of larger soil aggregates, improved soil structural stability, and enhanced maize growth. Thus, at 6000 kg·hm$^{-2}$, maize yield increased by 5.1% compared to the control group.

# Ascorbic Acid-Based Gel for Remediation of Chromium-Contaminated Soil

**ABSTRACT**

Soil contamination with hexavalent chromium (Cr(VI)) poses serious risks to ecosystems and human health due to its high toxicity and mobility. Conventional remediation techniques often face limitations such as difficulty in material recovery, incomplete metal removal, or adverse effects on soil microbiota. In this study, a novel bulk material (APP) composed of polyvinyl alcohol (PVA), polyethyleneimine (PEI), and ascorbic acid (AA) was developed and evaluated for its effectiveness in remediating Cr(VI)-contaminated soil.

The APP material was applied to contaminated soil at dosages of 1 wt% and 3 wt% over a 120-day period. Results demonstrated that the 3 wt% treatment achieved a Cr(VI) removal rate of 64.82% and a total Cr removal of 17.11% (312.47 mg/g APP) by 120d, with stabilization observed after 45 days. The material showed good stability, with minimal Cr leaching upon washing. BCR sequential extraction revealed a decrease in water-soluble and residual Cr fractions, indicating effective activation and removal of Cr rather than mere immobilization.

Physicochemical analyses (FTIR, 2D-COS, SEM-EDS, XPS) indicated that Cr(VI) was reduced to Cr(III) and adsorbed onto APP via functional groups such as -OH and -CO-NH-. Microbial community analysis showed that APP application reduced chromium stress, leading to a decrease in chromium-tolerant bacteria (*Bacillota, Pseudomonas*) and an increase in beneficial genera (*Arthrobacter, Rhizobium*). BugBase analysis further confirmed a reduction in stress-tolerant phenotypes and potential pathogens, indicating improved soil ecological health.

These findings suggest that APP is a promising, environmentally friendly material for the remediation of Cr(VI)-contaminated soils, combining high adsorption capacity, ease of recovery, and positive effects on soil microbial ecology.

ykianpoo@kean.edu

**ABSTRACT**

A mean daily intake of 145.6 g per adult highlights the significance of rice as the primary dietary grain in China, and its role as the major route for human exposure to methylmercury (MeHg) – a neurotoxic compound that forms in paddies and bio-accumulates in rice grains. The low-oxygen anaerobic environment of paddy fields enhances the activity and conversion efficacy of Hg-methylating microorganisms, stimulating the *in situ* transformation of inorganic Hg into MeHg. The latter is the major pathway for MeHg accumulation in rice grains. Soils rich in clay and organic carbon have higher Hg holding capacity and a higher risk of MeHg transfer to rice crops.

Given the national background Hg content in soils averages 0.06 mg $kg^{-1}$ (range 0.03 to 0.1 mg $kg^{-1}$), Hg pollution in Chinese paddy soils is significant, with total Hg ranging from 0.012 to 150 mg $kg^{-1}$. Although no national dataset exists for MeHg, surveys suggested that Hg and MeHg concentrations ranged from 1.06 to 22.7 (mean 4.74) and 0.03 to 8.71 µg $kg^{-1}$ (mean 0.68), respectively, in rice grains. Higher Hg and MeHg levels occur in soils from southern regions (Guizhou, Guangdong, Hunan, Yunnan, Hainan) in relation to the industrial activities, coal combustion, and non-ferrous metal mining, while atmospheric deposition remains the primary pathway of Hg accumulation in soils. Besides, farming practices including fertilization schemes, wastewater irrigation, and straw return can either enhance or suppress MeHg accumulation in soils and its transfer to rice plants. Mitigation of MeHg risks in paddy soils includes application of biochar, sulfur, or iron oxide amendments to immobilize MeHg. Further, optimized water management or crop rotation can also suppress microbial methylation – practices that are crucial for sustainable rice production and public health protection in China.

# Atmospheric Deposition and Trace Element Contamination in Urban Garden Soils and Vegetables in Kingston, New York (US)

**Salvatore Engel-Di Mauro**[1*]

[1] *Department of Geography and Environmental Studies, State University of New York at New Paltz, New Paltz, USA*

*engeldis@newpaltz.edu

**ABSTRACT**

The contribution of atmospheric deposition to the contamination of vegetables and soils was studied in three urban vegetable gardens located in Kingston, New York (US) for As, Ba, Cd, Co, Cu, Ni, Pb, and Zn. Leaf Al was used as indicator of particle attachment or lodging. Surface and subsurface soil sampling was carried out along a cross-town transect and within gardens. Monthly atmospheric bulk deposition samples were gathered over one year and tested for trace element content. Experimental raised beds were built in each garden, consisting of 20 cm deep root pouches filled with imported loamy sand soil (pH 7.5-8.0; soil organic matter 16.5-17.0%). *Brassica oleracea var. acephala* (Winterbor kale) was grown in root pouches under three treatments featuring an increasing degree of specimen cover (imported soil only, and imported soil straw mulch with/without row cover). Leaves were sampled from the kale grown on the experimental beds after 110 d and from local supermarket specimens. Leaves were first washed with deionised water and then EDTA solution to distinguish the degree of particle adhesion and to account for local splash and redeposition. Root pouch soil was sampled at two depths (0-1 cm and 15-20 cm). Irrigation water, straw mulch, and imported soil were sampled prior to and following the field experiment.

Results showed a tendency for legacy soil Cu, Pb, Zn concentrations to be higher than recommended safe levels for New York State. Particle Al and trace element content correlated significantly, suggesting a common regional source. Raised bed soil trace element contamination was low, except Cu and Zn, owing to high amounts for those elements in straw mulch and imported soil. Irrigation water bore very low contaminant levels. Soil surface contamination levels decreased slightly with increasing cover. Straw mulch trace element content varied significantly only by location, suggesting local (intra-garden) sources. Kale exhibited low contamination levels except for Zn (median of 2.5 ppm), with values similar to those of supermarket specimens. Leaf Al concentrations correlated significantly with leaf trace element concentrations (particle lodging) except Cu and with both deionised and EDTA wash extractions (particle adhesion) except for As. Leaf As, Cd, Co, and Pb are inferred to be mainly from particle lodging and attachment by means of both atmospheric deposition and local redeposition. Leaf Ba, Cu, Ni, Zn are mostly explainable by uptake from imported soil. While the degree of contamination was generally very low for all trace elements except Zn (due principally to Zn-rich imported soil and straw mulch), increasing the extent of raised bed cover still allowed dust influx from both regional and local sources, and thereby some kale contamination.

**ABSTRACT**

Phytoremediation is a cost-effective solution for large-scale rehabilitation of contaminated soils, but its efficiency is often limited. Combining soil fauna, such as earthworm, with plants is a promising approach to enhance remediation. This study investigated the bioaugmentation effects of three ecological categories of earthworms (epigeic *Amynthas cortices, endogeic Amynthas robustus,* anecic *Amynthas aspergillum, and* anecic *Metaphire guillelmi*) on Sedum *plumbizincicola* in Cd- and Zn-contaminated mining soils at different contaminated levels under controlled laboratory condition for 90 days. We assessed physiological states and metals concentration in different tissues of *S. plumbizincicola,* and metals availability. Results indicated that earthworm introduction significantly promoted the vigorous growth of *S. plumbizincicola* and enhanced both its robustness and the soil phytoextraction efficiency. Specifically, the biomass of both aboveground tissues and roots was higher in inoculation *S. plumbizincicola* with earthworms *A. cortices, A. aspergillum*, and *M. guillelmi* than only cultural *S. plumbizincicola*. Earthworm activities increased Cd and Zn concentrations in the harvestable aboveground tissues by 5.95%-76.7% and 7.49%-20.8%, respectively. As for the ecological categories of earthworms, epigeic (*A. cortices)* and anecic (*A. aspergillum* and *M. guillelmi)* were particularly effective in enhancing soil nutrient mineralization and metal bioavailability, further promoting the transfer of metals from roots to aboveground tissues. The transfer factors of Cd and Zn increased by up to 98.3% and 110%, respectively. The highest plant biomass, metal concentrations, and metal uptake amounts of *S. plumbizincicola* were observed at the medium contamination level, roughly two to three times greater than at other levels. Furthermore, earthworm species within the same ecological category exerted distinct effects on metal bioavailability, which varied with contamination level. For instance, in medium-contamination soil, *A. aspergillum* increased metal concentration in soil solution through its burrowing and digestion activities, whereas *M. guillelmi* showed an opposite effect. However, in high contamination level, those two species of earthworm showed same trend of reducing the influence, especially *A. aspergillum*. Its suggests that earthworms employ trade-off strategies between survival and growth in metal-stressed environments. Random forest analysis identified aboveground biomass as the dominant factor in enhancing phytoremediation, followed by metal transfer capacity, available phosphorus, and alkali-hydrolysable nitrogen. In conclusion, earthworms, especially epigeic and anecic species, can effectively enhance the phytoextraction of metals by *S. plumbizincicola*, with remediation efficiency being species-specific. This study provides insights into the synergistic use of hyperaccumulators and soil fauna for rehabilitating multi-metal polluted soils, offering a viable strategy for environmental restoration.

# Particle-nanoparticle transformations in metal-contaminated soils

**M.Schindler**[1*]

[1] *Department of Earth Sciences, University of Manitoba, Winnipeg, MB, Canada)*

*Michael.Schindler@umanitoba.ca

**ABSTRACT**

Metals are often released into soil through atmospheric deposition of micrometer-sized particles. Common sources of metal-bearing particles include industrial activities (e.g., smelters), traffic, mine waste, and urban activities (e.g., house paint). In contrast, leisure activities, such as shooting ranges, do not contribute similar amounts of metal-bearing particles. In all these cases, the weathering of the deposited micrometer-sized particles results in their transformation into metal-bearing incidental nanoparticles (NPs). The formation of these incidental NPs is governed by the slower dissolution kinetics of the micrometer-sized phases relative to their faster precipitation kinetics. Combining focused ion beam and ion mill technologies with transmission electron microscopy reveals that these particle-to-nanoparticle transformations can be highly complex, involving the formation of different generations of nanoparticles and unexpected phases not commonly observed in soils. For example, wind-blown transport and deposition of chalcopyrite-related phases ($CuFeS_2$) from a mine waste pile onto nearby soils lead to their transformation into covellite (CuS) and chalcocite ($Cu_2S$) NPs within soil organic matter (SOM), a process commonly seen during the supergene enrichment of copper in ore deposits[1]. Emission and deposition of Zn-Fe-oxides on smelter-affected soils result in the formation of euhedral NPs of spinel phases like franklinite ($ZnFe_2O_4$) and Zn-bearing magnetite on SOM and clay mineral surfaces[2]. Deposition of micrometer-sized Pb-Cr-Zn-Ti-bearing paint flakes onto residential soils results in the formation of multiple NP generations, including hexavalent Cr-bearing phases such as crocoite, $PbCrO_4$, and phoenicochroite ($Pb_2CrO_5$)[3]. Finally, the weathering of metallic Pb and Sb phases in micrometer-sized gunshot residues from a shooting range produces a complex assemblage of numerous Pb- and Sb-bearing NPs[4]. In all these cases, the transport and bioaccessibility of metals released during the weathering of micrometer-sized particles are strongly influenced by the stability of their respective incidental NPs (considering solubility and aggregation) and the matrices in which these NPs form.

**ABSTRACT**

The adage "we are what we eat" underscores the profound connection between human health and the natural resources we depend on—soil and water. This presentation explores the dual role of trace elements in human health, emphasizing essential nutrients (iron, zinc, and selenium), toxic heavy metals (cadmium), and their complex interplay. While the Green Revolution of the 1960s revolutionized agriculture through semi-dwarf crop breeding, boosting global grain yields, it inadvertently reduced essential mineral concentrations in staple crops like rice and wheat, contributing to widespread micronutrient deficiencies. Focusing on selenium, our multi-center cohort study (N=36,000 participants) revealed a significant positive correlation between serum selenium levels—linked to regional soil selenium content—and diabetes prevalence across China. This suggests that selenium supplementation in most Chinese regions may elevate health risks rather than confer benefits. For toxic elements, a soil-rice-human cohort study (N=1,500) demonstrated that cadmium-contaminated soils elevate dietary cadmium exposure, increasing risks of kidney dysfunction, gut microbiota disruption, and liver cancer. Critically, we identified dynamic interactions between essential and toxic elements across the soil-food-human continuum, with implications for nutrient absorption, toxicity mitigation, and disease susceptibility. These findings underscore the urgency of adopting a One Health framework—integrating agricultural, environmental, and public health strategies—to address micronutrient deficits and heavy metal toxicity holistically. By balancing crop productivity with nutritional quality and environmental safety, such approaches can safeguard human health while promoting sustainable ecosystems.

**ABSTRACT**

Soil pollution, particularly heavy metal contamination, poses a critical environmental challenge with implications for human health and ecosystems. This study investigated the potential of agricultural waste materials: Cassava peel (CP), Conventional charcoal (CC), Maize husk (MH), Maize stover biochar (MSB), Oilpalm frond biochar (OFB), and Rice husk (RH) to immobilize heavy metals in contaminated soils and to identify the most suitable immobilization agent.

A neutral loamy sand arable soil (pH 7.34), sampled in 1 kg portions in triplicate, was spiked with intervention levels of selected heavy metals (Cd - 380, Cr - 240, Ni - 720, and Pb - 210 mg $kg^{-1}$). Each soil sample was amended separately with an equivalent of 10 t $ha^{-1}$ of the respective additive before being packed into leaching columns. The columns were watered with 100 ml of distilled water at 7-day intervals for 90 consecutive days. Heavy metal concentrations in both leachate and soil samples collected from each column were analyzed to evaluate the efficiency and capacity of the immobilization agents.

The results showed that heavy metal retention in the soils depends on the additives. Control had significantly higher values compared to most other amendments, with the lowest values observed in CP (155.60 mg $kg^{-1}$ Cd), MH (4.23 mg $kg^{-1}$ Cr and 174.37 mg $kg^{-1}$ Ni) and CC (83.43 mg $kg^{-1}$ Pb). In the leachates, RH, MH, CP, and CC showed the highest concentrations of Cd, Cr, Ni, and Pb, respectively. MH had significantly low immobilization efficiency for Cd (4.85%) and Pb (7.55%) but highest for Cr (97.92%) and Ni (49.75%) with OFB and CC respectively exhibited significantly higher values for Cd (42.91%) and Ni (61.64%). The additives did not differ distinctly in their immobilization capacities, except for MH, which had the lowest values for Cd (190.51 mg $l^{-1}$) and Pb (113.40 mg $l^{-1}$), whereas CC and OFB showed better capacities. Overall, the immobilization potential of the additives was ranked as OFB > CC > RH > MH > MSB > CP > Control while the immobilization capacity was as OFB > Control > CC > RH > MSB > MH > CP. Biochar portrayed a better potential in heavy metals immobilization particularly in a neutral soil condition.

*sunshengsheng@gdaas.cn

## ABSTRACT

Serpentine soils represent critical natural reservoirs of chromium (Cr) and nickel (Ni), posing substantial environmental threats through metal lateral migration into surrounding ecosystems. While conventional views emphasize ionic migration as the dominant pathway for Cr and Ni, the role of colloidal migration remains overlooked. In this study, we systematically investigated mineralogy, chemical speciation, colloidal characterization, and migration modeling of Cr and Ni along a typical serpentine toposequence, to achieve a comprehensive understanding of the driving mechanism for their lateral migration via ionic, colloidal and particulate pathways.

Characterization of soil colloids by field flow fractionation and scanning transmission electron microscope showed that colloidal Cr and Ni mainly coexisted with Fe-oxides. Fe-oxide colloids were identified as the primary carriers for colloidal Cr and Ni migration from soil to aqueous phase, whose formation was governed by low pH, high organic matter (OM) and Fe-oxide mineralogy. Quantitative analysis of migration pathways revealed that Cr migrated from soil to water primarily in colloidal Cr(III) (53-79%), with Cr(VI) ions as a secondary pathway, whereas Ni migration was dominated by ionic form (73%-94%). Path modeling indicated that Cr migration was strongly driven by Mn-oxide-mediated Cr(VI) formation and modulated by soil OM and pH. In contrast, colloidal Cr was stably hosted in Fe colloids with little variation along the toposequence, making its migration dependent on Fe colloid mobility. For Ni, weathering enhanced ionic migration but reduced colloidal migration by promoting Ni release from Fe-oxides.

These findings challenge conventional paradigms by establishing colloidal Cr(III), rather than Cr(VI), as the dominant migration pathway, highlighting the crucial yet overlooked role of colloidal migration in heavy metal dispersion. This study provides a quantitative framework for understanding Cr and Ni lateral migration in serpentine environments, contributing to more accurate risk assessment and management strategies.

# Long-Term Effects of Repeated Organic Amendment Applications on Cadmium Bioavailability: Insights from a Five-Year Pot Experiment

**Comeliau S.[1*], Bergen J-C.[1], Paquet C.[1], Marit E.[1], Biron P.[1], Houtart A.[1] & Colinet G.[1]**

[1] *University of Liège (Gembloux Agro-Bio Tech, Water – Soil – Plant Exchanges, Gembloux, Belgium)*

*sibylle.comeliau@uliege.be

**ABSTRACT**

Understanding the long-term effectiveness of amendments and the mechanisms of metal immobilization is essential for managing cadmium (Cd) contamination in agricultural soils. Although short-term studies (1-2 years) dominate the literature, the cumulative effects of repeated organic amendment applications are poorly documented. Past industrial activities in Belgium have led to widespread low-level soil contamination (< 1 to 5 $mg \cdot kg^{-1}$ Cd), raising concerns about food safety as excessive Cd levels have been found in vegetables from private and market gardens. A five-year pot experiment (2020-2025) was conducted using soil from a contaminated market garden in the Province of Liège, Belgium (pseudo-total Cd: 1.5 $mg \cdot kg^{-1}$, initial pH $CaCl_2$: 5.6). The pots (5L capacity, five replicates) initially received control, biochar and green waste compost treatments. In 2021, lime was added as a fourth treatment. The amendments were reapplied each spring and Swiss chard was cultivated outdoors annually, with systematic monitoring of soil pH and $CaCl_2$-extractable metals. Green waste compost showed the most significant and persistent increase in pH. A marked pH rise and a sharp decline in $CaCl_2$-extractable Cd occurred after the second compost application. Subsequent annual applications primarily maintained and stabilized these effects. Biochar induced more gradual changes in pH and Cd. No significant effects were observed during the first year across all amendments. Lime addition also increased soil pH, though to a lesser extent than compost. Significant interactions were identified between lime and the other amendments, which complicates the interpretation of the overall effects of the treatments. Compost reduced Cd bioavailability beyond the effect of pH alone, likely through the enrichment of soil organic matter and increased cation exchange capacity. After five years, most compost-amended plants fell below the European food safety standards, showing that plant Cd responds slowly and requires long-term amendment applications. Unlike field conditions, pots exhibited stable, monotonic trends with minimal seasonal fluctuations in pH or $CaCl_2$-extractable Cd. This stability reflects the controlled irrigation regime and the limited, enclosed root environment. Furthermore, plants grown in pots produced significantly lower biomass than field-grown crops, highlighting the necessity of field experiments to validate these observations under realistic agronomic conditions. Even in pots with very low $CaCl_2$-extractable Cd and near-neutral soil pH, vegetable Cd concentrations occasionally exceeded European limits, demonstrating that low soluble Cd alone does not guarantee food safety. This five-year study shows that repeated applications of organic amendments progressively reduce Cd bioavailability, with green waste compost yielding the strongest results. However, achieving stable improvements in soil pH and Cd immobilization requires 2 to 3 years of repeated applications.

# Managing Cadmium Uptake in Vegetables with Repeated Applications of Amendments: Lessons from a Multi-year Field Experiment

**Comeliau S.[1*], Bergen J-C.[1], Paquet C.[1], Marit E.[1], Biron P.[1], Houtart A.[1] & Colinet G.[1]**

[1] *University of Liège (Gembloux Agro-Bio Tech, Water – Soil – Plant Exchanges, Gembloux, Belgium)*

*sibylle.comeliau@uliege.be

**ABSTRACT**

Food safety has become a major concern in Belgium due to excessive cadmium (Cd) levels in vegetables grown in private and market gardens, even in areas with low soil contamination (< 1 to 5 mg·kg$^{-1}$ Cd). Past industrial activities in central Belgium, particularly in the Meuse-Vesdre valleys, caused significant atmospheric depositions that continue to affect food production today. Although the role of soil pH in controlling Cd mobility and plant uptake is well established, achieving neutral or slightly alkaline pH appears insufficient to ensure compliance with European food safety standards under these low-level contamination scenarios. A three-year field experiment (2023-2025) was conducted in two market gardens in the Province of Liège, with pseudo-total soil Cd levels of 1–2.5 mg·kg$^{-1}$ and initial pH of approximately 5.5. Using a randomized complete block design with three to five replicates, four treatments were established: control, lime application (marine-derived $CaCO_3$), biochar amendment and green waste compost amendment. Swiss chard and lettuce were cultivated over several seasons. Soil samples were collected seasonally to measure soil pH and $CaCl_2$-extractable metal concentrations, while edible tissues were analyzed for total metal content. Compost application significantly increased soil pH compared to control, sometimes exceeding lime addition, and substantially reduced $CaCl_2$-extractable Cd. Lime also increased pH effectively, while biochar demonstrated more moderate effects. However, no significant amendment effects were observed during the first year, suggesting that repeated applications are necessary before measurable impacts on Cd bioavailability emerge. Strong seasonal variability in soil pH and $CaCl_2$-extractable Cd levels was observed across years, independent of the effects of amendments. This highlights the influence of environmental factors (temperature, moisture, etc.) on plant biomass production and metal mobility. Despite substantial increases in soil pH (often exceeding 6.0) and reductions in extractable Cd in amended plots, analyses of vegetables suggest that achieving compliance with the EU limits remains challenging. Both Swiss chard and lettuce frequently exceeded regulatory thresholds. These results highlight the limitations of conventional pH-based remediation strategies in low-contamination contexts. Geochemical modeling is essential for elucidating Cd speciation in soil solution and identifying additional immobilization mechanisms beyond the effects of pH. Long-term, integrated approaches combining predictive modeling and temporal monitoring of multiple geochemical processes are necessary to ensure vegetable safety and develop effective, site-specific remediation strategies in low-contamination agricultural contexts.

# Effects of plant growth-promoting bacteria and its mechanisms towards Brassica juncea L. growth and Cd phytoextraction

**Qiong Wang[1], Xin Sun[1], Ying Feng[2], Xiaoe Yang[2]**

*[1]School of Resources and Environment, Anqing Normal University, Anqing 246000, People's Republic of China*

*[2]MOE Key Laboratory of Environmental Remediation and Ecological Health, College of Environmental and Resource Sciences, Zhejiang University, Hangzhou 310058, People's Republic of China*

172502@aqnu.edu.cn

**ABSTRACT**

In recent years, with the development of the global Microbiome Project, more and more microorganisms have been used to assist phytoremediation of heavy metal-contaminated soils. Numerous plant growth-promoting bacteria (PGPB) have been verified to play a beneficial role in promoting plant growth and facilitating heavy metal uptake of their host plants, which consequently improved phytoremediation efficiency. However, little is known about the functional mechanisms and application effects of these PGPB on the non-host plants with promising remediating potential. Here, 12 different PGPB strains isolated from a hyperaccumulator *Sedum alfredii* Hance were adopted to investigate their effects on *Brassica juncea* L. growth and Cd accumulation. The results showed that two strains, namely *Burkholderia* SaMR10 and *Sphingomonas* SaMR12 were identified as the promising microbes for oilseed rape to improve phytoremediation efficiency of Cd contaminated soils. Furthermore, the colonization pattern of SaMR12 was observed by a confocal laser scanning microscope, which showed SaMR12 entered the roots through the conjunction of taproot and lateral roots, and then was transported to stems and leaves. Cd exposure resulted in the damage of the antioxidant system in oilseed rape, which induced the production of hydrogen peroxide ($H_2O_2$), increased the content of malondialdehyde (MDA) and proline accumulation. Under Cd stress, SaMR12 inoculation could alleviate the Cd-induced damage of *B. juncea* by decreasing the concentrations of $H_2O_2$, MDA and proline, increasing the activities of antioxidative enzymes, and regulating the GSH-AsA cycle. Through these ways, SaMR12 inoculation facilitated plant growth and Cd accumulation of *B. juncea* under Cd stress, which further contributed to the elevated phytoextraction efficiency. In addition, inoculation of SaMR12 could alleviate Cd-induced damage and enhance plant growth by restoring photosynthetic activity and maintaining electron transport functionality. Simultaneously, the field experiment indicated that the combined application of PGPB strains was more effective towards oilseed rape growth and Cd phytoremediation. However, the investigation into its microbial ecological mechanisms showed that original ecological niches were not a major factor in the growth-promoting attributes, Cd phytoextraction efficiency and changes in bacterial community structure, suggesting ecological niche was not the primary determinant for effective bioaugmentation inoculants construction. The above results expanded the current knowledge about bacterial inoculation and provided fundamental guidance for the production of PGPB consortia as bioaugmentation agents in Cd-contaminated fields to further facilitate Cd phytoremediation and develop sustainable agriculture.

## ABSTRACT

Sulfur plays an essential role in agricultural production, but few studies have been reported on how sulfur simultaneously impacts the transformation of cadmium (Cd) and arsenic (As) in the soil-rice system. This research selected two soils co-contaminated with both Cd and As, varying in acidity and alkalinity levels, to study the impacts of elemental sulfur (S) and calcium sulfate ($CaSO_4$) on the migration and accumulation of Cd and As by rice. Results indicated that two types of sulfur had a substantial ($P < 0.05$) impact on decreasing the contents of Cd (28.3-50.4%) and As (20.1-38.6%) in brown rice in acidic and alkaline soils. They also increased rice biomass (29.3-112.8%) and reduced Cd transport coefficient (27.2-45.6%) significantly ($P < 0.05$). Notably, sulfur augmented the generation of iron plaque on rice root surfaces, which increased the fixation of Cd (17.6-61.0%) and As (14.0-45.9%). SEM-EDS results also indicated that the rice root surface exhibited significant enrichment of Fe, Cd, and As. The mechanism of simultaneous Cd and As immobilization by sulfur application was mainly ascribed to the contribution of iron plaque. Additionally, sulfur reduced the contents of Cd and As in soil porewater and promoted the transformation of As(III) to As(V) to reduce the toxicity of As. The K-edge XAFS of As in iron plaque also confirmed that sulfur application significantly promoted As(III) oxidation. Sulfur also promoted the activities of antioxidant enzymes and the contents of NPT, GSH, and PCs in rice plants. In general, this study establishes a foundation for sulfur to lower As and Cd bioavailability in paddy soils, enhance iron plaque and rice resistance, and reduce heavy metal accumulation.

## ABSTRACT

Sulfur can regulate cadmium (Cd) and arsenic (As) bioavailability in flooded paddy field. However, in classical drought-flood rotation systems with alternating redox conditions, the geochemical behavior of Cd and As under sulfur amendment remains uncertain. This study investigated the dual effects of sulfur in a mustard-rice rotation system and its impact on the migration and transformation of Cd and As crop production safety. The results showed that sulfur application during the upland season significantly boosted Cd and As bioavailability, enhancing the hyperaccumulator mustard's ability to extract heavy metals. Specifically, the Cd and As contents increased by 31.8%-35.5% and 17.1%-25.2% in the aboveground, and by 43.0%-44.1% and 33.1%-36.5% in the underground. Additionally, mustard's antioxidant system was significantly improved, leading to a 12.6%-14.8% increase in biomass. During the paddy season, residual sulfur from the mustard season significantly reduced Cd and As bioavailability and mobility by promoting the formation of iron plaque on rice roots. Consequently, Cd and As contents in brown rice decreased by 48.4% and 45.8%, respectively, with Cd meeting the requirement of quality safety standards. Microcosm experiments confirmed a distinct interaction between sulfur application and water management: sulfur enhanced heavy metal mobilization under drought conditions, while drastically reducing their bioavailability under flooded conditions. To summarize, sulfur enhances heavy metal accumulation during the mustard season for "pollution remediation" and ensures "safe production" during the rice season by blocking the absorption of heavy metals. The proposed sulfur-mediated "remediation-production" mustard-rice rotation system offers a sustainable and efficient remediation strategy for Cd-As co-contaminated soils.

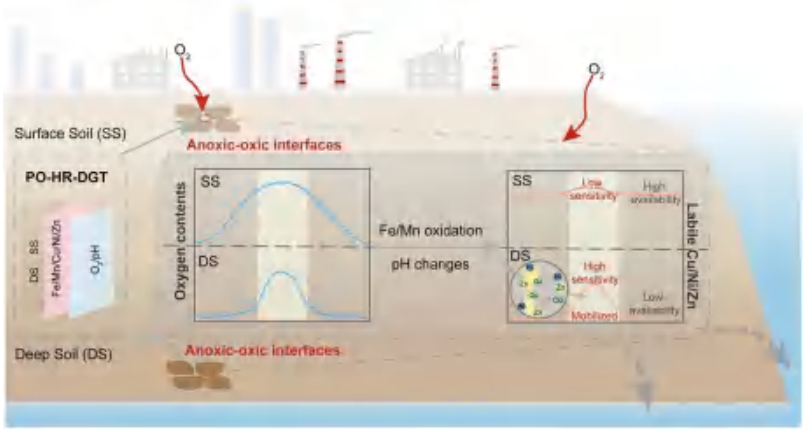
**ABSTRACT**



Industrial sites in coastal cities experience fluctuating redox conditions driven by climate change, forming anoxic-oxic interfaces and influencing the availability of heavy metals (HMs). What remains elusive is how oxygen contents influence the formation of anoxic-oxic interfaces and HMs mobilization in industrial soils with varying physicochemical properties. Here we investigated the mobilization mechanisms of HMs (Fe, Mn, Cu, Ni, and Zn) at anoxic-oxic interfaces in different depths soils at a historical industrial site using high-resolution in-situ techniques, including planar optodes (PO) and diffusive gradients in thin-films (DGT). The PO accurately captured O2 and pH distributions, revealing greater $O_2$ diffusion in surface silty loam soil compared to deep silty clay loam soil. Results showed distinct redox-mediated HMs mobilization patterns between surface and deep soils. Surface soils exhibited rapid Fe(II)/Mn(II) oxidation, yet Cu, Ni, and Zn remained relatively stable due to higher contamination and DOC content. Conversely, deep soils displayed significant Cu, Ni, and Zn mobilization at anoxic-oxic interfaces, correlating to the changes of $O_2$ and pH. These findings demonstrate the critical role of soil properties and microscale redox dynamics in controlling HMs behavior, offering valuable insights for managing contaminated industrial sites.

**Keywords:** Redox microzones, Different soil properties, In-situ sampling, High-resolution visualization, Heavy metals availability

**Highlights:**

a) Anoxic-oxic interfaces simulated in varying depth industrial soils.
b) PO-HR-DGT enabled in-situ 2D microscale multi-parameter mapping in industrial soils.
c) Surface soils showed Fe/Mn oxidation but stable Cu, Ni, and Zn labile concentrations.
d) Deep soils exhibited significant Cu, Ni, and Zn mobilization at anoxic-oxic interface.
e) Soil properties could govern redox driven metal behavior under climate fluctuations.

**ABSTRACT**

Cadmium (Cd) accumulation in rice poses a significant threat to food safety and human health. Plant growth-promoting endophytes (PGPEs) offer a promising strategy to mitigate Cd stress. Yet, the mechanisms underlying microbe-mediated reduction of Cd uptake, particularly through specific plant-microbe interactions, remain poorly understood. Here, we demonstrate that the root endophyte Bacillus sp. RE35, a Cd-tolerant and high-IAA producer isolated from rice, established an effective apoplastic niche and significantly enhanced Cd retention in roots through a multi-level mechanism. Successful colonization of RE35 in the root apoplast, confirmed by the red fluorescent protein labeling, strain-specific gene quantification and colonization-related genes analysis, promoted extensive root morphological remodeling via both de novo and salvage pathways of IAA biosynthesis under Cd stress. Notably, RE35 inoculation drastically reshaped Cd distribution, increasing cell wall-bound Cd by 64.7% while reducing shoot Cd accumulation by 24.1-49.7%. This enhanced apoplastic trapping of Cd was attributed to a comprehensive cell wall remodeling program, activated through RE35-induced expression of plant receptor kinases (e.g., LRR-RLKs, LysM-RLKs) and the upregulation of key genes involved in the biosynthesis of pectin, hemicellulose, and lignin. In parallel, RE35 modulated host Cd transport by downregulating influx transporter genes (OsNRAMP5, OsZIP5/9) and upregulating the vacuolar sequestration gene OsHMA3. Our findings reveal a Cd-responsive regulatory network where endophytes enhance apoplastic immobilization by coordinating auxin signaling, receptor kinase activation, and cell wall remodeling, providing a mechanistic basis for sustainable agriculture in contaminated environments.

# A Basin-Scale Synthesis of Inorganic Contamination Across Slovenia's Major Floodplains

**Nejc Golob[1*], Marko Zupan[1], Rok Turniški[1], and Vesna Zupanc[1]**

[1] *University of Ljubljama, Biotechnical faculty, Department of Agronomy*

*nejc.golob@bf.uni-lj.si

**ABSTRACT**

In Slovenia, metal-rich lithologies align with a long industrial history, and the increasing frequency of flood events caused by climate change is remobilizing potentially toxic elements of both geogenic and anthropogenic origins. Floods mobilize and redistribute metal-contaminated sediments, affecting soil functions, degrading farmland, and altering human exposure pathways. This study offers a comprehensive basin-scale synthesis of inorganic contamination (primarily Pb, Zn, Cd, Hg) in soils and sediments on floodplains across Slovenia's four main river basins (Sava, Drava, Mura, Soča). National and international monitoring data, published geochemical datasets, and literature were integrated with GIS-based spatial analysis, combining geological, pedological, hydrological, land-use, and flood hazard layers to quantify the overlap between contamination sources and flood-prone areas. Results reveal a recurring pattern: historical mining and smelting have transformed natural ore deposits into persistent hotspots. The industrialized Sava Basin hosts multiple sources, including the former Celje Zn smelter, the Jesenice steelworks, and the Litija Pb–Hg district, with overbank sediments locally exceeding background concentrations by several orders of magnitude. The Drava Basin is dominated by the Meža Valley Pb–Zn–Cd plume exported to Croatia. The agricultural Mura Basin is characterized mainly by geogenic As and diffuse Cd. The Soča Basin continues to be affected by the Idrija mercury mine, which was historically one of the world's largest and released large quantities of mercury into the environment. Significant amounts of mercury remain stored in floodplain sediments, and ongoing transport via the river system ensures that it continues to reach the Adriatic Sea. Climate change-induced intensification of extreme flooding, such as the 2023 event affecting 86% of Slovenian municipalities, increases contaminant remobilization and associated health risks. Slovenia thus serves as an example of how legacy metal pollutants persist and re-enter fluvial systems under changing climate conditions. These findings emphasize the urgent need for accelerated remediation of key hotspots, secure containment of historical waste, systematic sediment and floodplain monitoring, and sustained transboundary collaboration.

## ABSTRACT

The Eastern Metropolitan Municipal Solid Waste (MSW) Landfill Complex, bordering the East Kolkata Wetlands (Ramsar Site 1208, India), represents a critical anthropogenic hazard. Long-term disposal of MSW and sewage irrigation in the adjacent agro ecosystem have compromised the native Inceptisol. Pb, Cr and Zn concentrations have surpassed the maximum permissible limits (mg/kg) for agricultural soils set by the World Health Organization (WHO). Spatial mapping of dehydrogenase activity (DHA) revealed a pronounced heterogeneity identifying suppressed soil microbial functioning. While some rhizosphere pockets exhibited strong activity, majority of the sites remained below 10µg TPF (triphenylformazan)/ml and ~15% showed undetectable DHA (<1µg/ml), suggesting widespread metabolic inhibition due to metal toxicity. A significant portion of metals remained as labile fractions after sequential extraction using Tessier's method, suggesting a high risk of bioavailability.

Waste-derived adsorbents were studied to rehabilitate this matrix; screening against commercial zeolites (positive control) identified washed eggshell (ES) and sawdust (SD) as superior candidates, with ES exhibiting removal efficiency comparable to the zeolite benchmark (>96%). Their regeneration potential was also confirmed across 3 consecutive cycles. Response Surface Methodology (RSM) based on a Box–Behnken Design (BBD) was used to optimize batch adsorption parameters. The quadratic model for SD ($R^2 = 0.90$; $p = 0.04$) identified pH 6.0 and a dose of 0.5g as optimal for Pb(II) removal**(Fig.1)** while exhibiting enhanced selectivity for Cr(III) in ternary systems. ES functioned as a "super-adsorbent" for Pb and Zn, achieving >99% removal.

Building on optimized parameters, pot experiments evaluated treatment efficacy using spinach (*Spinacia oleracea*) to assess food safety benefits and Indian mustard (*Brassica juncea*) for stabilization efficiency. The assessment included labile metal fractions, leachate and biological response monitoring. Results confirm that the amendments significantly reduced metal bioavailability and were accompanied by a statistical resurgence of DHA and actinomycetes populations. This study establishes an economical protocol converting local waste into soil amendments, demonstrating that optimized ES and SD, effectively stabilize metals and restore soil biological functions.

# Quantifying Metal Transport by Water Erosion: A Field-Based Assessment in a Semiarid Mediterranean Former Mining Area (SE Spain)

**Álvarez-Rogel, José[1*], Aguilar-Garrido, Antonio[1], Martínez-Sánchez, J. José[1], Conesa, H.M.[1], and González-Alcaraz, M. Nazaret[1]**

**ABSTRACT**

This study presents a water-erosion use-case within the broader soil-pollution project SOILPROM, aiming to quantify the dispersion of metals and metalloids driven by storm-generated runoff in the former mining district of La Unión–Sierra de Cartagena (SE Spain). The upper Rambla del Beal drains a landscape heavily contaminated by century-long mining activities, where sediments originate from several types of metalliferous mine wastes. In the upper channel, soils show extremely high metal(loid)s concentrations (e.g., As up to 650 mg $kg^{-1}$, Pb and Zn frequently above 10,000 mg $kg^{-1}$, Cu commonly >100 mg $kg^{-1}$, Mn often >1,500 mg $kg^{-1}$, and Cd between 10–100 mg $kg^{-1}$.

Field monitoring is conducted along ~1.5 km of the upper El Beal wadi, where three flow-regulating dams intercept stormwater and sediment. Their contributing sub-catchments were delineated as 4 ha, 33 ha, and 19 ha. To quantify sediment deposition, 69 erosion nails were installed across the waterbed. The initial height between the ground surface and the top end of each erosion nail was measured before the monitoring period. After each storm event, the height was measured again, and the difference relative to the pre-storm measurement yielded the amount of sediment deposited Core samples were extracted beside selected nails and inserted to the depth of accumulated sediment, previously determined from nail measurements.

To characterise runoff, 14 PVC pipes per dam, perforated at heights between 5 and 50 cm, were installed to collect stormwater and transported sediments. Water samples were analysed for pH, electrical conductivity, and dissolved metals, and sediments for grain size, pH, salinity, and total metal content. Maximum water marks on dam walls enabled estimation of runoff volumes.

Catchment-scale parameters (slope, vegetation cover, surface stoniness, soil pH, salinity, metal content, texture, structure) were assessed to explain erosion responses. The first results reveal strong contrasts in sediment yield among dams, driven by differences in catchment morphology and substrate properties.

The observed metal dispersion poses a significant environmental risk: runoff is often highly acidic, enhancing the solubility and mobility of metals, while sediments display elevated concentrations of As, Pb, Zn, Cd, Cu, and Mn. These factors strongly increase the potential for downstream transport and ecological exposure during storm events. These integrated measurements provide the basis for quantifying metal dispersion under varying storm magnitudes and for supporting forthcoming hydrological and sediment-transport modelling, and the design of remediation measures.

# Stabilizing Urban Soil Lead: Long-Term Effects of Soil Amendments on Bioaccessibility and Speciation

**Chandima Wekumbura[1*], Ganga M. Hettiarachchi[1], and Eduardo Gutierrez[1] and Amila Mudiyanselage[1]**

[1] *Department of Agronomy, Kansas State University, Manhattan, Kansas, USA*

*cchandim@ksu.edu

**ABSTRACT**

Urban soil contaminated with lead (Pb) from various sources poses a significant environmental health risk, particularly increasing Pb exposure among young children. Soils in Kansas City, Missouri, have reported Pb levels ranging from background to alarmingly high levels, similar to those in other older cities. This three-year field study aimed to reduce Pb bioaccessibility and to identify the underlying mechanisms by using affordable phosphate-based amendments that promote the formation of sparingly soluble Pb-phosphate minerals. The reduction in bioaccessible Pb was evaluated after in situ incorporation of five soil amendments (selected from a laboratory incubation study) at three vacant lots with total Pb concentrations ranging from 60 to 800 mg $kg^{-1}$. A modified physiologically based extraction technique (PBET) simulating the gastric dissolution process was used to determine Pb bioaccessibility, along with an in vitro bioaccessibility assay (IVBA) at pH 2.5. Soil Pb speciation was determined using X-ray absorption spectroscopy data collected at the Stanford Synchrotron Radiation Light Source, and soil Pb fractionation was determined using a sequential extraction procedure. At Site 1, a significant reduction in bioaccessible Pb, as measured by PBET, was evident one month after amendment incorporation and continued thereafter, with ammonium polyphosphate (APP) achieving a 35% reduction and Class A biosolids a 20% reduction compared to the untreated control. Although bioaccessible Pb results from the PBET extraction showed a significant treatment effect, the IVBA extraction did not ($p < 0.05$), indicating that the PBET method is more sensitive in detecting treatment effects due to its extraction solution chemistry. The other two sites (2 and 3) did not show immediate reductions in bioaccessible Pb, likely due to their low total Pb (<150 mg $kg^{-1}$), or low bioaccessible Pb (<12%) to begin with, and site-specific variability. Sites 2 and 3 began to show the treatment effect after 30 months of treatment, showing increased reduction in monoammonium phosphate and triple superphosphate treatment. Lead speciation analysis conducted on soils collected 1, 12, and 24 months after treatment at Site-1 indicated higher % of pyromorphite-like minerals in all treatments compared to the control. In addition, Pb sorbed to Fe-ferrihydrite was the major Pb species in all treatments. These results supported the continuous reduction of bioaccessible Pb levels at Site-1. Sequential extraction results, clay mineral characterization, PCA, and k-means cluster analyses also supported the above findings. Overall, the study demonstrated that soil amendments are effective in transforming soil Pb into less bioaccessible, pyromorphite-like minerals, even at low levels of Pb contamination from unknown sources in urban areas.

## ABSTRACT

Microbial Induced Carbonate Precipitation (MICP) represents a promising strategy for the remediation of heavy metal pollution coupled with carbon sequestration. This study elucidates the mechanisms and stability of MICP in removing cadmium (Cd), and demonstrates its efficacy in remediating Cd-contaminated paddy rice systems while simultaneously enhancing carbon sequestration, thereby establishing a complete pathway from fundamental research to practical application.

Functional MICP bacterial strains (*Sporosarcina pasteurii* DL-3) were isolated and identified. The removal of Cd via MICP was found to involve five synergistic mechanisms: co-precipitation, precipitation adsorption, cell surface crystallization, extracellular chemical adsorption, and intracellular accumulation. Stability assessments revealed that after MICP treatment, the Cd release rate of Cd-vaterite from solution across a pH range of 2.0–10.0 was 0.286–0.825 ‰. After soil Cd was fixed by vaterite and then eroded by acid rain for 60 days, the fixation rate of exchangeable Cd remained at 51.00%, while the dissolution rate of carbonate-bound Cd was - 0.18%.

The MICP bacterial strain was successfully loaded onto biochar (BC) to form a composite material (BC@DL-3). Pot and field experiments were conducted to evaluate the performance of BC@DL-3 in remediating Cd contamination and promoting carbon sequestration in a farmland–rice system. Compared to the control group, the BC@DL-3 treatment resulted in: no significant yield reduction in pot trials and an increase of 113.55 kg per mu in field trials; Cd content in rice grains decreased by 0.87 mg/kg (pot) and 1.22 mg/kg (field); the fixation rate of exchangeable Cd in soil reached 17.39% (pot) and 52.50% (field); and carbonate-bound Cd increased by 23.20% (pot) and 203.79% (field). These findings clearly indicate that BC@DL-3 can effectively reduce Cd bioavailability in soil and Cd accumulation in rice grains while maintaining or even improving crop yield. A life-cycle carbon budget assessment further demonstrated that while the lime treatment resulted in an emission of -2134.422 kg $CO_2$e per mu, the BC@DL-3 treatment led to carbon sequestration of 623.612 kg $CO_2$e per mu, corresponding to a carbon emission reduction of 129.22%.

# Reduction of lead bioavailability and phytotoxicity in Pb-slag contaminated soil using soil mixing and compost-modified biochar

**Eunice P. Ogundipe[1], Sifau A. Adejumo*[1], James A. Adediran[2] and Adeniyi O. Togun[1]**

**ABSTRACT**

Food security and human safety are being threatened by heavy metal contamination of agricultural lands. Several physical and biological methods have been employed separately for soil remediation. In this study, effects of combining soil mixing with compost (C) and cow-dung (CD) for reduction and immobilization of Pb in the soil as well as growth, Pb uptake and biochemical responses of maize grown on contaminated soil were investigated. Lead contaminated soil mixed with uncontaminated soil at different ratios to give 0%, 25%, 50%, 75% and 100% levels of contamination were further mixed with C and CD at four different levels (0, 10 20 and 30 t/ha) before planting of maize. Data were collected on maize growth and yield, Photosynthetic Pigments (PP), stress indicators (proline and glycine betaine) contents as well as Pb uptake by maize crop and post-cropping soil Pb concentrations. Pb concentration was reduced by 29-85% in soil mixtures while, C and CD further reduced Pb by 69-77% and 42-66%, respectively. Combined treatments reduced Pb uptake, enhanced maize tolerance and growth as no germination was recorded in 100% Pb contaminated soil. Dry matter accumulation and PP were more in maize crop grown on compost treated soils compared with those grown on soil mixtures only. Proline and glycine betaine contents in maize leaf were reduced in treated plants than untreated plants. Combination of soil mixing with organic amendments could be a better approach for reducing Pb uptake by maize crop and enhanced maize growth on contaminated soil.

# Spatial Patterns and Predictive Controls of Heavy Metals in Agricultural Ditch Network Across China

**Waqas Mohy-Ud-Din[1*], Tian Qiu[1], and Zhifeng Yan[1]**

[1] *School of Earth System Science, Tianjin University, Tianjin, China*

*E-mail mohyuddin.waqas5@gmail.com

**ABSTRACT**

Ditch systems work as hierarchical networks that support irrigation in agricultural land. In the event of rainfall, water runs off carrying the sediments which flow out of the upland to the downstream system via the ditch system. In this pathway, every ditch level offers a retention area where the sediments are deposited, and the heavy metals are gradually deposited. As runoff transitioned from cropland to connector (CD), branch (BD), and main ditches (MD), the concentration of metals rose in a stepwise manner, which indicated the progressive retention of metals in the ditch network prior to discharge to rivers. Even though this system controls metal transportation and concentrates metals in cropland, national-scale assessments of these dynamics remain limited. During this study, 166 sediments samples across six agricultural regions in China were analyzed for five metals (Cr, Ni, Cu, Cd, Pb) and the metalloid (As). Sediment concentrations showed clear regional contrasts and modest level-wise shifts along the cropland-ditch hierarchy. Chromium median concentration clustered between 20-27 mg $kg^{-1}$; however, the South-central China cropland showed the highest concentration at about 31 mg $kg^{-1}$. In contrast, the lowest median was recorded in MD of the Southwest region. In the case of the metalloid, the maximum concentration of As was observed in cropland (8.3 mg $kg^{-1}$) relative to CD-MD (6.6-6.9 mg $kg^{-1}$). The concentration of Cd was low, with national median of 0.12-0.17 mg $kg^{-1}$, but the median concentration in CD and BD was high (0.43-0.45 mg $kg^{-1}$) in the Southwest region. North China, East China and South-Central China had the highest concentrations and the greatest variation regionally. The Southwest region was in the middle of concentration range, whereas the Northeast and Northwest were at the bottom of the concentration spectrum. Random Forest models demonstrated relatively low predictive performance, with the highest CV $R^2$ values of Cr and As (0.261 and 0.270, respectively). The most significant predictors of As, Cd, Cr, and Pb concentration were sediment properties, especially silt (%) and sand (%) and soil organic carbon and total phosphate. Conversely, Ni and Cu were primarily driven by chemical properties of ditch system such as salt, TDS, turbidity, and pH. Generally, sediment properties governed the heavier metals, whereas Ni and Cu movement controlled by water chemistry. These patterns revealed that the ditches in agriculture system are a conduit and enrichment and thus strengthen their accumulation along the cropland-to-MD gradient. The regional variabilities also help to point out the areas where the pressures of metal accumulation are the greatest. The combined results underscore the coupled effects of ditch hierarchy and site-specific sediment water conditions shaping heavy-metal distributions across agricultural regions.

# Study on the coupled processes of Cd and Fe transfer in the soil-rice system: a remedial strategy using functional fertilizer

**LI Yi-chun*, LU Hai-feng, and XIAO An-wen**

*(Institute of Agricultural Resources and Environment, Guangdong Academy of Agricultural Sciences, Guangzhou 510640, China)*

*yichunli@gdaas.cn

**ABSTRACT**

At present, cadmium (Cd) pollution in paddy fields is one of the most important agricultural environmental problems that threatens human health via the global food chain. Developing state-of-the-art technologies and products that can simultaneously reduce Cd content while increasing iron (Fe) content in rice grain to ensure food safety and improve human health and nutrition has become a new challenge in the current remediation of Cd-contaminated paddy fields in China. In this study, an independently developed functional fertilizer was selected and a rhizosphere bag-pot experiment was carried out to deeply investigate how Fe redox cycle in the rhizosphere soil affect Cd phytoavailability, and how Fe uptake and translocation within rice plant influence Cd accumulation in the grain during the grain-filling stage. The results showed that upon the functional fertilizer was applied, the contents of HCl extractable Fe(II) and poorly crystalline Fe oxides rose by 35.97% and 21.83%, respectively, and the extremely significant and positive correlation between each other was observed; the organic matter-bound fraction of Fe was transformed to the acid soluble fraction of Fe, whereas the acid soluble fraction of Cd was transformed to the easily reducible manganese and poorly crystalline Fe oxide-bound fraction of Cd; the acid soluble fraction of Fe was not only significantly and negatively correlated with the $CaCl_2$ extractable Cd and extremely significantly and negatively correlated with the acid soluble fraction of Cd, but also extremely significantly and positively correlated with the easily reducible manganese and poorly crystalline Fe oxide-bound fraction of Cd; the contents of Cd and Fe in iron plaque decreased by 32.53% and 31.69%, respectively, and the extremely significant and positive correlation between each other was observed; the content of Cd in rice grain declined by 33.03% while the content of Fe in rice grain increased by 14.93%; the contents of Cd and Fe in root increased by 35.96% and 29.14%, respectively; the $TF_{Cd\text{-}LG}$ dropped by 34.65% and the $TF_{Fe\text{-}LG}$ rose by 23.52%, showing an extremely significant and negative correlation; Pearson correlation analysis and PCA revealed that the content of Cd in rice grain was predominantly governed by the content of Cd in iron plaque and the $TF_{Cd\text{-}LG}$. The functional fertilizer used in this study can simultaneously reduce the content of Cd and elevate the content of Fe in rice grain, offering an immediate pathway for safe rice production and enhancing grain Fe content. These findings provide an important References for the development of some state-of-the-art technologies and products to remediate Cd-contaminated paddy fields in China.

# Long-term persistence of immobilizing agents for reducing the phytoavailability of heavy metal(loid)s in contaminated soil

**Hyunmin Lee[1*], Kwang-Uk Kim[1], Jeongyun Yun[1], Wonbin Jo[1], Taehee Baek[2], Jinhwan Park[1], Kwon-Rae Kim[1]**

*[1] Department of Smart Agro-idustry, Gyeongsang National University, Jinju, Republic of Korea*

*[2] Department of Green Bio Science, Gyeongsang National University, Jinju, Republic of Korea*

*gusirse9868@naver.com

**ABSTRACT**

Immobilizing agents are widely used to reduce the phytoavailability of heavy metal(loid)s in contaminated agricultural soils; nevertheless, their long-term persistence remains insufficiently understood. This study evaluated the long-term persistence of immobilizing agents in soils contaminated with As, Cd, and Pb. Soils treated with immobilizing agents in 2014 were used for a cultivation experiment in 2017 and then reused for cultivation in 2025 without additional application of immobilizing agents, after which the results from both years were compared. A total of eleven treatments were established: an untreated control; single treatments(lime (L), biochar (B), gypsum (G), compost (CP), soil cover (SC)); and combined treatments(L+CP, L+G, L+SC, L+SMC (spent mushroom compost, SMC), L+CP+SC). The same crop species were grown in both 2017 and 2025, and soil pH, dissolved organic carbon (DOC), and concentrations of heavy metal(loid)s (As, Cd, Pb) in edible plant tissues were analyzed after harvest. Comparison of the two years showed that the lime-containing treatments consistently maintained a reduced phytoavailability of metal(loid)s. This persistence was attributed to the lime effect, which maintained elevated soil pH over time. Therefore, these results suggest that lime-based immobilizing agents provide a practical and long-lasting means to ensure safe crop production by reducing the phytoavailability of heavy metal(loid)s.

# Immobilization of Arsenic and Cadmium in Alkaline Soil Using Combined Red Mud–Phosphogypsum Amendment

**Namhee Yi[1*], Taehee Baek[1], KwonRae Kim[2]**

[1] *Department of GreenBio Science, Gyeongsang National University, Jinju, Republic of Korea*

[2] *Department of Smart Agro-industry, Gyeongsang National University, Jinju, Republic of Korea*

*chickpeas32123@gmail.com

**ABSTRACT**

Arsenic (As) and cadmium (Cd) exhibit contrasting geochemical behaviors in soil, making it difficult to simultaneously immobilize both contaminants using a single amendment. This study evaluated the potential of a combined amendment—red mud (RM), rich in Al/Fe oxides, and phosphogypsum (G), a Ca-rich material capable of moderating soil pH and coagulating dissolved organic carbon (DOC)—to stabilize As and Cd in alkaline soils. Fourteen alkaline soils (pH > 7.5) co-contaminated with As and Cd were collected and packed into 5 L pots. In 2023, RM (1% w/w) and G (1% w/w) were applied to each soil, followed by a one-year incubation period to allow stabilization processes to occur. Rice (*Oryza sativa L.)* was cultivated in 2024, after which soil pH, DOC, and As and Cd concentrations in rice were analyzed to assess RM+G-induced changes relative to untreated controls. Compared with the control, soil pH in the RM+G treatment decreased in all except one soil, from an average of 7.92 to 7.55. DOC concentrations also declined consistently across all soils, from 148.96 mg $kg^{-1}$ to 117.68 mg $kg^{-1}$. As concentrations in rice were reduced in most soils (12 out of 14), decreasing from an average of 0.85 mg $kg^{-1}$ to 0.56 mg $kg^{-1}$. Conversely, Cd concentrations in rice showed only a slight overall decrease (0.57 to 0.51 mg $kg^{-1}$), and notably, 9 out of the 14 soils exhibited higher Cd concentrations in the RM+G treatment than in the control. Overall, the RM+G amendment effectively reduced As uptake by moderating soil pH and DOC levels, whereas Cd showed inconsistent behavior, including increased uptake in many soils. These findings suggest that while RM+G is a promising amendment for As stabilization in alkaline soils, additional mechanistic investigation and follow-up studies are required to clarify Cd mobilization processes and optimize amendment strategies for the simultaneous stabilization of both contaminants.

# Organic Matter Regulates Soil Cadmium Bioavailability

**Chenchen Qu*, Jinzhao Chen, Ke Dai, Peng Cai, Wenli Chen, Qiaoyun Huang**

*National Key Laboratory of Agricultural Microbiology, Huazhong Agricultural University, Wuhan 430070, China*

**E-mail Address qcc@mail.hzau.edu.cn*

**ABSTRACT**

Organic matter is a crucial component of soil, playing a significant role in maintaining soil structure stability and fertility. Farmland management practices aimed at increasing soil organic matter (SOM) content and improving soil fertility are expected to be widely adopted. However, the impact of organic matter input on the chemical speciation and bioavailability of heavy metals in soil remains unclear. Through microcosm simulations, soil incubation experiments, and field remediation studies, we analyzed the influence of different functional components of organic matter and their interactions with minerals on the speciation distribution of cadmium (Cd). The results showed that the composition of soluble organic matter is a key factor regulating Cd mobility, with protein components promoting Cd migration into the solution. After the application of bio-organic fertilizer, the reduction in soil Cd mobility was the primary cause of decreased Cd uptake, and surface complexation modeling further indicated that SOM lowered Cd bioavailability by shifting its speciation from electrostatic adsorption toward organic complexation. Rice Cd accumulation showed a significant negative correlation with extracellular polymeric substances (EPS) content, and the combination of limestone and bio-organic fertilizer significantly increased EPS content and the proportion of EPS-bound Cd. Additionally, organic matter promoted the activation of iron oxides and the formation of stable mineral-organic-Cd complexes through coprecipitation with iron oxides. These findings demonstrate that farmland soil remediation aimed at organic fertilization is a feasible approach.

# Evaluation of Environmentally Important Elements from Glacial Ice-Water and Associated Glacial Sediments

**A. Kashmala Jadoon** School of Environmental Science and Engineering, Nanjing University, Nanjing, China. kashmalajadoon7@gmail.com**, B. Syeda Fazoon Kazmi** Department of Environmental Sciences, East China Normal University Minhang Campus, Shanghai, China**, C. Sidra Arshad** Department of Environmental Sciences, COMSATS University Islamabad, Abbottabad Campus, Pakistan.

**ABSTRACT**

Glaciers are land-based ice masses ranging from small cirque glaciers to massive ice sheets like those in Greenland and Antarctica. Glaciers are significant sources of fresh water on planet Earth. The Hindukush–Karakoram–Himalayan (HKH) glaciers provide the water supply to more than half of the human population of the globe, for agricultural activities, biodiversity survival, and ecosystem services. Unfortunately, global warming is causing loss of the mountain cryosphere, with direct impacts on the lives of people living in the vicinity and an indirect impact to those living downstream. In recent years, the loss of glacial ice has been forecasted to cause problems such as sea level rise, changes in water availability, and release of contaminants that reside in the surfaces of glaciers or within them. In this regard, mineralogical sediments play a significant role in the geochemistry of glaciers and element cycling. The ice loss is changing the physicochemical properties of glacier-fed rivers and their aquatic communities. Recent studies have highlighted how glacial microbial diversity varies by region. The richness, abundance, and diversity of microbial populations are greatly affected due to glacier melting and surface exposures. This study analyzed elemental pollutants found in the glaciers of Pakistan and investigated the diverse bacterial communities residing therein. Samples of ice and sediments were collected from the Gilgit, Hunza, and Swat glaciers in northern Pakistan. Nine elements, including co-factors, heavy metals, and nutrients, were assessed using atomic absorption spectrophotometry. The research findings indicate higher concentrations of the elements K, Fe, Cu, and Cr in Hunza glacier ice (Hgi) and Ni, Zn, As, and Cd in Gilgit glacier ice (Ggi). In terms of glacier sediments, Swat (Sgs), Gilgit (Ggs), and Hunza (Hgs) samples showed the highest concentrations of K, Cu, Ni, Zn, As, Pb, Cd, and, respectively, of Fe, and Cr. The amount of Cu and Cr is the same in Swat glacier ice and Swat glacier foot. However, the concentration of some elements (As, K, Pb, Zn) is higher in Swat glacier ice, while the amount of some elements (Cd, Ni) is greater in Swat glacier foot. Furthermore, microbial cultivation techniques revealed diverse bacterial communities inhabiting the sampled glaciers. Phylogenetic analysis of the bacterial isolates, based on 16S rRNA gene sequences, showed high homology (99–100%) with previously reported species. The resultant phylogenetic tree grouped the bacterial isolates, such as *Serratia marcescens*, *Cupriavidus* sp., and *Bacillus cereus*, with closely related species known for their roles in nutrient cycling, environmental resilience, and metal tolerance. These findings highlight the ecological significance and adaptive potential of microbial communities in glacier environments, emphasizing their role in elemental cycling and environmental resilience.

# Monitoring Cadmium in Soils, Fertilizers, and Baby Leaf Vegetables in Southern Italy: Regulatory and Environmental Insights

**P. Adamo, F.A. Carbone,L. Signorini, A. Maddaloni, A.G. Caporale**

Department of Agricultural Sciences, University of Naples Federico II, Portici (Naples), Italy

paola.adamo@unina.it

**ABSTRACT**

Cadmium (Cd) contamination in agricultural soils and its transfer to crops is an increasing concern for food safety and public health. In the EU, no harmonized soil threshold values exist, and Member States apply diverse criteria. Although Cd in soil exceeds legal thresholds only in limited areas, its mobility and bioavailability are influenced by soil properties such as pH, texture, carbonate content, and organic matter, which can enhance crop uptake even at low total concentrations. Commission Regulation (EU) 2023/915 sets maximum levels for Cd in food, including leafy and baby leaf vegetables, emphasizing the need to monitor Cd occurrence and its controlling factors.

In March and July 2024, field campaigns in the Sele alluvial plain, southern Italy, sampled soils, baby leaf plants, and fertilizers from organic and conventional horticulture systems. Fields included "problematic" soils where farmers had previously grown baby leaf vegetables exceeding legal Cd limits, and "non-problematic" soils without prior exceedances. Multiple points per field were sampled, and all fertilizers applied during the year were collected to assess potential contributions to Cd inputs.

In the laboratory, soils were air-dried, sieved (<2 mm), and analyzed for physicochemical properties and total and bioavailable metals via acid digestion and ICP-OES/MS. Baby leaf plants were separated into roots and leaves, washed (an aliquot of 50% of each sample), freeze-dried, ground, acid-digested and analysed by ICP-MS for total metals and nutrients. Fertilizers were stored at 4°C, catalogued by type, use, and composition, and analyzed for total elements using mineralization protocols. Data quality was verified with certified References materials, retaining only elements with 80– 120% recovery and ≤20% coefficient of variation.

Problematic soils were clay-rich, while non-problematic soils were sandier. Clay favors metal adsorption and reduces mobility, whereas sandy soils enhance bioavailability. High calcium in all soils may limit solubility, but abundant organic matter in problematic soils can promote Cd complexation and availability. Total toxic metals remained below Italian threshold values, with minor exceedances for Be, Tl, and V due to volcanic soil origins.

In baby leaf vegetables, average Cd was 0.1 mg/kg (organic) and 0.04 mg/kg (conventional); Pb averaged 0.2 mg/kg (organic) and 0.5 mg/kg (conventional). Washing markedly reduced metal content, with non-washed leaves showing Cd and Pb up to 233% higher, reaching EU limits. Fertilizers generally had low Cd and Pb, although an organo-mineral liquid product showed the highest levels, suggesting replacement could reduce crop accumulation.

These results indicate that baby leaf crops, due to short cycles and frequent harvest, may accumulate more metals than full-leaf vegetables. Soils and crops largely comply with regulatory limits, but variability among lots and washed/unwashed differences highlight the need for continued monitoring and further study of metal bioavailability and accumulation.

# Simultaneous immobilization of arsenic and cadmium in paddy soil with co-application of birnessite and lime

**Jianyu Lin**[1*]

## ABSTRACT

The remediation of arsenic (As) and cadmium (Cd) co-contaminated paddy soils is challenging due to their contrasting biogeochemical behaviors. This study innovatively used the combination of birnessite and lime to mitigate the release of As and Cd in paddy soils. Soil incubation experiments revealed that anaerobic conditions mobilized As, whereas aerobic conditions released Cd. The birnessite-lime treatment effectively addressed both processes, reducing anaerobic porewater As by 29.49%–31.75% and aerobic porewater Cd by 70.76%–99.45% on the last day. Lime application enhanced Cd immobilization by elevating pH, promoting retention of Cd in carbonate precipitation (T2) and Fe/Mn oxide phases (T3). However, lime application stimulated Fe-reducing bacteria, decreasing Fe oxide-bound As (F3+F4) but increasing specifically adsorbed As (F2), thus rendering the net effect on As dissolution dependent on the balance of these processes. Birnessite counteracted the lime's negative aspect on F3+F4 via inhibiting anaerobic reductive dissolution of Fe oxides. Pot experiments confirmed that the combined treatment (1‰ birnessite and 0.5% lime) reduced As and Cd uptake in rice seedlings by 13.26%–37.57% and 43.76%–70.89%, respectively. Notably, excessive lime (1‰ birnessite_1% lime) elevated As bioavailability, highlighting the need for soil-specific dosing. This redox-adsorption coupled strategy offers a cost-effective solution for As-Cd co-contaminated paddies and similar waterlogged ecosystems.

**ABSTRACT**

Conventional assessments of heavy metal contamination in paddy systems focus predominantly on dissolved metal ions, largely neglecting colloidal forms—despite their prevalence in flooded soils. Trivalent chromium (Cr(III)), in particular, has been considered low-risk due to its presumed low solubility and precipitation tendency, leading to its systematic underestimation in environmental risk evaluations. Here, we show that under typical paddy redox fluctuations, Cr(III) readily forms stable colloids with markedly increased mobility and interfacial activity, thereby enhancing its bioavailability and potential for food-chain transfer.

We compared the uptake, translocation and subcellular distribution of soluble versus colloidal Cr using rice as a model system. In aqueous environments, inorganic chromium rapidly transformed into colloidal aggregates that strongly adsorbed to root surfaces. These aggregates acted as interfacial reservoirs, substantially promoting chromium accumulation in both roots and shoots. In contrast, strongly chelated soluble Cr remained stable in solution, showed limited interaction with roots, and was poorly taken up and translocated. Further size-fractionation experiments revealed that smaller Cr colloids were internalized via active cellular pathways, whereas larger colloids or those with a strong adsorption capacity were predominantly sequestered in cell walls and rhizosphere microenvironments.

Our findings demonstrate that colloidal transformation fundamentally reshapes the environmental behavior and risk profile of heavy metals in flooded soils. Recognizing colloidal species as dynamic and bioavailable pollutant forms is therefore essential for accurate exposure assessment, improved risk management, and effective mitigation of heavy metal contamination in rice-producing ecosystems.

**ABSTRACT**

Heavy metal (HM) contamination in peatland sediments is an emerging concern, yet evidence for Vietnamese peatlands remains limited. The study evaluated HM levels and ecological risks in three peatland districts of Long An Province, Viet Nam (Tan Thanh, Thanh Hoa and Duc Hue). Thirty surface sediment samples (5–15 cm; n=10 per district) were analyzed for Mn, Ni, Pb, Cd, Cu and Zn, together with pH, salinity, electrical conductivity (EC), total organic carbon (TOC) and texture. Pollution was interpreted using sediment quality guidelines and indices: contamination factor (CF), modified degree of contamination (mCd) and potential ecological risk index (RI). Source apportionment applied positive matrix factorization (PMF); relationships were explored using Spearman correlation and Bayesian network analysis. Cu and Ni were highest in Tan Thanh and reached 2–3 times the threshold effects level (TEL) and effects range-low (ERL) guidelines. CF indicated moderate-to-considerable degree pollution for Ni (CF=1.3 in Thanh Hoa; 3.2 in Tan Thanh) and moderate degree pollution for Cu in both areas (CF=1.3–2.4). mCd ranked contamination as Tan Thanh (1.3) > Thanh Hoa (0.7) > Duc Hue (0.4). RI suggested overall low ecological risk (mean RI=35.6). PMF identified six factors; the dominant factor contributed 49.2% and was strongly associated with Cd, Ni and Zn, consistent with fertilizer and pesticide inputs. HM concentrations were positively associated with pH, TOC and fine fractions (clay+silt). These results provide baseline evidence for HM status in Mekong Delta peatlands and support targeted management to reduce metal loading.

**ABSTRACT**

Mining-impacted soils in Thai Nguyen, Viet Nam are contaminated by heavy metals (HMs). The study assessed HMs occurrence (As, Cd, Cu, Pb, Zn) and evaluated the accumulation of HMs in native plants and factors impact them in contaminated mining sites in Vietnam: Ha Thuong lead–zinc (HT), Trai Cau iron (TC) and Hich Village lead–zinc (LH). Native species were screened for remediation potential, focusing on Erianthus arundinaceus (EA) and Phragmites australis (PA). Chelate-assisted phytoextraction was evaluated using ryegrass (Lolium multiflorum Lam.) amended with ethylenediaminetetraacetic acid (EDTA; synthetic), ethylenediaminedisuccinic acid (EDDS; biodegradable) and nitrilotriacetic acid (NTA; biodegradable), applied as a single dose (1:1) or split/sequential dose (0.5:1 + 0.5:1). Controls displayed normal growth without visible metal-toxicity symptoms. Across sites, chelates significantly increased metal concentrations in ryegrass shoots versus controls. Split dosing outperformed single dosing for As, Pb and Zn in LH soil; the EDTA split dose delivered the highest increases in Zn (6.15-fold), Pb (69.5-fold) and Cu (1.49-fold), while the NTA split dose maximized As (18.47-fold). In HT soil, single-dose chelates more effectively enhanced Zn in shoots than split dosing, highlighting site-specific response. Field observations indicated EA tolerated multi-metal stress and produced high biomass, supporting phytostabilization. EA has the potential for phytostabilisation of Cd-contaminated sites. Overall, combining tolerant native plants for stabilization with carefully managed (preferably biodegradable) chelate strategies for extraction offers a practical remediation pathway for mine-affected soils, provided leaching risks are controlled. These responses indicate that chelate type and dosing should be tailored to local soil conditions and target metals to balance removal efficiency and environmental safety.

**ABSTRACT**

The speciation of heavy metals in soil determines their mobility and toxicity, making the analysis of their speciation crucial for understanding their environmental migration behavior and conducting risk assessments. This study focuses on soil surrounding a lead-zinc tailings area in eastern Inner Mongolia, where the total concentrations and speciation distributions of four heavy metals—Zn, Pb, As, and Cu—were determined. The pollution level was assessed using the single-factor index and geo-accumulation index, while an improved Tessier sequential extraction technique was employed to analyze their speciation characteristics, thereby evaluating the ecological risks and migration potential of these heavy metals. The results showed that the average concentrations of heavy metals in the soil followed the order Zn > Pb > As > Cu, which were 31.39, 23.60, 16.12, and 12.50 times the background values, respectively. The pollution degree of heavy metals was ranked as As > Zn > Pb > Cu, with arsenic being the most prominent pollutant. Speciation analysis indicated that the four heavy metals primarily existed in the residual and iron-manganese oxide-bound forms, exhibiting relatively high environmental stability. Additionally, carbonate-bound copper, sulfide- and carbonate-bound zinc, organic-bound arsenic, and carbonate-bound lead also accounted for certain proportions. Risk assessment based on bioavailable forms revealed that the overall ecological risk of heavy metals in the soil ranged from low to moderate, with zinc having the highest bioavailability and arsenic the lowest. In summary, the soil in this area is contaminated by multiple heavy metals, with arsenic being the primary pollutant. Although heavy metals predominantly exist in less active forms, they still pose potential release risks.

**ABSTRACT**

ABSTRACT:Cadmium (Cd) is a heavy metal element with high bioavailability. When rice is cultivated in Cd-contaminated soil, it often leads to excessive Cd accumulation in grains, posing a serious threat to food security and human health. Therefore, investigating the mechanisms to reduce Cd accumulation in rice is of significant importance. Auxin (IAA), a key endogenous factor regulating plant growth and stress responses, has been reported to influence Cd uptake and accumulation in plants, though its regulatory mechanisms remain unclear. The study indicates that: (1) Under Cd stress, there are differences in IAA response between the two rice lines, with the IAA concentration in the roots of the high-accumulation rice line Lu527-8 being significantly higher than that of the common rice line Lu527-4. Combined with transcriptome analysis, it was found that the expression patterns of the primary IAA response factor auxin up-regulated small RNA (OsSAUR) and the key rate-limiting enzyme gene in the phenylpropanoid biosynthesis process, namely phenylalanine ammonia-lyase gene (OsPAL), were consistent, suggesting that IAA may regulate lignin synthesis through OsPAL, thereby affecting the development of the apoplastic barrier; (2) Exogenous IAA reduced Cd accumulation in rice by limiting root Cd uptake, with Cd accumulation decreasing by 27.72% and 8.20% in Lu527-8 and Lu527-4, respectively. IAA limited apoplastic and symplastic Cd uptake in the roots of Lu527-8 by enhancing the development of the apoplastic barrier and reducing the expression of Cd transporters. However, for Lu527-4, IAA only limited the symplastic Cd uptake process in roots by decreasing the expression of Cd transporters. This is the main reason for the significant difference in Cd accumulation reduction between the two rice lines. In summary, under Cd stress conditions, exogenous IAA application can reduce Cd accumulation in the roots of the high-Cd-accumulating rice line Lu527-8 by simultaneously regulating both apoplastic and symplastic pathways, whereas the common rice line Lu527-4 primarily relies on the regulation of the symplastic pathway.

**Key Words:** auxin; Cd accumulation; rice; apoplastic barrier; transporter

# Regulatory Effects of Nitrogen and Acetate on Arsenic Adsorption by Bentonite in an Anaerobic System

**Xinyun Meng [1*], Jing Liu [1], and En Ci[1]**

[1] *College of Resources and Environment, Southwest University, Chongqing, China*

*mengxinyun@foxmail.com

**ABSTRACT**

Arsenic contamination has become a global environmental issue, posing significant threats to both ecosystems and human health. Statistics indicate that over 200 million people worldwide are at risk of arsenic exposure. To address this challenge, various remediation technologies have been developed and applied. Among them, adsorption has been recognized as one of the most promising techniques due to its high efficiency, cost-effectiveness, and operational simplicity. Bentonite, a natural clay mineral, has demonstrated great potential for arsenic remediation. However, research on the influence of nitrogen compounds on arsenic adsorption by bentonite in agricultural and aquatic environments remains limited. In this study, batch experiments were conducted under anaerobic reducing conditions to systematically investigate the effects of exogenous nitrogen addition on arsenic adsorption by bentonite. Furthermore, the regulatory role of low-molecular-weight organic acids, particularly acetate, in this system was explored. The results revealed that: (1) the arsenic adsorption efficiency of bentonite exhibited a significant negative correlation with the amount of exogenous nitrogen added, while the chemical form of nitrogen (nitrate or ammonium) had no significant effect; (2) acetate exerted a dual effect on arsenic adsorption: moderate acetate concentrations (0.2-0.5 g) enhanced arsenic adsorption, whereas excessive acetate (>0.8 g) significantly inhibited the adsorption capacity of bentonite. These findings provide valuable theoretical insights into the application of bentonite for arsenic remediation in anaerobic reducing environments and highlight the necessity of optimizing exogenous nitrogen and organic acid concentrations in practical applications.

*weizhang@msu.edu

**ABSTRACT**

Metals and metalloids (hereafter termed as metals) are ubiquitous in agricultural ecosystem. Food crops can take up both toxic and nutritional metals from soils, resulting in their transfer through food chain and subsequent dietary intake by humans. The lack of essential metals and/or the excess of toxic metals in crops and diets can cause adverse health outcomes including severe chronic diseases. Thus, the entire composition of metals (i.e., metallomes) in crops should be studied and managed to enhance nutrition and food safety. Here we hypothesize that crop metallomes can be optimized by agricultural practices such as plant breeding, soil water and nutrient management, cropping practices, etc. We have studied how soil water conditions, plant growth stages, and soil amendment applications could influence the metallomes of carrot (*Daucus carota* subsp. *Sativus*) and wheat (*Triticum aestivum*) grown in sandy soil under laboratory and greenhouse conditions. Our results showed that metallomes in carrots and wheat were primarily controlled by plant growth stages, with limited effect from soil water conditions. Interestingly, wheat kernels showed different metallomes among varying soil water conditions. For carrot seedlings the correlated metallomes in carrot roots did not significantly change with soil amendments, whereas the non-correlated metallomes could be influenced by soil amendments. We then explored the metallomes of carrots grown to maturity in greenhouse with single or combined soil amendments (e.g., biochar). We are further studying crop metallomes under field conditions and explore environmental and biological controls on crop metallomes using multi-omics approaches. It could be possible to optimize crop metallomes through agricultural practices for enhanced nutrition and food safety, thus improving public health.

**ABSTRACT**

Rice is a major crop in China with a strong tendency to accumulate cadmium (Cd), posing serious risks to grain safety. α-Ketoglutarate (AKG), a key tricarboxylic acid cycle intermediate, has known roles in abiotic stress responses, but its effects on Cd tolerance and accumulation in rice remain unexplored. Exogenous AKG (50 μmol/L) was applied to investigate the mechanism regulating Cd tolerance and accumulation under both hydroponic and soil conditions. Under hydroponic experiments, exogenous AKG significantly reduced Cd translocation by 56.8–63.9%, and decreased shoot Cd accumulation by 54.9–60.6%. It alleviated photoinhibition and oxidative damage by enhancing photosynthesis and antioxidant activities while lowering $H_2O_2$ and MDA. Mechanistically, multi-omics analyses showed AKG confers Cd tolerance and Cd restriction concentration-dependently. Under moderate Cd stress, AKG predominantly enhances the ascorbate-glutathione cycle and flavonoid biosynthesis for antioxidative defense, while upregulating *OsHMA3* and reinforcing the endodermal barrier to restrict Cd transport. Under severe Cd stress, AKG shifts to activating melatonin biosynthesis and further suppressing transporters like *OsIRT1*. Additionally, AKG reduced grain Cd by 40.7% and increased yield by 31.6% under soil conditions. These results demonstrated the effective role of AKG in integrated Cd mitigation and provide a novel strategy for safe rice production in Cd-contaminated soils.

# Accumulation characteristics and risk prediction of Cu and Zn contents in typical facility soils in China

**ABSTRACT**

Excessive accumulation of trace elements in the protected cultivation soil has become an important factor for the degradation of soil quality. In particular, both copper (Cu) and zinc (Zn) are micronutrient elements required for plant growth and heavy metal in the soil environment. It is highly demanding to consider the Cu, Zn cumulative risks. Therefore, this study aims to investigate the accumulation characteristics and risk prediction of Cu, Zn content in the protected cultivation soil. A total of 131 soil samples were also collected using 5-point sampling in the typical regions of 16 cities in 7 provinces and 1 autonomous region (including Liaoning, Hebei, Shandong, Henan, Shaanxi, Jiangsu, Yunnan, and Ningxia) in China. The cumulative status and risk characteristics of Cu and Zn were systematically analyzed using the total and available content of the soil. The relationship between the accumulation of available Cu, Zn, and the planting years was fitted to predict the risk of Cu and Zn accumulation exceeding the limit value. The results showed that: 1) The total Cu and Zn exhibited an accumulative characteristic in the protected cultivation soil, except that Cu presented a slight decrease in Jiangsu. The effective state content of Cu and Zn (except that Zn at a relatively rich level both in Shaanxi and Jiangsu) reached an extremely rich level, where there was no state below the critical value. Noted that the soil background values in each province were compared with the abundance and deficiency indexes of soil available trace elements in the agricultural system. 2) The total amount of Cu and Zn in the soil exceeded the standard by 16.03% and 4.58%, respectively, compared with the screening value of farmland soil. The average exceeding limit rate reached 16.92%, while Liaoning, Henan and Yunnan were observed the most serious up to 33.33%, 62.50%, and 32.00%, respectively, compared with the risk limits of soil available Cu and Zn. 3) The risk assessment showed that the overall performance of protected cultivation soil was safe using the effective state. The samples from Liaoning, Henan, and Yunnan reached the level of lightly, lightly pollution, and warning value level, respectively. The cumulative risks of elemental Cu were more serious than Zn element. 4) There was a significant positive correlation between the accumulations of soil available Cu and Zn with the corresponding planting years ($P<0.05$). The continuous replanting for 6.7, 20.5, and 19.3 years led to the accumulation of available Cu in soils with acidic, neutral, and alkaline limit values of characteristics reach risk, respectively, under the current protected cultivated conditions. At the same time, the continuous replanting for 32.5, 67.9, 91.9 years led to the accumulation of available Zn in the soils with acidic, neutral, and alkaline limit values of characteristic reach risk. The bioavailable state of trace element was used to evaluate the exceeding limit rate of Cu and Zn, while the cumulative risk in the protected cultivated soil, in order to achieve the safe utilization via transforming the excess bioavailable to low state, (such as residue, oxidizable, and reducible state). Therefore, there was a high risk in the accumulations of Cu and Zn in the protected cultivated soil in the practice, where the trends were ever increasing year by year. Consequently, it is necessary to take reasonable and safe measures (including restoration technology and selection of agricultural materials), further to ensure the healthy and sustainable development of protected cultivated agriculture. The extension limit is 3000 characters with spaces in total, this including Acknowledgments and References if any.

## ABSTRACT

High soil pH is generally known to inhibit cadmium (Cd) bioavailability, yet wheat grains from alkaline wheat-growing regions in China often exceed Cd safety thresholds. This paradox may be partly explained by the overlooked contribution of colloidal Cd to wheat Cd uptake. Nevertheless, research on colloidal Cd in alkaline wheat soils remains limited, particularly regarding two key issues: First, differences in mineral composition among soil types may alter the binding forms and stability of colloidal Cd, thereby influencing its bioavailability. Second, freeze–thaw cycles (FTCs), which are common in farmlands of northern China, may promote the release of colloidal Cd from aggregates of different sizes. Therefore, the objectives of this study were to 1) clarify the effect of soil type (characterized by differences in mineral composition) on the bioavailability of colloidal Cd in alkaline soils; 2) elucidate the mechanisms underlying the mobilization and release of colloidal Cd from aggregates with different particle sizes during FTCs. In this study, we collected colloidal Cd from Cd-contaminated soils and conducted hydroponic experiments to verify the bioavailability of soil colloidal Cd and their influencing factors. Furthermore, we employed stable Cd isotope tracing technology to quantitatively analyze the release characteristics of colloidal Cd in soil aggregates of different particle sizes during FTCs.

Results shows that over 90% of Cd in soil solution exists as colloids. Colloidal Cd content was weakly related to total soil Cd but showed significant positive correlations with soil pH and colloidal Al content. AF4 analyses revealed that Cd primarily forms mineral–organic colloidal complexes with aluminosilicates, with particle sizes ranging from 100 nm to 1 μm. Hydroponic experiments confirmed that colloidal Cd is bioavailable to wheat, indicating that colloids are an important Cd source rather than inert carriers. In addition, soil FTCs significantly increase the content of colloidal Cd in soil. Isotope tracing results indicated that macroaggregates are the primary source of colloidal Cd during FTCs (contribution rate: 49.6%–65.1%). The fine fraction contributed only marginally (< 5%), despite its higher Cd concentration. SEM–μCT–DSC analyses further showed that macroaggregates, characterized by larger pores and higher free water content, readily disaggregated and released colloidal Cd during FTCs, while fine particles resisted disaggregation and acted as sinks for Cd colloids. Overall, our findings demonstrate that colloidal Cd are the dominant form of Cd in alkaline soils and can significantly contribute to Cd uptake by wheat. Furthermore, FTCs in alkaline soils intensifies the release of colloidal Cd, and this suite of processes may further facilitate Cd accumulation in wheat grown in alkaline soils.

**ABSTRACT**

The contamination of agricultural soils with cadmium (Cd), arsenic (As), and their combined pollution has become increasingly severe in China. This study systematically investigated the response characteristics and ecological mechanisms of soil microbial communities during the aging process of Cd, As, and their combined pollution through soil microcosm incubation experiments combined with amplicon and metagenomic sequencing technologies. Results revealed that Cd/As aging significantly altered microbial community structure and function. During aging, bacterial α-diversity exhibited an initial decrease followed by an increase, while fungi showed the opposite trend. High-concentration Cd-As co-contamination demonstrated synergistic toxicity that persistently suppressed microbial diversity. Medium- and low-concentration Cd/As treatments and their combinations significantly induced the enrichment of heavy metal-tolerant taxa in later aging stages, including increased relative abundance of genus *VBCG01* (bacteria) from 1.88% to 2.03%-3.45%, and *Mortierella* (fungi) from 16.82% to 17.01%-20.28%. Co-contamination enhanced the complexity of bacterial-fungal-cross-domain ecological networks, indicating its role in driving microbial functional differentiation and dynamic equilibrium of resource competition while enhancing system resilience. Community assembly analysis showed deterministic processes in bacterial communities initially increased then decreased with aging time, whereas fungal communities exhibited the reverse pattern, reflecting their distinct ecological adaptation strategies under heavy metal stress. Both microbial kingdoms initially responded to environmental factors through nutrient salts/ion exchange before shifting to organic matter/K+ metabolism coordination in later stages. Based on community mean tolerance breadth (CMTB) and response asynchrony (CMRA) analyses, co-contamination groups showed the highest resistance potential in late aging stages, while Cd/As single pollution demonstrated more persistent negative impacts. PLS-PM analysis revealed that aging processes modified bioavailable heavy metal fractions and soil physicochemical properties, thereby regulating microbial community characteristics and resistance potential, with fungi contributing more significantly to resistance. These findings provide theoretical foundations and data support for ecological risk assessment and microbe-driven remediation strategies in contaminated farmland ecosystems.

**ABSTRACT**

The fragile karst ecosystems in eastern Yunnan are confronting severe challenges from soil metallic pollutants (SMPs). This study innovatively constructs a "Source-Risk-Driver" (SRD) framework to systematically unravel the dynamics of SMP contamination through three dimensions: source identification, risk quantification, and driver prioritization. By integrating pollution indices, positive matrix factorization (PMF), and Geodetector models, a multidimensional analysis was conducted on six SMPs in the region. Key findings include: (1) SMPs originate from the interplay between karst geological processes (e.g., carbonate weathering) and anthropogenic activities (agricultural inputs, industrial emissions, and transportation). PMF source apportionment revealed that 17.9% of the pollution load stems from agro-natural synergistic sources. (2) The Natural-Agricultural Composite Source dominated ecological risks (contribution rate: 77.17%), primarily driven by cadmium. (3) Geodetector quantification identified SMP concentration gradients, socioeconomic pressures (GDP and population density), and climatic stressors (temperature and evapotranspiration) as the primary drivers of risk spatial differentiation. The SRD framework elucidates, for the first time, the cascading linkages from pollution sources to risk manifestation and their socio-environmental drivers in karst regions. This provides a theoretical basis for implementing sourceoriented control strategies (e.g., prioritizing agro-natural synergistic source management) and establishing crosssectoral governance frameworks (e.g., reconciling mineral exploitation with ecological conservation policies).

**ABSTRACT**

The chemical forms of heavy metals in soil determine their mobility and toxicity, making the analysis of these forms crucial for understanding their environmental transport behavior and conducting risk assessments. This study focused on soils surrounding a lead-zinc tailings area in eastern Inner Mongolia, measuring the total concentrations and speciation distribution of four heavy metals: zinc, lead, arsenic, and copper. Pollution levels were evaluated using the single factor index and the geo-accumulation index, while an improved Tessier sequential extraction method was employed to analyze their speciation characteristics. The results indicated that the pollution degree of heavy metals in the soil followed the order: As > Zn > Pb > Cu. These four heavy metals primarily existed in residual and iron-manganese oxide-bound forms, exhibiting high environmental stability. The speciation of metals can be modified by the addition of various types of humic acids and different concentrations of iron-manganese oxides. Four types of humic acids were utilized: fulvic acid (FA), humic acid (HA), humin, and total humic acids. The addition of total humic acids resulted in an increase in the bioavailable forms of zinc (Zn) and arsenic (As), while the bioavailability of lead (Pb) and copper (Cu) decreased. Conversely, the introduction of the other three types of humic acids led to a decrease in the bioavailability of Zn, Pb, and Cu, whereas the bioavailability of As increased, with the bioavailable forms diminishing as the concentration of humic acids increased. Over time, the bioavailable forms of Pb and Cu in the soil increased following the addition of humin and humic acid, while the bioavailable form of As in the soil increased after the addition of fulvic acid and humin. Upon the addition of varying concentrations of iron-manganese oxides, the predominant forms of As were found to be residual and primarily sulfide-bound states. Zn predominantly existed in iron-manganese oxide-bound and residual states, while Pb primarily occurred in iron-manganese oxide-bound, primary sulfide-bound, and residual states. Cu was mainly found in organic-bound, primary sulfide-bound, and residual states. Throughout the aging period, the bioavailable fractions of all four heavy metals exhibited a decreasing trend. In conclusion, the soil in this area is contaminated by multiple heavy metals, with As identified as the primary pollutant. Although these heavy metals primarily exist in low-activity forms, there remains a potential risk for their release.

# Colloidal Cd Mobilization During Reductive Dissolution of Cd-Birnessite by Organic Matter: Role of pH-Dependent Mineral Transformation and Organic Fractionation

**Yanjun Jiang[1,2*], Yufeng Lin[1], Kengbo Ding[1,2], Ye Xiao[1,2], Weihua Zhang[1,2], Rongliang Qiu[1,2], Ye-tao Tang[1,2]**

**ABSTRACT**

Cadmium (Cd) immobilized on manganese oxides ($MnO_x$) in soils can undergo remobilization through reductive dissolution by natural organic matter (OM). However, the dominant Cd species released in this process remain incompletely understood, particularly under different pH conditions. Herein, we investigated dynamic Cd speciation during anaerobic reduction of Cd-bearing birnessite by Suwannee River Fulvic Acid (SRFA), revealing a progressive dominance of colloidal Cd throughout the experiment. This trend amplified at higher pH, as evidenced by its ultimate contribution of 36.6%, 57.8%, and 77.1% to total dissolved Cd at pH 4.5, 6.0, and 8.0, respectively. Moreover, two distinct colloidal Cd fractions were identified by asymmetrical flow field-flow fractionation, extend X-ray absorption fine structure, and Fourier transform ion cyclotron resonance mass spectrometry. The first fraction (1 kDa–50 nm) carried 27.7–45.6% dissolved Cd via complexation with SRFA derivatives, exhibiting lower oxidation state, higher susceptibility to reoxidation, and increased Cd release risk. The second fraction (200–450 nm) carried 8.9–31.6% dissolved Cd and evolved from organic aggregates into $MnO_x$-OM colloids. These composite colloids could enhance colloidal Cd stability and potential mobility, especially under pH 6.0 and 8.0, due to stable crystalline manganite/hausmannite formation and enriched oxidized organic matter. We highlight that the released colloidal Cd during $MnO_x$ reductive dissolution under varying pH could exhibit variable mobility, reactivity, and environmental risk.

**ABSTRACT**

To examine the characteristics of heavy metal contamination in soils, pollution sources, and the risk to agricultural product quality in typical heavy metal mining areas, a study was conducted in a city in Guizhou Province with a history of concentrated lead-zinc mining activities. A total of 1,500 surface soil samples were collected to measure the contents of eight heavy metals: Cd, Pb, Cr, Cu, Ni, Zn, Hg, and As. The study combined the Random Forest (RF) model and Positive Matrix Factorization (PMF) receptor model for comprehensive source analysis, and used the Geo-accumulation Index (Igeo) and Potential Ecological Risk Index (RI) to assess pollution levels and ecological risks, while also investigating the enrichment effect of heavy metals in maize. The results showed that the average content of all eight heavy metals exceeded the background values of soils in Guizhou, with Cd reaching severe pollution levels (Igeo = 1.79). The sources of soil heavy metal pollution were primarily natural and anthropogenic, contributing 27.38% and 72.62% respectively. Among anthropogenic sources, transportation, atmospheric deposition, crop-focused agricultural activities, and metal mining-based industrial activities contributed 12.05%, 15.2%, 34.62%, and 10.75% of heavy metals, respectively. The Random Forest (RF) model evaluation indicated a complex interaction between factors affecting heavy metal accumulation, with pesticide and fertilizer usage playing significant roles. The RI was 441.84, classified as Level III, indicating medium to high risk, with potential risk from Cd needing special attention. Maize showed significant differences in bioaccumulation capacity for different heavy metals: the Cd enrichment factor was 0.04, demonstrating strong accumulation; Cr, Hg, and As enrichment factors ranged from 0.008 to 0.03, showing moderate accumulation; while Pb had the lowest enrichment factor of 0.002. These findings provide a scientific basis for precise prevention and control of soil heavy metal pollution in the region.

**ABSTRACT**

This study investigates how land use types mediate air-surface $Hg^0$ exchange in three karst catchments including Shawan, Chenqi, and Huilong in Southwest China. Using dynamic flux chamber (DFC) and Hg isotope analysis. This study demonstrates that the dominant factor regulating the direction and magnitude of $Hg^0$ fluxes is land cover, and this finding holds true across regions with varying soil Hg backgrounds. In Shawan, annual $Hg^0$ emissions were highest from bare land at 4.55 ng $m^{-2}$ $h^{-1}$, while grassland functioned as a net sink with an uptake flux of -1.82 ng·$m^{-2}$ $h^{-1}$. In Chenqi, moderate emissions were observed from dry agriculture land at 5.67 ng·$m^{-2}$ $h^{-1}$, while forest and grassland acted as net sinks during autumn. In Huilong, dry agriculture land emissions as high as 267.2 ng·$m^{-2}$ $h^{-1}$ were observed, which was approximately tenfold higher than that from forest areas. Mercury emissions peaked in summer across all sites due to high temperature and strong solar radiation. Mercury isotope analysis showed significant kinetic fractionation, with $\delta^{202}Hg$ values as low as -2.75‰ in emissions from low-vegetation areas, indicating preferential release of lighter Hg isotopes during volatilization. Soil organic carbon (SOC) emerged as a key mediating factor, showing a significant positive correlation with Hg concentration but a negative correlation with $Hg^0$ flux, underscoring its role in inhibiting Hg re-emission. This study demonstrates that maintaining well-vegetated landscapes can reduce Hg emissions by over 90% compared to disturbed surfaces. These findings highlight the critical importance of land use specific management, such as preserving forest cover and regulating agricultural practices for mitigating Hg dispersion and strengthening ecosystem sink capacity in vulnerable karst regions, providing a scientific basis for targeted Hg risk control and ecological sustainability strategies.

**Keywords:** $Hg^0$ flux magnitude; land use effect; Hg isotopes; air-surface exchange; karst area

Highlight:

(1) Vegetation cover reduces $Hg^0$ emissions by over 90% compared to bare or disturbed land, transforming landscapes from net sources to sinks.

(2) Mercury isotopes confirm that low-vegetation areas favor kinetic release of light Hg, while vegetation shifts reduction pathways and suppresses volatilization.

(3) Soil organic carbon enhances Hg retention and strongly inhibits re-emission, highlighting its key role in sustaining the sink capacity of vegetated ecosystems.

**Acknowledgments:** This work was supported by the National Natural Science Foundation of China (42107497).

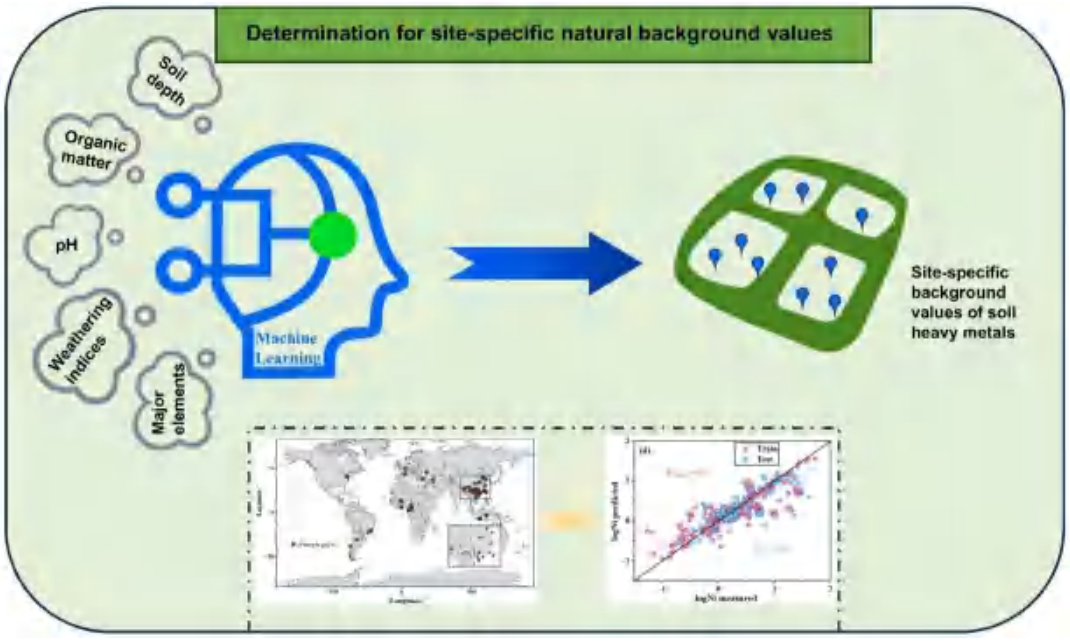
# Machine learning-supported determination for site-specific natural background values of soil heavy metals



**Jian Wu[1*], Chengmin Huang[1]**

[1] *Department of Environmental Science and Engineering, Sichuan University, Chengdu 610065, China*

*Wujian20210912@163.com

**ABSTRACT**

Heavy metal natural background values play a crucial role in distinguishing anthropogenic sources from natural sources to assess human impacts in polluted areas, thereby accurately formulating environmental policies. However, due to limitations imposed by human activities, research methods, and regional constraints, the determination of heavy metal background values, particularly on site or profile scale, is often challenging, highlighting the urgent need for new methodologies. To establish a comprehensive dataset containing heavy metal concentrations and soil properties, the study systematically collected and screened 82 soil profiles from areas minimally affected by human activities, resulting in a total of 2185 data sets. Using soil depth, pH, organic matter, weathering indices (SAF, BA), $Fe_2O_3$, MgO, $Na_2O$, CaO, and $K_2O$ as model input variables, the predictive performance for site-specific background levels of Cd, Cr, Cu, Ni, Pb, and Zn was compared across four advanced machine learning models (RF (random forest), XGBoost (extreme gradient boosting), ANN (artificial neural network), SVR (support vector regression)). The results indicated that the optimal model for predicting background values of Cd, Cr, and Ni was XGBoost (MAE = 0.14 – 0.17; MSE = 0.04 – 0.06; $R^2$ = 0.82 – 0.87), while RF was used for Cu, Pb, and Zn (MAE = 0.01 – 0.18; MSE = 0.02 – 0.06; $R^2$= 0.89 – 0.95). Importance assessments using RF and SHAP revealed that pH is a key controlling factor for Cd and Ni, $Fe_2O_3$ significantly impacts Cr, Cu, and Zn background levels, and $K_2O$ is the main controlling factor for Pb. The machine learning models developed can effectively predict the background levels of these six heavy metals based on major elemental and soil physicochemical properties, particularly achieving accurate predictions for Cu and Zn using just two input variables. This machine learning prediction framework is based on major elemental compositions and the physical/chemical properties of soil, enables precise and cost-effective point-to-point environmental assessments, thereby offering significant potential for practical applications.

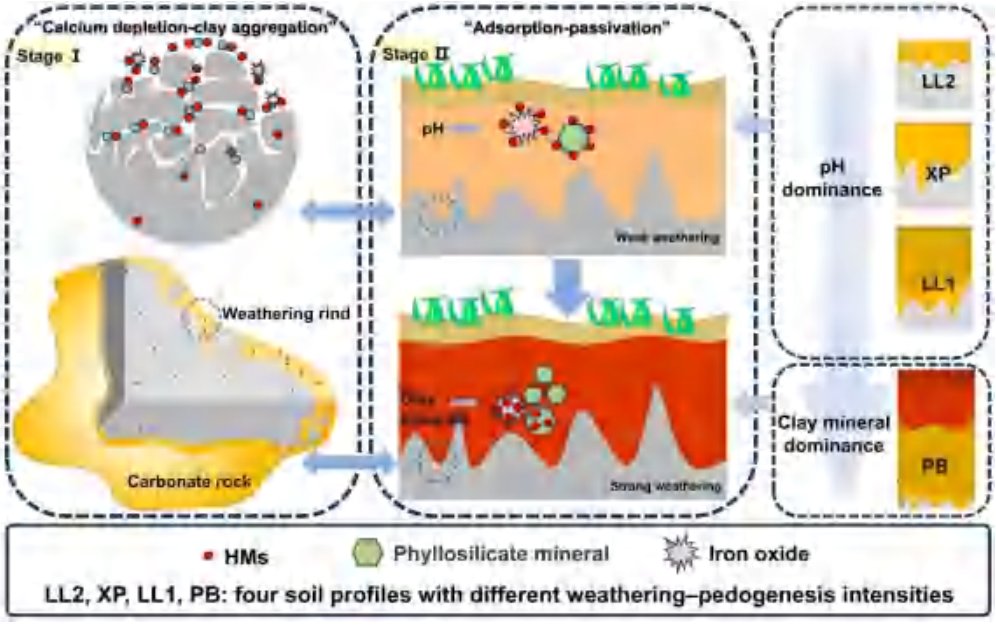
# Two-stage heavy metal enrichment during carbonate rock weathering-pedogenesis: Micro-scale evidence from soil-rock interface



**Jian Wu[1*], Chengmin Huang[1]**

[1] *Department of Environmental Science and Engineering, Sichuan University, Chengdu 610065, China*

*Wujian20210912@163.com

## ABSTRACT

Carbonate rock weathering could lead to selective enrichment of heavy metals (HMs), posing potential ecological risks, however, the geochemical behavior of HMs and the dominant controls on chemical weathering within the soil-rock systems remain incompletely understood. This study systematically investigated four soil profiles at different pedogenic stages and weathering rinds at the soil-rock interface in a representative karst region of China, focusing on Cd, Cr, Cu, Pb, Zn, and Ni. Bulk concentrations and sequential extraction results showed that both total contents and residual fractions of these HMs increased with pedogenesis. In-situ microanalyses of the soil-rock interface, using LA-ICP-MS and SEM-EDS, revealed marked increases in Al, Si, Fe and HMs, accompanied by Ca depletion, from bedrock to weathering rinds. Redundancy analysis (RDA) indicated that pH and clay minerals exerted key controls on HMs accumulation across pedogenic stages. Integrating macro- and micro-scale evidence, we proposed a two-stage enrichment pattern: during early carbonate dissolution, HMs were concentrated due to Ca leaching and clay mineral formation; subsequently, elevated soil pH facilitated further enrichment, while ongoing pedogenesis promoted their encapsulation or structural incorporation into clays. These findings provide critical insights into heavy-metal dynamics in karst soils and establish a theoretical basis for pollution control and risk assessment in carbonate terrains.

## ABSTRACT

Soil heavy metal pollution has become a global environmental issue due to its toxicity, cumulative nature, and resistance to degradation. As a significant agro-pastoral transition zone in northern China, Chifeng City features extensive livestock farming and high utilization rates of animal manure resources. However, heavy metals in manure entering the soil through field application may pose pollution risks. This study assessed the current status and potential risks of soil heavy metal pollution in Chifeng City by calculating the static environmental capacity (ΔQ), heavy metal input from livestock manure (Qo), and the livestock carrying capacity of cultivated land (LCCF), based on data from the 2013 and 2023 Chifeng City Statistical Yearbooks and relevant literature. Results indicate: (1) The environmental static capacities for cadmium (Cd), chromium (Cr), lead (Pb), arsenic (As), and mercury (Hg) exhibit a trend of higher environmental static capacity in the eastern region and lower capacity in the western region. Notably, the environmental capacity for Cd has significantly decreased, dropping from a maximum capacity of 27.38 kg (2013) to a maximum of only 1.63 kg (2023). The continuous accumulation of livestock manure production has resulted in input levels exceeding soil carrying capacity. (2) Among heavy metals generated from livestock manure, the primary pollution contribution areas for Cd, Cr, and As shifted from Songshan District, Wengniute Banner, and Aohan Banner to Aohan Banner, while Pb and Hg were mainly concentrated in Ningcheng County and Karqin Banner; (3) Analysis of livestock carrying capacity on cultivated land indicates Cd has already exceeded standards, with Songshan District showing the highest excess (97 pig equivalents per hectare); (4) Analysis of livestock carrying capacity across different crops reveals oilseed crops have the highest capacity (45,029 pig equivalents per hectare) due to straw removing a significant amount of heavy metals. In summary, the primary risk of soil heavy metal contamination in Chifeng City stems from increased input due to livestock manure application to farmland, with particularly prominent issues of reduced environmental capacity for Cd and regional exceedances. It is recommended to rationally optimize livestock farming layouts based on the heavy metal carrying capacity of farmland, achieving "farming determined by land capacity."

# Mining-induced arsenic contamination: cascading effects on soil biogeochemistry, microbial community structure and human health risks

**S. Chakraborty[1*] and P. Bhattacharyya[2]**

[1] *Agricultural and ecological research Unit, Indian Statistical Institute, Giridih, India*

*E-mail: cshr.work@gmail.com

**ABSTRACT**

Mica mining in Jharkhand, India, has led to elevated arsenic (As) contamination and altered soil biogeochemistry in surrounding agricultural fields, raising concerns about crop safety, ecological health, and dietary exposure risks. This integrated study assessed soil, rice grain, and microbial responses due to active mining. Total soil As was substantially higher in agricultural zones near the mines ($44.74 \pm 1.01$ mg kg$^{-1}$) than in the control zone ($4.79 \pm 0.11$ mg kg$^{-1}$). Subsequently, rice grains gown on the contaminated areas accumulated markedly more As ($1.09 \pm 0.08$ mg kg$^{-1}$) than the control zone ($0.11 \pm 0.02$ mg kg$^{-1}$). Sequential extraction revealed that As predominantly occurred in amorphous iron oxide-bound fractions and crystalline iron oxides, as compared to exchangeable and water-soluble phases; the amorphous fraction showed a significant positive correlation ($p < 0.05$) with As accumulation in rice tissues. Geostatistical mapping indicated that the spatial distribution of soil acidity closely mirrored that of As, suggesting a causal interaction between acidification and metalloid mobility. Soil biochemical indicators, including fluorescein diacetate, dehydrogenase, β-1,4-glucosidase, phosphatase, urease activities, along with basal respiration and microbial biomass carbon, were significantly inhibited in the contaminated zone. Metagenomics demonstrated pronounced reductions in both alpha and beta diversity in the contaminated zone, reflecting disruption of microbial community structure and functional potential. Human health risk assessment revealed total cancer risk values for children ($3.10 \times 10^{-2}$), men ($7.7 \times 10^{-3}$), and women ($8.4 \times 10^{-3}$), all exceeding the acceptable threshold ($10^{-5}$), although hazard indices for non-carcinogenic effects remained below toxic limits, with children being most vulnerable. Overall, the combined chemical, biochemical, and metagenomics evidence underscores the severe ecological and health risks posed by mining-induced As contamination. The insights gained provide a mechanistic understanding of soil-plant-microbe interactions under metalloid and acidity stress, offering a foundation for developing remediation strategies and promoting sustainable agricultural practices in mining-impacted landscapes.

## ABSTRACT

Hills around metropolis are regarded as ecological protective screens. At south China, such hills are always cultivated for planting tropical fruits or backyard vegetables. As well known, soil heavy metal pollution has becoming more and more serious during last decades (Hou et al, 2025). Soils of such hills were influenced by human activities and conversely have impact on urban environment even human health of the residence. Therefore, it is of significant importance for pollution control land management to assess soil heavy metal pollution and its potential ecological risks for hills within cities.

In order to reveal soil heavy metal pollution status and its influencing factors, one hundred topsoil samples collected from top to bottom hill transects of a backyard vegetable plantation (ZCPT, 18 samples), a newly developed orchard (CHWQ, 32 samples), a long-time Litchi orchard (ZCGC, 15 samples), upper (ZCZX-up, 23) and lower (ZCZX-down, 12) parts of a machine plowing path within a tens-year Litchi orchard were selected for heavy metal (including Cu, Zn, Ni, Pb, Cr, Cd, As, and Hg) content measurements. Consequently, heavy metal pollution and its potential ecological risks were assessed using geoaccumulation index ($I_{geo}$) and potential ecological risk index ($E^i_r$, RI), respectively.

Although all measured samples are belonged to acid soils, soil pH values of CHWQ are significantly higher than those of other areas, indicating some subsoils were overturned to surface layer during the consolidation process. The results indicate that hill soils are contaminated by heavy metals Cu, Zn, Pb, and Cd at different degrees. The $I_{geo}$ results reveal that all measured soil samples were suffered moderately to highly Cd pollution. Lightly soil Zn and Pb pollution are appeared at CHWQ and ZCPT, respectively. Soils within ZCZX-up are suffered lightly Cu pollution and moderately to highly Pb pollution. No obvious ecological risks are caused by the mentions Cu, Zn, and Pb pollution due to the less than 40 of $E^i_r$ values. However, the mentioned Cd pollution caused considerable and moderate ecological risks for soils within ZCGC and other areas, respectively due to calculated RI values.

Since both Igeo and $E^i_r$ values of Zn are significantly positive related with pH values and Zn pollution is only appeared at the newly developed orchard and, it can be deduced that soil Zn may be related to machinery or the overturned subsoils during orchard development. The Cd pollution degree and its ecological risks of soils within the long-time Litchi orchard (ZCGC) are obviously more seriously than those of other areas, indicating the controlled impact of long-term continuous fertilization, which is consistent with conclusion suggested by many previous studies (Fei et al, 2022; ). Notably, Cd contents of samples collected from flat grounds are significantly higher than those from slopes. Furthermore, soil Cd contents of ZCZX-down are obvious higher than those of ZCZX-up. These results indicate the vertical transportation of heavy metal Cd under acid conditions and enrichment in flat areas, which is further proved the speculation by Bi et al (2025).

**ABSTRACT**

Soil metal(loid) contamination (e.g., Pb, Zn, Cd) threatens agricultural safety in mining regions. Conventional remediation often sacrifices soil organic matter (SOM) for metal immobilization. Developing strategies that concurrently reduce soil metal(loid) bioavailability and enhance soil carbon sequestration is crucial. Arbuscular mycorrhizal fungi (AMF) immobilize soil metal(loid) and contribute to SOM, while iron-modified woody peat (Fe-Pt) provides strong heavy metals sorption sites. However, mechanistic evidence for their combined effects on organic carbon (OC) stabilization and soil metal(loid) fate within soil microstructure is limited.

This study investigated the synergy between AMF and Fe-Pt in co-achieving soil metal(loid) immobilization and OC sequestration in a Cd/Pb/Zn contaminated soil. We hypothesized that co-application would (1) enhance microaggregate formation and mineral-associated organic matter (MAOM) accumulation, (2) promote poorly crystalline Fe phases (e.g., ferrihydrite), and (3) lead to soil metal(loid) co-stabilization within MAOM. A factorial pot experiment with *Phaseolus vulgaris* L.combined Fe-Pt addition (0 or 2% w/w) and three AMF species (Rhizophagus irregularis—AMF1, Acaulospora scrobiculata—AMF2, Gigaspora margarita—AMF3). After six weeks, plant soil metal(loid) uptake, soil aggregates, OC fractionation (POM/MAOM), Fe/Zn speciation (XAFS), and microaggregate organic functional groups (SR-FTIR) were analyzed.

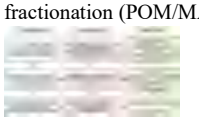

Figure 1 Diagram showing the structure organization of the present study, including the logical links among the research questions, research objectives, and methods and data.

Fe-Pt+AMF1 most effectively reduced plant Cd, Pb, and Zn uptake. Fe-Pt increased microaggregate proportion (from 39.79% to 47.48%) and total OC, with Fe-Pt+AMF1 further enhancing OC storage in MAOM. Fe k-edge EXAFS showed Fe-Pt+AMF1 promoted ferrihydrite formation while reducing hematite. SR-FTIR revealed a strong correlation between clay O–H and carboxyl/aromatic C (~ 1650 $cm^{-1}$) in microaggregates. Soil metal(loid) were preferentially enriched in MAOM, especially in Fe-Pt+AMF1. Zn k-edge XANES indicated Fe-Pt+AMF treatments decreased soluble Zn-goslarite and increased stable Zn-junitoite.

Figure 2 XRD spectra of the soils from different treatments (a), Fe species of soils from different treatments shown by Fe K edge XANES spectroscopy (b), the original (solid line) and linear combination fitted (LCF) (dashed line) k space Fe K edge EXAFS spectra of soils from different treatments (c), and distribution of Fe species in differently treated soils (d).

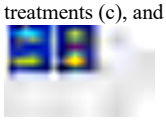

Figure 3 FTIR mapping of the microaggregate of Fe-Pt+AMF1 treatment.

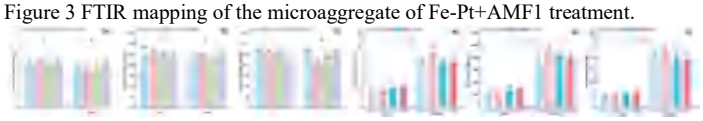

Figure 4 The contents of AAO extractable Cd (AAO- Cd) (a), Pb (AAO- Pb) (b) and Zn (AAO-Zn) (c) of soils from different treatments; the contents of total Cd, Pb and Zn (d-f) of POM and MAOM from Fe-Pt+AMF1 treatment.

Figure 5 The original (solid line) and linear combination fitted (LCF) (dashed line) k space Zn K edge XANES spectra of soils from different treatments (a), and distribution of Zn species in differently treated soils (b).

In conclusion, Fe-Pt+AMF1 synergistically immobilized soil metal(loid) and sequestered OC via: (i) Fe-Pt reducing soil metal(loid) stress on AMF, (ii) AMF-derived carboxyl/aromatic OC promoting MAOM, and (iii) Fe-Pt driving ferrihydrite formation, providing surfaces for OC and soil metal(loid) binding. This biotic–abiotic synergy enables coupled soil metal(loid) stabilization and OC sequestration within MAOM, offering a multifunctional remediation strategy for contaminated soils.

## ABSTRACT

Iron (hydr)oxide-enriched biochar (IEB) is a material with significant environmental applications, demonstrating considerable potential in soil remediation, pollutant immobilization, greenhouse gas emissions, and carbon sequestration. However, the stability of arsenic (As) immobilized by IEBs with different crystalline structures under redox fluctuations, as well as the role of dissimilatory iron-reducing bacteria (DIRB) in mediating the biotransformation of iron (hydr)oxides within IEBs and subsequent As retention, remain poorly understood. This study investigated the effects and mechanisms of Shewanella oneidensis MR-1 (MR-1) on As retention in ferrihydrite- and goethite-enriched biochar (FB and GB) during anaerobic and aerobic transitions and evaluated the passivation capabilities of the IEB in real flooding-drying As-contaminated soils. The results from batch experiments revealed that MR-1 did not significantly affect As retention in crystalline GB. However, during the 9 days anaerobic-aerobic cultivation period, MR-1 colonization of FBs increased ferrihydrite reduction and biotransformation, increasing electrostatic repulsion and leading to a 27.2% to 88.2% increase in dissolved As compared with the sterile control. Compared with the control, both FB and GB effectively reduced the amount of water-soluble As by 44.8% and 51.0%, respectively, after 100 days of flooding–drying incubation. The more stable passivation effect of GB also mitigated the adverse effects of As on pak-choi seed germination and growth. These findings provide valuable insights into how DIRB influences As retention in IEBs, highlighting the potential of crystalline IEBs as environmentally friendly and effective materials for passivating As in soils experiencing alternating flooding and drying conditions.

*E-mail: nguyenbinh@iuh.edu.vn

**ABSTRACT**

Heavy metal contamination of soils is an increasing environmental concern in regions experiencing rapid land-use change, intensive agriculture, industrial development, and mineral exploitation. This study quantified the distribution, dominant contaminants, and integrated pollution levels of heavy metals in surface soils (0–30 cm) across major land-use types in Lam Dong Province, Central Highlands of Vietnam. A total of 235 soil samples were collected from landfill sites, industrial land (CN), perennial crop systems (coffee and tea plantations), paddy fields, vegetable–flower cultivation areas, and bauxite mining zones. Concentrations of arsenic (As), copper (Cu), lead (Pb), zinc (Zn), chromium (Cr), and cadmium (Cd) were determined, and overall contamination was assessed using a Heavy Pollution Index (HPI). Across all land uses, Zn and Cr were the most abundant metals, with mean concentrations of 58.8 and 70.5 mg $kg^{-1}$, respectively, whereas Cd occurred at consistently low levels (0.30 mg $kg^{-1}$). Landfill soils exhibited the highest metal enrichment, particularly for Cu (97.5 mg $kg^{-1}$), Zn (162.6 mg $kg^{-1}$), and Pb (31.7 mg $kg^{-1}$), resulting in the highest HPI value (51.8). Industrial soils were characterized by Cr dominance (75.8 mg $kg^{-1}$), reflecting industrial emissions and long-term accumulation. In agricultural systems, perennial crops showed elevated Cr levels, with tea plantation soils reaching 129.8 mg $kg^{-1}$, exceeding regulatory thresholds. In contrast, arsenic was the primary contaminant in annual cropping systems, especially in vegetable and flower soils where As averaged 28.4 mg $kg^{-1}$, surpassing the guideline value of 20 mg $kg^{-1}$. Bauxite mining soils displayed a distinct Cr-enriched signature (116.9 mg $kg^{-1}$) consistent with the geochemical characteristics of bauxite parent materials. Overall, HPI values decreased in the order of landfill > tea plantation > bauxite mining ≈ vegetable–flower systems ≈ coffee plantation > industrial land > paddy land, confirming that land-use type is a key determinant of both the magnitude and composition of heavy metal contamination in soils and underscoring the need for land-use-specific soil management and monitoring strategies.

## ABSTRACT

Cadmium (Cd) contamination in agricultural soils poses a growing threat to food safety and soil sustainability, particularly in intensively managed cropping systems[1,2]. Here, we reconstructed historical and future Cd dynamics in paddy soils using Qiyang County, China, as a representative case. By combining soil acidification and mass-balance modelling with scenario analysis, we quantified Cd inputs, outputs, soil accumulation, and transfer to rice affected by soil pH changes under contrasting soil types and management strategies.

Our results show that atmospheric deposition has been the dominant source of Cd input to croplands since 1985, contributing up to 80% of total inputs, while manure represents the second-largest source, particularly in calcareous soils. Soil pH strongly controlled Cd fate: in calcareous soils, over 90% of Cd inputs accumulated due to low Cd availability, whereas in non-calcareous soils only 44% accumulated, with substantial losses through crop uptake and leaching. Progressive soil acidification markedly enhanced Cd leaching, leading to net Cd depletion from non-calcareous soils and Cd concentrations in soil solution exceeding WHO water-quality guidelines at pH < 4.5.

Scenario analysis revealed clear trade-offs between soil fertility management and Cd risk mitigation. Enhancing manure recycling effectively mitigated soil acidification but substantially increased soil Cd accumulation in soil and rice grain. Liming raised soil pH and reduced Cd uptake by rice at short to medium term, yet could further enhance Cd accumulation if total Cd inputs remained high, failing to avoid Cd contamination at long term. Optimal risk mitigation required integrated management, combining liming to maintain soil pH above critical thresholds with reductions in total Cd inputs. Two contrasting mitigation pathways were identified: prioritizing reductions in manure Cd content limited manure recycling which benefits on soil fertility and agricultural sustainability, whereas prioritizing reductions in atmospheric Cd deposition allowed higher manure recycling but required stronger Cd emission controls.

Our findings highlight the central role of soil pH and Cd inputs in regulating Cd accumulation and food-chain transfer. Integrated strategies targeting fertilizer use, manure recycling, liming, and Cd emission control are essential to safeguard crop quality while maintaining soil fertility in Cd-vulnerable agroecosystems.

**ABSTRACT**

Arsenic (As), a highly toxic and carcinogenic metalloid, is often exceeds permissible limits in paddy soils Bangladesh. Fe-modified biochar has been reported as an effective amendment for remediating As-contaminated soils; however, its stability and influence on As/Fe dynamics under the waterlogged paddy soils is poorly understood. This study evaluated the stability and efficacy of Fe-modified biochar derived from agricultural waste, using $^{57}Fe$ stable isotope as a tracer to determine As adsorption and dissolution from waterlogged reduced soil. Sugarcane trash (St) and maize stover (Ms) were pyrolyzed (300, 500, and 700 °C) to produce five different biochar including Fe-modified, $^{57}Fe$-modified and $H_2O_2$ activated types. The Fe- and $^{57}Fe$-modified biochar were produced by loading the feedstocks with non-labeled Fe and $^{57}Fe$ solutions, respectively. The produced biochar were then activated with $H_2O_2$ by soaking the biochar into 5% $H_2O_2$ solution in a hot water bath for 6 h. The results revealed that the pyrolysis temperature has significant influence on the biochar yield, while higher yield was obtained at 300°C followed by 500°C and 700°C. 1% biochar was added to As-contaminated grey lowland soil (2.6 mg $kg^{-1}$) and incubated for 90 days under reductive conditions at 30 °C. The stability of Fe-modified biochar was evaluated by monitoring the $^{57}Fe/^{56}Fe$ ratio in soil solution. Fe-modified biochar produced at higher pyrolysis temperatures exhibited greater stability, as evidenced by lower Fe dissolution under reductive conditions. Non-activated Fe-modified biochar, particularly Ms-derived biochar produced at higher temperatures, was most effective in suppressing As dissolution. This was supported by lower total Fe and Fe(II) concentrations in soil solution and incubated soil. Higher Fe dissolution from St-derived Fe-modified biochar was confirmed by increased $^{57}Fe/^{56}Fe$ ratios in soil solution. In contrast, Ms-derived Fe-modified biochar showed lower Fe dissolution, indicating greater stability and enhanced As suppression. Earlier studies reported that the physicochemical properties of biochar depend on the feedstock material, which might be the reason behind the lower stability of St-derived biochar. Additionally, $H_2O_2$-activated normal biochar produced at lower temperature demonstrated better As suppression than activated Fe-modified biochar produced at the same temperature. Therefore, this study concludes that non-activated Fe-modified biochar derived from maize stover and produced at higher pyrolysis temperature has strong potential to effectively adsorb As and mitigate associated risks in waterlogged paddy soils. Nevertheless, stability was found to be reduced with the passage of time, suggesting a potential challenge towards long-term effectiveness of Fe-modified biochar under waterlogged conditions, which demands further research to unveil the effects of long-term and repeated application of Fe-modified biochar under reductive conditions.

**ABSTRACT**

Soil contamination by multiple heavy metals, such as cadmium (Cd) and lead (Pb) is a global challenge that threatens ecology and human health. However, many remediation approaches overemphasize pollutant removal but overlook the recovery of soil multifunctionality. Here we successfully isolated a heavy metal-tolerant plant growth-promoting fungus *Corticiaceae* sp. ZJ 06 from soil, and explored its application in ecological restoration of Cd and Pb co-contaminated soil. The Corticiaceae sp. ZJ 06 showed rapid cell proliferation and strong tolerance to Cd and Pb. After inoculation of this functional strain, DTPA-extractable Cd and Pb were dramatically reduced by 85.8% and 60.2%, respectively. Importantly, residual fractions accounted for 76% and 61% of total heavy metals respectively, suggesting a long-lasting biostabilization of Cd and Pb after remediation. Furthermore, soil organic matter, total nitrogen, available nitrogen, available phosphorus, available potassium, and cation exchange capacity increased significantly by 30%, 23.8%, 86.5%, 28.7%, 204%, and 40.8%, respectively. Soil microbial diversity was increased and some functional microbes such as Basidiomycota were enriched. Genes related to nitrogen fixation, phosphorus solubilization, and potassium dissolution were significantly upregulated. Molecular mechanisms underlying carbon, nitrogen, phosphorus, and sulfur cycling were identified as key drivers of ecological restoration in heavy metal-contaminated soils. Overall, the remediated soil exhibited a coordinated improvement in soil multifunctionality, reflected by enhanced contaminant regulation, nutrient cycling, carbon sequestration, and biological functions. This work highlights a viable strategy for the ecological restoration of soils contaminated by multiple heavy metals.

# Core microbiomes of Cd-hyperaccumulators and its contribution to plant performance

**Tingqiang Li*, Jipeng Luo, Wenzhe Gao**

*College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, 310058, China*

*litq@zju.edu.cn

**ABSTRACT**

Plants evolve with persistent core microbiomes that extend host functional repertoires, yet the assembly patterns and functions of these communities remain insufficiently understood, limiting their application in enhancing plant performance. We investigated bacterial communities in the bulk soil, rhizosphere and root endosphere of various Cd-hyperaccumulators, and identified core microbes linked to key plant traits using 16S rRNA gene sequencing. Microbiome assembly along the soil-root continuum was predominantly shaped by plant species and compartment type rather than by soil type and pollution level, with host selection intensifying from the rhizosphere to the root endosphere. Stochastic processes dominated the assembly of endosphere generalists (59%), but less so for rhizosphere generalists (45%). We identified 24 rhizosphere and 9 root endophytic generalist species as core microbiomes, which were more strongly driven by host selection than non-core taxa. These core microbiomes were markedly enriched in their respective compartments, with over 60% consistently detected across controlled and field settings. Endophytic core microbes conferred greater biotic connectivity in cooccurrence networks and were stronger predictors of plant metal accumulation than soil-derived cores, whereas rhizosphere cores were more closely associated with plant biomass production and nitrogen and phosphorus acquisition. These compartment-specific contributions to plant phenotypic properties were further validated through SynComs with isolates of core microbes.

Furthermore, we examined the phylogenetic profiles and plant-beneficial traits of the core microbiota that consistently inhabits the rhizosphere of four divergent Cd hyperaccumulators and an accumulator. We evidenced the existence of a conserved core rhizosphere microbiota in each plant distinct from that in the non-hyperaccumulating plant. Members of Burkholderiaceae and Sphingomonas were the shared cores across hyperaccumulators and accumulators. Several keystone taxa in the rhizosphere networks were part of the core microbiota, the abundance of which was an important predictor of plant Cd accumulation. Furthermore, an inoculation experiment with synthetic communities comprising isolates belonging to the shared cores indicated that core microorganisms could facilitate plant growth and metal tolerance. Using RNA-based stable isotope probing, we discovered that abundant core taxa overlapped with active rhizobacteria utilizing root exudates, implying that the core rhizosphere microbiota assimilating plant-derived carbon may provide benefits to plant growth and host phenotype such as Cd accumulation. Our study suggests common principles underpinning hyperaccumulator microbiome interactions, where plants consistently interact with a core set of microbes contributing to host fitness and plant performance.

**Key words:** core microbiome, synthetic community, Cd accumulator, keystone taxa, heavy metal, remediation strategies

# Soil Water Regimes Control Cadmium Bioavailability and Translocation in Rice Systems

**Wanjing Wang**[1*]

[1] *Wanjing Wang (Interdisciplinary Research Centre for Agriculture Green Development in Yangtze River Basin, College of Resources and Environment, Southwest University, Chongqing, China)*

*18279126095@163.com

## ABSTRACT

Cadmium (Cd) contamination of agricultural soils poses a persistent risk to food safety and human health, particularly in rice-based agroecosystems where rice (Oryza sativa L.) readily absorbs Cd and translocates it into edible grains. In paddy soils, Cd behavior is strongly regulated by hydrological conditions, as soil water status controls redox potential, soil chemistry, microbial processes, and root physiological activity. Although wetting and drying are known to affect Cd bioavailability, the mechanisms by which soil water regimes govern Cd migration and accumulation within soil–rice systems remain incompletely understood.

Here, we investigated how contrasting soil water regimes regulate Cd bioavailability, migration, and accumulation under graded Cd contamination. By integrating soil physicochemical properties, biological responses, and plant Cd accumulation patterns, we elucidated process-based mechanisms linking soil water status to Cd behavior across the soil–plant continuum.

Across all Cd levels, soil water regimes exerted dominant control over soil properties and Cd speciation. Flooded and adequately watered soils maintained reduced conditions, increased pH, and suppressed bioavailable Cd through enhanced adsorption and stabilization in low-solubility forms. In contrast, low soil moisture promoted oxidative conditions, facilitating Cd desorption and dissolution and markedly increasing Cd mobility. Consequently, soil Cd bioavailability consistently followed the order low moisture > moderate moisture > flooding.

These water-driven changes were directly reflected in plant responses. Rice grown under low soil moisture exhibited enhanced Cd uptake and increased root-to-shoot translocation, resulting in elevated grain Cd concentrations that frequently approached or exceeded food safety thresholds under moderate to high Cd exposure. Flooded conditions effectively constrained Cd entry into plants by limiting both root uptake and translocation, producing the lowest grain Cd accumulation. Moderate soil moisture achieved reduced Cd bioavailability while maintaining favorable plant growth.

Across all treatments, Cd distribution followed the order root > stem > leaf > grain, indicating that roots acted as the primary Cd sink. Translocation efficiency was strongly water-dependent, increasing under low soil moisture and decreasing under flooded conditions. At high Cd exposure, translocation efficiency declined, suggesting physiological constraints on Cd transport.

Overall, this study demonstrates that soil water regimes fundamentally govern Cd bioavailability, migration, and accumulation in soil–rice systems by regulating soil redox conditions, soil chemistry, microbial processes, and plant uptake pathways. Soil water status functions as a core environmental control shaping Cd behavior from soil chemistry to plant physiology, highlighting hydrological regulation as a key process controlling Cd risk in paddy agroecosystems.

# Aqueous and colloidal dynamics in size-fractionated paddy soil aggregates with multiple metals contaminants under redox alternations

## ABSTRACT

Soil contamination by multiple metals is a significant concern due to the interlinked mobilization processes. The challenges in comprehending this issue arise from the poorly characterized interaction among different metals and the complexities introduced by spatial and temporal heterogeneity in soil systems. We delved into these complexities by incubating size-fractionated paddy soils under both anaerobic and aerobic conditions, utilizing a combination of techniques for aqueous and colloidal analysis (Figure 1). The contaminated paddy soil predominantly consisted of particles measuring <53 μm, 250-53 μm, and 2000-250 μm, with the <53 μm fractions exhibiting the highest concentrations of multiple metals. Interestingly, despite their higher overall content, the <53 μm fractions released fewer dissolved metals. Furthermore, glucose enhanced the release of arsenic while simultaneously promoting the sequestration of other metals such as Pb, Zn and Cu (Figure 2). Utilizing asymmetric flow field-flow fractionation, we unveiled the presence of both fine (0.3 kDa-130 kDa) and large (130 kDa-450 nm) colloidal pools, each carrying various metals with different affinities for iron minerals and organic matter (Figure 3). Our results highlighted the pivotal role of the <53 μm fraction as a significant reservoir for multiple metals contaminants in paddy soils, in which the colloidal metals were mainly associated with organic matter. These findings illuminated the size-resolved dynamics of soil metal cycling and provided insights for developing remediation strategies for metal-contaminated soil ecosystems.

# Heavy Metal Contamination and associated ecological risks in Soils around Buddha Nullah drain, Punjab, India

**Rishabh Pawar[1*], Dhanwinder Singh[1], Sumita Chandel[1], Harsimran Kaur[1], Kuldeep Singh[1] and Rajeev Sikka[1]**

*[1] Department of Soil Science, Punjab Agricultural University, Ludhiana 141004, India*

*rishabhpawar31@gmail.com

**ABSTRACT**

Soil pollution by heavy metals has emerged as a major environmental concern in peri-urban and industrially influenced agricultural regions, where long term anthropogenic inputs compromise soil quality and sustainability. The soils of these regions are increasingly exposed to heavy metal inputs resulting from industrial effluents, waste water irrigation, urban runoff and intensive land use. Such inputs alter soil quality and lead to pronounced spatial variability in metal accumulation. The present study evaluated the spatial distribution and contamination status of Arsenic (As), Cadmium (Cd), Chromium (Cr), Lead (Pb) and nickel (Ni) in soils around Buddha Nullah drain, Ludhiana, Punjab, India, using a combined analytical, pollution indexing and Geographic Information System (GIS) approach. About 150 geoReferencesd grid based surface (0-15 cm) and sub-surface (15-30 cm) soil samples from soils on both sides of Buddha Nullah drain were collected to determine the heavy metal pollution potential across locations exhibiting varying degrees of anthropogenic influence. The total concentrations of As, Cd, Cr, Pb and Ni were determined using standard methodologies, whereas bioavailable fractions were extracted using suitable chemical extractants to detect plant-available pools. Thematic maps showing the distribution of both total and bioavailable metal fractions were created by integrating the geographic coordinates of the sampling sites into a GIS platform and using spatial interpolation techniques. Pollution indices, such as contamination factor (CF), enrichment factor (EF), geo-accumulation index (Igeo), and pollution load index (PLI) were computed utilizing suitable background References values to evaluate contamination severity and anthropogenic enrichment. The spatial distribution of these indices facilitated the identification of sites with increased metal loading and cumulative contamination. The results demonstrated marked regional variability in heavy metal concentrations throughout the studied area. Ni and Cr were identified as the predominant metals in total concentrations, especially in soils adjacent to industrial areas and along wastewater impacted agricultural corridors, signifying significant anthropogenic contribution. The surface layer of soils showed greater metal accumulation compared to subsurface soils reflecting recent inputs and limited vertical translocation. The analysis of the pollution index corroborated these observations. The contamination factor and enrichment factor values revealed moderate to significant contamination of Ni and Cr at different locations, but Igeo categorization varied from uncontaminated to moderately contaminated for As, Cd, and Pb. The pollution load index additionally highlighted localized zones bearing cumulative heavy metal stress, predominantly due to higher levels of Ni and Cr. The combination of pollution indices with GIS-based spatial analysis proved effective in delineation of contamination hotspots and spatial patterns of heavy metal accumulation. The study establishes a spatial framework for assessing soil quality and emphasises the necessity of regular monitoring along with site-specific soil management approaches in industrially impacted agricultural landscapes.

# Mitigation of Heavy Metal Transfer from Soil to Lettuce Using Pyrophyllite: A Soil–Plant Study

**E.Sijahović[1*], H.Čivić[1], L.Karić[2] and M.Tvica[3]**

[1] *University of Sarajevo – Faculty of Agriculture and Food Sciences, Plant Nutrition, Sarajevo, Bosnia and Herzegovina*

[2] *University of Sarajevo – Faculty of Agriculture and Food Sciences, Vegetable production, Sarajevo, Bosnia and Herzegovina*

[3] *University of Sarajevo – Faculty of Agriculture and Food Sciences, Pedology, Sarajevo, Bosnia and Herzegovina*

*e.sijahovic@ppf.unsa.ba

**ABSTRACT**

Heavy metal contamination in agricultural soils poses a serious threat to food safety due to their potential uptake by edible crops. Effective remediation strategies are essential to reduce heavy metal bioavailability and limit their transfer through the soil–plant system. Aluminosilicate materials, such as pyrophyllite, have been reported to immobilize metals in the soil matrix and decrease plant accumulation.

This study evaluated the effect of pyrophyllite application on the uptake of heavy metals (Pb, Cu, Ni, Cd, Cr, Co, Mn, Fe, and Zn) by roots and leaves of lettuce **(***Lactuca sativa* 'Shangore' F1**).** Plants were grown in contaminated soil with and without pyrophyllite amendment, and metal concentrations were quantified using standard analytical techniques. Statistical analyses were performed using ANOVA followed by Tukey's post-hoc test ($p < 0.05$) to determine significant differences between treatments.

Results indicated that pyrophyllite significantly reduced Cd, Mn, Cu, Fe, and Zn concentrations in both roots and leaves compared to control plants, while Pb, Ni, Cr, and Co were largely unaffected. Reduction percentages ranged from 5% to 25% depending on the element and plant tissue. These findings demonstrate that pyrophyllite effectively limits heavy metal transfer from soil to lettuce, reducing the potential risk for human consumption and supporting its use as a practical soil remediation measure.

**ABSTRACT**

Soil is one of the most important component to investigate in sense of trace metals and polycyclic aromatic hydrocarbon pollution since it can accumulate and bond these organic and inorganic pollutants, which is especially relevant for sensitive ecosystems of the polar regions in regard of environmental risks produced by global climate change. In this work we present the results of research performed in both Arctic and Antarctic (projects from 2015 to 2025) regions with the aim of comprehensive investigation of biogeochemical features and soil pollution status in permafrost-affected soils. We will present data on detailed investigation of pollution status of soils in remote areas of the Arctic (Yamal region, Svalbard archipelago, Yakutia) and Antarctic (Bunger Hills, Schirmacher oasis, Larsemann Hills, Maritime Antarctica) regions. We found that our results on trace elements content in soils of various East Antarctic regions are not completely in agreement with the idea of practically uncontaminated Antarctic ecosystem, which was previously reported. Various human activities performed at local scale have been found as a relevant source for increase of metal levels in studied Antarctic environments. In general terms, obtained values if pollution indices (Igeo, contamination factor, degree of pollution, environmental risk, pollution load index) for trace elements were under or slightly above the 0 level, indicating low to moderate pollution of the studied soils. This study contributes new data on trace element accumulation in soils strongly influenced by ornithogenic factor. Bioaccumulation of metals in seabirds occupying the highest position in the food chain occurs, transfer of bioaccumulated metals into terrestrial ecosystems through birds excreta should be investigated in more detail. In Arctic soils we found poorly manifested eluvial-illuvial differentiation of trace elements in soil profiles of natural soils. The highest content for most of the studied trace elements has been revealed in Histic topsoil horizons (serves as a strong sorbent of microelements) as well as in anthropogenically-disturbed areas. Another reason for increased trace elements content in natural soils is connected with the formation of geochemical barrier on the superficial layer compared to the topsoil horizons. Principal component analysis allowed to estimate the probable sources of specific trace metals and their relationship with soil variables. Results of this study also revealed the predominance of light PAHs in studied soils. The content of heavy PAHs (only benzo(a)pyrene was quantified) does not exceed the maximum permissible concentrations values adopted by all Russian, Canadian, Argentinian and US legislation. At the same time, the content of benzo(a)pyrene, which is a marker of anthropogenic contamination, is relatively low or equal to 0 in soils of References landscapes.

**ABSTRACT**

The model experiment shows the effect of artificial and natural sorbents, such as hydrolysed polyacrylonitrile (HYPAN), HYPAN +potassium humate (Sakhalin humate) and mycelium of species *Alternaria alternata* on the content of mobile forms of heavy metals (HM) in sod-podzolic soil (*Umbric Albeluvisols Abruptic*) before and after contamination of the copper, zinc, cadmium and lead salts. The soils were collected in the summer of 2024 near the village Chashnikovo (Moscow region, Russia). It is shown that the positive effect of treatment of contaminated soil with polymers is observed at all levels of HM load. At the same time, the greatest effect of remediation with sorbents used by the authors was observed in the presence of 'Sakhalin humate'. In general, the most effective reduction of mobile forms was observed at maximum soil contamination (in the experiment – 6 threshold limit value of HM).

**Keywords:** remediation, HYPAN, 'Sakhalin humate', *Alternaria alternata*, copper, zinc, cadmium, lead, sod-podzolic soil.

## ABSTRACT

Copper (Cu)-contaminated soils near mining areas are typically strongly acidic, triggering substantial release of reactive aluminum (Al) from solid phases. However, Al-Cu bio-interaction effects remain understudied, despite their potential critical role. This study employed short- and long-term hydroponic experiments, along with pot trials using a Cu-contaminated soil, to investigate Al co-stress effects on Cu uptake and translocation. A multiscale approach integrating the streaming potential, zeta potential, and surface electrical potential was employed to characterize charge properties across the root surface-cell wall-cell membrane continuum. Advanced spectroscopic and metabolic techniques were integrated to elucidate the electrochemical and molecular mechanisms underlying Al-mediated Cu uptake. Results showed that Al co-stress reduced the amount of exchangeable Cu on maize root surfaces and inhibited its absorption and translocation. The coordinated decrease in electronegativity and functional group abundance of root continuum was the key electrochemical adaptation mechanism. D-galactose, malate and trehalose were critical regulators of hemicellulose biosynthesis and cell wall remodeling. Disorders in sugar-lipid and glutathione metabolism activated energy-priority survival strategy, prioritizing the synthesis of energy-efficient and persistent antioxidants (e.g. vitexin) and nucleotide to sustain cellular homeostasis. This study provides potential target metabolites and electronegativity adjustment strategies for improving crop adaptation to acidic polluted environments.

**ABSTRACT**

It is imperative to derive the precise threshold of cadmium (Cd) in soil for rice safety production and human health protection. The traditional soil Cd threshold derivation is mainly based on the total amount of Cd and a single risk of Cd pollution, without considering Cd bioaccessibility, multiscale risks and spatial heterogeneity. This fails to synergistically protect safe rice production and human health, and often lead to over- and non-protection issues. Here, we conducted a systematic peri-urban soil-rice grain paired field sampling in the largest megacity of China, where a new multiscale risks-bioaccessibility coupling (MRBC) framework was established to improve the derivation of regional-specific soil Cd threshold. The framework is valid and reliable when applied to regional field-collected datasets. Soil Cd threshold is tailored based on soil properties, multiple risks protection objectives and bioaccessibility of Cd. Results indicated that pH, EC, and SOM concentration were major soil factors influencing the Cd bioaccumulation of rice and soil Cd threshold. Derived soil Cd threshold concentration considering $HNO_3$ and $CaCl_2$-extractable Cd decreased. However, when further considering the health risks of Cd intake through soil-rice-human transfer chain, integrating the gastrointestinal bioaccessibility significantly increased soil Cd threshold. Overall, the derived soil Cd threshold based on MRBC framework indicated that the current soil Cd environmental criteria in China were too conservative and may over-protect the regional-specific rice production and human health. Our findings improved existing soil threshold derivation techniques and enabled more precise and scientific soil environmental quality management.

**ABSTRACT**

The cadmium (Cd) uptake inhibition mediated by mycorrhizal symbiosis is a highly promising phytoremediation strategy characterized by ecological friendliness, targeted regulation, and synergistic efficiency, yet its underlying mechanisms remain incompletely understood. This study employed a multidisciplinary approach integrating physiological analysis, Cd translocation characterization, and transcriptomics to systematically elucidate the molecular mechanisms by which arbuscular mycorrhizal fungi (AMF) inhibit Cd uptake and translocation in rice. The results showed that under Cd stress, AMF successfully colonized rice roots, inhibited Cd influx at root tips (50%-52%) and xylem Cd loading (52%), restricted Cd translocation to shoots, and significantly reduced Cd concentration in roots (31%) and shoots (68%). Concurrently, AMF regulated the translocation of nutrients such as P 、Ca 、Zn and Cu to maintain ionic homeostasis, alleviated Cd-induced damage to leaf cellular structure, and improved photosynthetic performance. Transcriptomic analysis revealed AMF-driven molecular reprogramming in plants: downregulating the expression of metal uptake transporter genes (*OsCAX3/8*) and translocation-related genes (*OsCCX2*), while upregulating vacuolar sequestration genes (*ABCC9/HMA3/VIT2*) and efflux genes (ABCG52/14/48). Furthermore, AMF modulated ionic homeostasis through arbuscular mycorrhiza-specific induced genes (*OsPT11*, *OsHA1*) and other transporter genes (*CCX3/ZIP5/COPT4*, etc.). This study clarifies the multi-level regulatory mechanisms by which AMF alleviates Cd stress in rice, providing an important theoretical foundation for the application of AMF in the phytoremediation of Cd-contaminated soils and the sustainable production of safe crops.

# Tracing Cadmium Migration and Transformation from Atmospheric Deposition to Rice via Isotopic Fingerprinting

**Jun Zhou[1, 2*], Ruizhi Xia[1, 2], Yuran He[1, 2], Jing Zhou[1, 2]**

*[1] State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China*

*[2] University of Chinese Academy of Sciences, Beijing 100049, China*

**ABSTRACT**

Atmospheric deposition is a major pathway for cadmium (Cd) input into agricultural ecosystems, yet quantifying its contribution to crop uptake remains challenging. This study integrated field open-top chamber experiments, greenhouse simulations, and Cd stable isotope analysis to elucidate the migration and transformation processes of atmospherically deposited Cd in soil-rice systems. Results revealed that newly deposited Cd undergoes rapid aging in soils, with its bioavailability strongly influenced by deposition type (wet/dry). Isotopic signatures demonstrated that bioavailable Cd in soil is primarily governed by dry deposition, a pattern consistently reflected in rice grains regardless of exposure pathway. Using an isotope mixing model optimized with process-specific fractionation factors, we quantified that atmospheric deposition contributed 29–65% to the soil bioavailable Cd pool. Notably, foliar uptake of atmospheric Cd contributed over 50% to rice grains, surpassing root uptake of legacy soil Cd. The study establishes Cd isotopes as a robust tool for distinguishing Cd sources and pathways, providing a refined approach for quantitative source apportionment in agroecosystems. These findings underscore the critical role of atmospheric deposition in Cd accumulation in rice and highlight the importance of emission control strategies alongside soil remediation.

**ABSTRACT**

Biochar has attracted increasing attention for its environmental applications, particularly in the sustainable management of agricultural and livestock wastes and the remediation of contaminated soils and waters. Owing to its high sorption capacity, biochar is widely used to remove toxic elements from contaminated water through adsorption onto its surface. However, the environmental fate of spent biochar saturated with toxic elements after use, and its suitability as a soil amendment, remain insufficiently understood. In this study, wheat straw and cattle manure biochars, along with their lead (Pb) saturated counterparts referred to as spent biochars, were applied to soil in an eight week incubation experiment to evaluate the potential risk of Pb contamination in amended soils and to examine the distribution of Pb among different geochemical fractions. The pH values of Pb saturated biochars were 37 percent and 29 percent lower than those of the original wheat straw and cattle manure biochars, respectively, indicating that Pb sorption reduced biochar alkalinity. Such pH changes may influence soil fertility, Pb mobility, and the stability of Pb associated with biochar surfaces following soil application. Overall, these results provide new insight into the environmental implications of recycling spent biochar to soil, particularly with respect to Pb stability, mobility, and bioavailability across different geochemical fractions.

## ABSTRACT

Synchronized soil washing of arsenic (As) together with cadmium (Cd) and lead (Pb) remains a major challenge in remediation of brownfield soils, as improvements in cationic metal extraction often fail to achieve proportional enhancement in As removal due to fundamentally different geochemical behavior and removal controls. The mechanistic basis of this mismatch remains insufficiently resolved.

In this study, a carboxyl-based composite eluent (OG), composed of oxalic acid (OA) and the biodegradable chelator tetrasodium salt of N,N-bis(carboxymethyl)-L-glutamic acid (GLDA), was developed and evaluated using naturally contaminated site soils spanning acidic, neutral, and alkaline conditions. Under optimized conditions (0.1 mol·$L^{-1}$ OA blended with 0.2 mol·$L^{-1}$ GLDA at equal volumes, pH 4, 2 h), OG exhibited a pronounced synergistic effect on As removal in soils, increasing extraction by approximately two-fold relative to OA alone and nearly one order of magnitude relative to GLDA alone ($p< 0.05$), while simultaneously strengthening Cd and Pb removal. This enabled coordinated removal of anionic and cationic contaminants beyond the additive performance of individual washing agents. Mechanistic analyses indicate that the observed synergy arises from coupled dissolution-complexation processes rather than enhanced aqueous transport. OA promotes ligand-induced and partial reductive dissolution of Fe/Al-associated As-bearing mineral phases, whereas GLDA stabilizes dissolved metal species through complexation and suppresses secondary immobilization of As. Notably, the magnitude of synergistic As enhancement declined with increasing soil pH, despite elevated apparent As mobility under alkaline conditions, as pH-dependent carrier stability progressively constrained mineral dissolution and redefined the rate-limiting step for As extraction.

From a remediation strategy perspective, these findings demonstrate that effective synchronized soil washing requires targeting pH-dependent carrier stability in addition to contaminant speciation. The proposed composite eluent provides a mechanism informed framework for remediating As, Cd and Pb co-contaminated brownfield soils under relatively mild chemical conditions, while clarifying the boundaries within which synergistic enhancement can be maximized.

# Long-term organic fertilization reduces cadmium bioavailability via enhanced binding to organic fractions and Fe-bearing minerals

**ABSTRACT**

Fertilizers provide essential plant nutrients but may introduce toxic cadmium (Cd), posing soil ecosystem risks. However, mechanisms governing Cd mobility and stabilization under different fertilization regimes remain unclear. In this study, soils from a 27-year field experiment were investigated under three treatments: inorganic fertilizer only (NPK), inorganic fertilizer with pig manure (NPKM), and no fertilizer (CK). Total and bioavailable Cd were quantified using chemical extraction and the diffusive gradients in thin films technique. Results indicated that NPKM increased total soil Cd 5-fold relative to NPK, but the proportion of bioavailable Cd (bioavailable Cd/total Cd) was 4-fold lower. Dissolved organic matter incubation coupled with Fourier transform infrared (FTIR) spectroscopy, two-dimensional correlation spectroscopy, and Fe K-edge X-ray absorption fine structure (Fe-XAFS) revealed that NPKM promoted the formation of active soil minerals, particularly reactive Fe-bearing minerals, and altered Cd-binding sequences in soil functional groups. In NPKM soils, wavelet analysis indicated atomic-scale Fe-Cd coordination (R = ~1.8 Å, k = ~12 Å−1), suggesting that Fe–bearing minerals served as nucleation sites for Fe-Cd cluster formation. Synchrotron radiation-based FTIR spectroscopy (SR-FTIR) further demonstrated strong correlations ($p < 0.0001$, r2 = 0.34–0.85) between organic and inorganic functional groups, indicating that Fe–Cd clusters co-assembled with organic matter into stable organo-mineral complexes. These complexes effectively immobilized Cd, thereby reducing its mobility. This study established a novel multi-spectroscopy approach for elucidating Cd-binding mechanisms in soils, providing new insights into sustainable agriculture and soil remediation.

# Arbuscular mycorrhiza orchestrates phenotypic plasticity of a critical suite of functional traits in plants under vanadium stress

**Ziwei Cao[1], Jinlong Wang[1,2], Jingfan Qi[1,2], Yuyao Wang[1,2], Yijie Sun[1,2], Kinjal J. Shah[1], Shujuan Zhang[1*]**

**ABSTRACT**

Vanadium (V) pollution in soil is a serious problem in some parts of China. Arbuscular mycorrhizal fungi (AMF) have shown promise in improving the remediation of V-polluted soil, but their role in orchestrating the complex phenotypic plasticity of plants under V stress remains poorly understood. We used the green foxtail （*Setaria viridis*） as the tested plant and
set three levels of soil V pollution: low (150 mg V $kg^{-1}$), medium (500 mg V $kg^{-1}$), and high (1000 mg V $kg^{-1}$). By inoculating plants with (+AMF) and without (-AMF) *Rhizophagus irregularis*, two AMF treatments were created. Plant biomass, morphological characteristics, and soil and plant V concentrations were all considerably increased by AMF inoculation at all V levels. Only at high V levels did the biological enrichment factor and translocation factor increase. The cell wall (58–64%) and soluble components (24–32%) in plant leaves exhibited a larger percentage of V than the organelles (10%-15%). The +AMF plant's leaf organelle V concentration was much lower than the -AMF plant's. Furthermore, concentrations of thiol derivatives were elevated by AMF. The functional relationships between plant fitness and important characteristics, like shoot/root ratio, shoot V concentration, biological enrichment factor, root V content, and leaf concentrations of thiol derivatives, were significantly altered by AMF. Further more, AMF significantly altered the magnitude of phenotypic plasticity in traits indicted by coefficient of variation (CV) and phenotypic plasticiy index (PPI). Phenotypic differentiation is primarily driven by AMF, according to principal component analysis (PC1). Our results show that AMF functions as a master regulator of phenotypic plasticity rather than only reducing V toxicity. By coordinating a response at the organ, subcellular, and physiological levels, it improves internal detoxification. This gives the use of AMF to improve phytoremediation in V-polluted soils a mechanistic foundation.

## ABSTRACT

Antibiotic resistance genes (ARGs) are emerging environmental pollutants able to persist and disseminate in metal contaminated soils through metal induced co-selection mechanisms. Therefore, remediation of metal contamination in soils through soil management strategies has great potential in mitigation of ARGs in soil bacterial communities. In this study, Cd contaminated soil was water flooded to obtain anaerobic conditions with different organic materials (wheat straw and soybean meal) to remediate cadmium (Cd) contaminated paddy soils. The resistance profiles (including antibiotic and metal resistance determinants) and biological pollutants (including high risk ARGs, soil-borne pathogens, virulence factors (VFs)) were further evaluated using metagenomic sequencing. Our results showed that anaerobic biological treatment in soil was able to practically promote the Cd immobilization in polluted soils and the reduced Cd bioavailability (e.g. CaCl2 extracted Cd and exchangeable Cd) further decreased the relative abundance of ARGs and metal resistance genes (MRGs) in the soil bacterial community. Changes in the soil resistome were able to attributed to a changing bacterial composition and reduced oxidative stress in soil under anaerobic biological treatments. In addition, our approach was also able to effectively weaken environmental risks posed by the soil bacterial community, including high risk ARGs, soil-borne human pathogens and VFs. In conclusion, this study provides a theoretical framework and technological strategy for synchronously mitigating of both ARGs and Cd contaminations in agricultural soils, which offers significant contributions to soil health preservation and sustainable environmental management.

## ABSTRACT

Plant species inhabiting industrial areas have evolved resilience in stressed environments and represent potential valuable resources for remediating polluted sites. However, data describing the potential of xeric plant species in sustainable green applications remain scarce. This study aims to evaluate the effectiveness of mycorrhiza-amended xeric plant species Lygeum spartum, in coping with arid conditions for phytoremediation and ecological restoration of degraded and contaminated lands. A six-month controlled pot experiment was conducted to assess leaf length, enzymatic activities, and secondary metabolites. Toxic metals and metalloids (TMMs) fate was evaluated using translocation factor (TF), bioaccumulation factor (BF) and removal efficiency (RE). Fungal inoculation positively impacted growth, increasing leaf size by 64.6 % and enhancing chlorophyll content - Chl a (0.73 mg g−1 DW) and Chl b (0.64 mg g−1 DW). Root uptake of Cd, Ni, Zn, Cu, Co, Cr and Pb was significantly enhanced in mycorrhizal plants ($p < 0.05$), and inoculation improved translocation of Zn, Cr and Co, with TFZn = 1.67, TFCr = 1.11 and TFCo = 1.05 respectively. Secondary metabolites included flavonoids, total phenols, glutathion-S-transferase, carotenoids, and antioxidants such as peroxidase (POD, 4.25 µmol min−1 mg−1 proteins), ascorbate peroxidase (APX, 2.14 µmol min−1 mg−1 proteins) and superoxide dismutase (SOD, 17.04 66 U mg−1 protein). However, no improvement was observed in catalase activity or free radical scavenging potential. Therefore, xeric plant species amended with mycorrhiza are effective in TMM phytoremediation in arid environments and can be used for the restoration of degraded lands. Further, mycorrhiza could be used as sink cultures for the Phyto management and sustainable eco-restoration.

## ABSTRACT

Mercury (Hg) is a globally distributed toxic element with well-established risks to ecosystems and human health, particularly following methylation and biomagnification in aquatic food webs. While Northern Hemisphere studies have shaped current understanding of Hg cycling, comparable continental-scale assessments in the Southern Hemisphere remain limited, constraining the accuracy of global Hg models and the development of regionally appropriate management frameworks. Australia provides a unique opportunity to address this gap due to its highly weathered soils, diverse biomes, low anthropogenic Hg emissions, and strong oceanic influence on atmospheric inputs.

We quantified background Hg concentrations and their environmental controls using fine (<75 µm) top and bottom outlet sediment samples collected at the outlet of 1,141 large catchments as part of the National Geochemical Survey of Australia, covering approximately 76% of the continent (~ 5.84 million km²). Total Hg concentrations ranged from 0.97 to 556 ng $g^{-1}$ in top outlet sediments (mean ± SD: 23.5 ± 27.5 ng $g^{-1}$) and from 0.90 to 525 ng $g^{-1}$ in bottom outlet sediments (19.1 ± 22.3 ng $g^{-1}$). More than 98% of samples were below 100 ng $g^{-1}$, indicating generally low natural Hg concentrations across Australian soils.

Spatial analyses revealed higher Hg concentrations in southeastern Australia, particularly Tasmania and temperate and Mediterranean forest biomes, and lower concentrations in arid and grassland regions. Differences among States and Territories were driven primarily by underlying soil and vegetation characteristics rather than lithology or land use alone. Organosols and ferrosols exhibited the highest Hg concentrations, reflecting strong retention by organic matter and iron-rich mineral phases.

Boosted regression trees and random forest models identified loss on ignition (proxy for soil organic matter) and an index of ferrosols as the dominant predictors of Hg concentrations, with additional contributions from soil nitrogen, lead, nickel, and vegetation structure (leaf area index). Water availability played a comparatively minor role, consistent with Australia's low runoff and highly variable rainfall. Spatial prediction at 0.005° resolution highlighted elevated Hg in forested, iron-rich soils and comparatively uniform low concentrations across much of the arid interior.

Our results demonstrate that Hg distribution in Australian soils is controlled primarily by pedogenic and biogeochemical factors rather than anthropogenic inputs, providing a robust baseline for identifying contaminated sites and future changes. This continental-scale assessment improves representation of Southern Hemisphere processes in global Hg frameworks and supports evidence-based implementation of the Minamata Convention on Mercury.

# Sample preparation and characterize of soil dissolved organic matter

**Qing-Long Fu**[1]

[1] *School of Environmental Studies, China University of Geosciences Wuhan, China*

*E-mail fuqinglong@cug.edu.cn

**ABSTRACT**

Soil dissolved organic matter is one of the most active chemical components in soils, playing critical roles in governing the environmental fate, transport, behavior and toxicity of trace and heavy metals and organic containments and affecting the biogeochemical cycles of carbon and nitrogen in aquatic and terrestrial systems. The ecological function of soil DOM is affected by its chemical composition and structures. Herein, we have compared the traditional DOM extraction method with the HCl-assisted high pressure extraction using the ultrahigh-resolution mass spectrometry (e.g. Fourier transform ion cyclotron resonance mass spectrometry, FT-ICR MS). The HCl-assisted high pressure extraction method gives much higher DOC yields, but yet not affect the chemical composition of soil DOM as compared with tractional DOM extraction with ultrapure water. The Fourier transform ion cyclotron resonance mass spectrometry was further offline hyphenated with high performance liquid chromatography (HPLC) to elucidate the polarity of soil DOM in governing its disinfection byproducts formation. Much more chemical formulas were observed in the HPLC-FT-ICR MS as compared with the traditional direct infusion mode.

## ABSTRACT

Monitoring bioremediation often relies on tools that indirectly assess microorganism activity. These tools include genomic techniques that indicate the presence of necessary microorganisms but not necessarily the activity, and analytical techniques that confirm the degradation of contaminants but not necessarily the mechanism. Direct measurements of soil proteins and enzymes can provide the necessary information via soil proteomics. Although soil proteomics has advanced through mass spectrometry, most studies still rely on protein-denaturing extraction methods. The inability to distinguish between the catalytically active and inactive enzyme fractions in soils limits proteomic applications for bioremediation monitoring. Further, the influence of soil properties on the recovery of active enzymes is rarely considered, limiting the quantitative potential of proteomics applications. This study applied an indirect, non-denaturing extraction method; comprising (l) sucrose density gradient centrifugation to separate cells from soil, (2) sonication to lyse cells, and (3) centrifugation to recover soluble enzymes; to evaluate how soil physicochemical characteristics affect the extractability of intracellular perchlorate-reducing enzymes. Across 81 soil samples, final enzyme recoveries ranged from 0.34% to 9.91%, reflecting strong matrix-dependent variability. Spearman correlations identified pH, cation exchange capacity (CEC), and $Ca2^{+}$ as significant drivers of cell recovery, and pH, EC, % sand, CEC, $Cu2^{+}$, $Mn2^{+}$, and $Zn2^{+}$ as significant for enzyme recovery. Expanded regression modeling (linear, standardized, polynomial, and interaction models) revealed deeper mechanistic controls: $Al3^{+}$ and $Na^{+}$ were the strongest predictors of cell release, while $Al3^{+}$, $Cu2^{+}$, and $Zn2^{+}$; including nonlinear and metal–metal interactions (Al×Zn, Al×Mn, Na×Mn); explained over 45% of the variability in enzyme extraction. These patterns reflect cation bridging, ionic-strength thresholds, and clay-associated sorption effects. Together, the results demonstrate that soil chemistry exerts strong control over intracellular enzyme recovery, with implications for improving soil proteomics and enhancing the detection of active bioremediation processes.

**ABSTRACT**

Chromium (Cr), with high toxicity, is one of the primary controlled heavy metals in China. Understanding the soil chemistry of Cr facilitates to effectively control the mobility and bioavailability of Cr in the contaminated soil sites and agricultural lands, thus mitigating the contamination risk of underground water and crops. Organo-mineral complexes (OMC), widely present in the soil environment, have multiple active components, including metal oxides, organic matter etc., and provides active binding sites for Cr immobilization. synchrotron-based Scanning transmission X-ray microscopy (STXM) spectroscopy was demonstrated to simultaneously characterize the distribution and speciation of C, Cr, and related mineral elments (i.e. Fe), providing a unique platform to investigate the binding mechanisms of Cr and OMC. Here, we summarized the past research achievements on the interactions of Cr with organo-iron oxides complexes, particular at the molecular level using advanced synchrotron-based STXM techniques. The future perspective in this research field was also proposed according the development of synchrotron-based techniques.

**ABSTRACT**

Cadmium bioavailability is sensitive to redox fluctuations, with its fate linked to the coupled dynamics of Fe, S, and C. This study examines the behavior of Cd-loaded ferrihydrite (Fh) with/without organic matter (OM) undergoing S(-II)-induced reduction followed by O2-induced reoxidation. During sulfidation, S(-II) was fully consumed, and Fh was partially reduced to Fe(II) species, with some OM released from the Fh surface. Meanwhile, Cd initially adsorbed on Fh was completely converted to CdS, regardless of Cd loading or the presence of OM. Upon reoxidation, Fe(II) species were reoxidized to Fe(III) oxides, which recaptured OM, while solid-phase S(-II) was oxidized to S0 and sulfate. Concurrently, partial oxidation of CdS occurred, mainly driven by $H_2O_2$ generated during Fe(II) oxidation, with minor contributions from ·OH and O2, but OM inhibited CdS oxidation, primarily by scavenging $H_2O_2$. Released Cd from CdS oxidation was predominantly readsorbed on Fe(III) oxides. Additionally, released Cd was partially structurally incorporated into newly-formed Fe(III) oxides while some CdS was encapsulated within Fe(III) oxide aggregates. However, OM interactions with Fe(III) oxides reduced the formation of these Cd species. These findings provide insights into the molecular-scale mechanisms governing Cd dynamics in redox-dynamic environments.

*zqshi@scut.edu.cn

**ABSTRACT**

Soil minerals play a critical role in controlling the stability and transformation of organic carbon (OC) in soil environment through both chemical and physical processes. Understanding of the mechanisms of OC sequestration by minerals is essential for predicting the OC turnover in soil. Numerous studies have shown that mineral compositions, morphology, structure are the key factors accounting for OC sequestration by minerals, but the microscopic investigation of OC interaction with minerals is complicated by the complexity of soil organic matter and dynamic properties of reactive minerals. Therefore, it is desired to directly visualize the dynamic interactions between OC and different soil minerals with high spatial resolutions.

In this talk, we will present our recent efforts in imaging the OC (and its chemical species) interactions with typical soil minerals (e.g., Fe and Mn oxides) at nano- to sub-nano scales by employing the spherical aberration corrected scanning transmission electron microscopy (Cs-STEM) coupled with electron energy loss spectroscopy (EELS). Our studies have provided mechanistic insight into the stabilization of OC during the Fe oxide transformation processes and OC distribution on Mn oxides during the coupled reactions of adsorption and oxidation. EELS results have provided direct evidence of the spatial distribution of OC and its species (e.g., carboxyl and phenol C) at the mineral surfaces and the bulk of minerals. Different OC species have shown distinct patterns of interactions with minerals, which was further affected by the dynamic composition of minerals under different environmental conditions. Our results would help to elucidate the nanoscale sequestration mechanisms of OC by various soil minerals and to develop quantitative models for OC turnover in soil environment.

## ABSTRACT

Soil colloids are critical yet mobile components that regulate the fate of nutrients and contaminants in the environment. However, the mechanistic links between freeze-thaw-induced soil structural changes and colloid release dynamics, particularly across seasons, are poorly quantified. We bridged this gap by simultaneously quantifying aggregate turnover via rare earth oxide tracers and 3D pore architecture via X-ray μ-CT to unravel colloid release mechanisms. We compared two distinct seasonal regimes: autumn freeze-thaw (AFT, rapid thaw) and spring freeze-thaw (SFT, gradual thaw). Results revealed a fundamental seasonal dichotomy. AFT significantly disrupted soil structure, whereas SFT had a minimal effect. AFT preferentially broke down 0.5–0.25 mm aggregates, inhibiting their re-aggregation and thereby driving colloid release from this key fraction. Colloid release was positively correlated with increased porosity, pore number, and pore branch density—metrics that were significantly enhanced by AFT but not by SFT. X-ray μ-CT visualized the creation of a vertical porosity gradient rich in macropores and elongated pores, with changes in total porosity and connectivity markedly greater under AFT. These results demonstrate that colloid release is mechanistically driven by the co-evolution of pore architecture—specifically, the development of connected macropores for transport and abundant regular small pores for colloid detachment—a process activated effectively by rapid thawing but mitigated by gradual thawing.

**ABSTRACT**

Manganese (Mn) redox cycling critically regulates soil organic carbon (SOC) turnover, especially in the forest litter layer. However, the molecular-level mechanisms underlying the Mn oxide-mediated decomposition and polymerization of dissolved organic matter (DOM) from litter remain poorly understood. Integrating excitation–emission matrix spectroscopy (EEM) and Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS), we investigated molecular mechanisms of δ-$MnO_2$-driven transformations of natural leaf litter-derived DOM samples across an ambient pH gradient (4, 6, 8). Results reveal that δ-$MnO_2$ simultaneously drives decomposition and polymerization of DOM, with pH modulating their relative contributions. At higher pH (pH 8), δ-$MnO_2$ facilitates aromatic condensation and coupling involving Mn(IV)→Mn(III)-mediated single-electron transfer, forming highly aromatic humic-like polymers and reducing electron-donating capacity, thereby enhancing oxidative resistance. Under lower pH (pH 4), δ-$MnO_2$ drives depolymerization and aromatic ring-opening by selectively cleaving oxygen-rich aromatic species. This process is dominated by multi-electron transfer, with Mn(IV) reduced to Mn(II) via successive electron donation from DOM. Additionally, initial DOM composition impacts its transformation pathway. Specifically, high-aromaticity, high-molecular-weight fractions preferentially decompose, whereas low-aromaticity DOM tends to polymerize. These findings highlight the dual roles of Mn oxides in stabilizing organic matter, driving both the breakdown and reassembly through pH-regulated redox reactions.

# Elucidating the Molecular Mechanisms of Microplastics in Heavy Metal Transformation

**Fei Dang[1*], Yingnan Huang[1]**

[1] *Institute of Soil Science, CAS, Nanjing, China*

*E-mail Address of Presenting Author:fdang@issas.ac.cn

**ABSTRACT**

Microplastics, now pervasive across various environmental compartments, pose a significant concern due to their ability to adsorb heavy metals and, more critically, to transform their chemical forms. They can alter metal speciation via redox reactions and serve as methyl donors, thereby accelerating the methylation of mercury—a process with crucial implications for toxicity and bioaccumulation. This study aims to clarify the underlying molecular mechanisms through which microplastics mediate these transformations, utilizing cutting-edge spectroscopic and chromatographic techniques.

## ABSTRACT

Field rapid determination of soil accessible Cu(II) was important for environmental safety and human health risk assessment. In this study, an inexpensive red, green, and blue (RGB) color sensor was used for quantitative color difference analysis of the colored solution for soil accessible Cu(II) with bis-cyclohexanone oxalydihydrazone as color reagent to develop a new method for analyzing soil accessible under field conditions. First, the calibration curve for RGB color sensor method was established in the standard solutions of Cu(II). Then the "hand shaking + standing" field extraction method for accessible Cu(II) was developed. Finally, the method was applied in contaminated soils in the laboratory and in the field, and set the values determined by atomic absorption spectroscopy (AAS) as the standard ones. Results indicated that in the range of 0.1–5 mg·L$^{-1}$ Cu(II), the RGB Euclidean chromogenic difference values were directly linear correlated with the concentration of Cu(II) ($R^2 > 0.999$). The interference of Fe(III) and Mn(II) could be eliminated by adding citric acid. The "hand shaking + standing" field extraction method could effectively extract the accessible Cu(II) from soil with the high extraction rates. The concentrations of accessible Cu(II) in various polluted soils determined by RGB color sensor method were consistent with that determined by AAS, with the relative error within ±5%, the relative standard deviation ≤ 20%. The recovery of Cu(II) in RGB color sensor method was between 97% and 105%, which could meet the requirements of trace analysis of accessible Cu(II) in the field. The high accuracy and precision of RGB color sensor method was reconfirmed in the rapid field quantitative assessment of soil accessible Cu(II). Due to that the RGB color sensor was low cost, rechargeable, portable, mobile, ambient light resistant, the method would have a great potential for the determination of accessible Cu(II) in contaminated soils.

**ABSTRACT**

Molecular diversity has been proposed as a critical factor controlling soil organic matter (SOM) persistence. However, in contrast to dissolved organic matter, molecular diversity of solid phase organic matter remains largely unexplored. Here, we show the molecular diversity features of solid phase organic matter through a direct mass spectrometric scan of particulate and mineral associated organic matter (POM and MAOM) that show a strong relationship with carbon turnover rates, collected from a long-term grassland recovery experiment after 0, 23, and 43 years. We found that the highest molecular diversity (Hill Number = 1603±124) existed in SOM that had the slowest carbon turnover rate. Molecular diversity of MAOM exhibits greater correlation ($R^2 = 0.95$, $p < 0.001$) with SOM persistence than that of POM. Molecular diversity became increasingly enriched from top to subsoil horizons (360% increase), consistent with a breaking down of large molecules into a range of low- to high-molecular-weight molecules. Soil depth and total iron content were main factors impacting the diversity change of POM and MAOM, highlighting the combined control of microbial decomposition and mineral interaction in shaping molecular features of solid phase organic matter. Together, these results suggest that molecular diversity may not operate as a limiting factor for carbon utilization by decomposers but as an ecosystem property that incorporates organo-mineral interactions.

# The Role of Molecular Environmental Science in Addressing a Changing Climate

**Donald L. Sparks**

Department of Plant and Soil Sciences, University of Delaware, Newark, Delaware, USA

dlsparks@udel.edu

**ABSTRACT**

The use of state-of-the-art, *in-situ* small spatial and temporal scale spectroscopic and microscopic techniques have greatly advanced our understanding of biogeochemical reactivity and speciation of contaminants and carbon in natural, heterogeneous systems such as soils, sediments, particulates, and aquatic systems. The use of synchrotron-based tools especially have been instrumental in advancing research frontiers in molecular environmental science. Recently, the use of small-scale analytical tools to address vexing questions and challenges related to climate change have provided new insights in several research areas in soil and environmental sciences including: impacts of drought on transport and toxicity of soil particulates and metal contaminants, wildfire effects on redox transformations of geogenic elements, and the role of sea level rise, flooding, and salinity on toxic metal(loid), nutrient, and carbon speciation and cycling. The geochemical aspects of these environmental change phenomena will be linked to human health as well as social issues.

# Application of liquid chromatography coupled with FT-ICR MS for analysis of soil dissolved organic matter

**Xiudi Lv[1], Qinglong Fu[*]**

[1] *School of Environmental Studies, China University of Geosciences Wuhan, China*

*E-mail 15254609369@163.com

**ABSTRACT**

Soil dissolved organic matter (DOM) is a crucial component of the global carbon cycle. Soil DOM exhibits extensive physicochemical properties and often interacts with the abundant iron-containing minerals widely existing in the soil, thereby affecting the chemical form, bioavailability and stability of organic carbon. However, analytes at low concentrations or low ionization efficiency are difficult to detect due to the complexity of soil DOM by conventional analytical method namely direct infusion by Fourier transform ion cyclotron resonance mass spectrometry (DI-FT-ICR MS). Herein, we succeeded in fractionating of different polar organic molecules using high performance liquid chromatography (HPLC) and subsequently acquired the ultrahigh-resolution mass spectra of each concentrated fraction by FT-ICR MS. Compared with DI-FT-ICR MS, HPLC-FT-ICR MS not only identified more chemical formulas, but also improved the detection of low abundance compounds. In addition, molecular structure information of some specific soli DOM components was obtained using collision-induced dissociation for further insight into relationships between DOM and minerals in the soil. This work demonstrates that offline hyphenated of HPLC-FT-ICR MS is an effective analytical method for soil DOM characterization at the molecular level.

## ABSTRACT

Given that acetochlor (ACT) persists in soil for extended periods, disrupting microbial community structure and causing phytotoxicity to sensitive crops, this study investigated the potential of phosphate-modified biochar (PBC-800) to remediate ACT-contaminated soil. Incorporating 0.5 % PBC-800 into fluvo-aquic, red, and black soils increased their adsorption capacities by 80.4 mg $g^{-1}$, 76.6 mg $g^{-1}$, and 76.0 mg $g^{-1}$, respectively. Even after six months of aging, the $K_f$ values remained 1.6 to 5.1 times higher than in untreated soils. PBC-800 also accelerated ACT degradation across all three soil types, reducing residual ACT levels by 34.3 % to 76.4 % after 60 days, and shortening the degradation half-life by 5 to 7 days. High-throughput sequencing revealed that ACT reduced soil microbial diversity and disrupted community structure, while 0.5 % PBC-800 amendments promoted the growth of degradation-capable genera such as *Rhodococcus*, *Lysobacter*, and *Gemmatimonas*, enhancing microbial ecosystem stability. Furthermore, the amendment of soil with 0.5 % PBC-800 reduced ACT residue concentrations in maize and soybeans by 76.5 % to 82.9 %, and restored plant biomass, leaf chlorophyll content, and mesophyll cell ultrastructure to levels comparable to the control. Therefore, amending ACT-contaminated soil with PBC-800 mitigates ecological and environmental risks, boosts microbial activity, and safeguards plant health.

# Interactions of selenium and heavy metals in paddy systems: Mechanisms and risk assessment

**Xuefeng Yang[1] and Hua Zhang[1*]**

*[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, 550081, China*

**Corresponding email: zhanghua@mail.gyig.ac.cn (Prof. Hua Zhang)*

**ABSTRACT**

Selenium (Se) plays a critical role in environmental and human health, yet its interactions with other heavy metals in paddy systems remain insufficiently understood. This knowledge gap limits our ability to assess Se's environmental effects and its potential for mitigating heavy metal pollution. To address this, we systematically investigated the biogeochemical behaviors of Se and major toxic metals—including mercury (Hg), cadmium (Cd), and arsenic (As)—within the soil–rice–atmosphere continuum of paddy ecosystems[1-3].

Our results demonstrated that Se exhibits widespread antagonistic relationships with these metals, significantly reducing their accumulation in rice tissues. Such antagonism is most evident between Se and Hg, which serves as a representative example of Se–metal interactions. For the Se–Hg system, we summarized both microscopic processes and macroscopic manifestations of their interactions and proposed a dual-pump driving mechanism operating at the "soil–root" and "atmosphere–leaf" interfaces[1].. At the soil–root interface, $HS^-$ ($H_2S$), $Fe^{2+}$, and microorganisms play key roles in Se and Hg transformations through oxidation–reduction, methylation, and demethylation processes. Se also enhances the formation of iron plaques, reduces Hg absorption, and promotes HgSe complex formation, thereby limiting Hg translocation into roots. In the aboveground part, Se–Hg transformations likely occur within leaves, which serve as the main sites for Hg/Se uptake and bioaccumulation, forming the second driving mechanism.

Beyond Hg, Se shows comparable inhibitory effects on Cd and As uptake in rice. For the Se–Cd system, hydroponic experiments under gradient concentrations of Se and Cd revealed a mutual inhibition of their absorption, transport, and accumulation in rice [2,3]. The uptake of Cd decreased sharply when the molar ratio R(Se/Cd) exceeded 1, whereas Se uptake was suppressed at R(Cd/Se) greater than 20. This threshold behavior suggests that the formation of insoluble Cd–Se complexes in roots plays a key role in regulating Cd translocation. Furthermore, Se enhanced the antioxidant defense capacity of rice under Cd stress by activating enzymatic and nonenzymatic antioxidant systems. Couplings among multiple antioxidant subsystems—such as the AsA–GSH cycle, GS–PCS coupling, and GPX–SOD pathways—were identified in aerial tissues, providing a physiological basis for Se-mediated Cd detoxification.

Overall, this study elucidates the mechanisms and thresholds of Se–metal interactions in paddy ecosystems. The findings reveal Se's unique dual role as both a micronutrient and a natural regulator of heavy metal bioavailability and toxicity. These insights provide a theoretical foundation for risk assessment and for the development of Se-based soil amendments and remediation strategies to ensure safe rice production in metal-contaminated farmlands.

## ABSTRACT

Residual fluridone (FLU) in field soil poses a significant threat to crop growth in rotation systems. Therefore, it is imperative to investigate the phytotoxicity threshold of FLU and explore solutions to mitigate damage. In this study, the effects of residual levels of FLU and its phytotoxicity in a FLU-sensitive rotation crop maize were investigated. Study at 80 field sites indicated that the average detection rate of FLU was 81.25 %, with the highest residual concentration of 5346 μg/kg dw, which could induce death in maize seedlings. We then measured the absorption of FLU by maize seedlings from soil pore water (SPW) in hydroponic experiments and obtained the no-significant-effect concentration of FLU (4.2-5.3 μg/L). To investigate the ability of rice husk biochar (RH500) to adsorb FLU in different soil environments, isothermal adsorption experiments were conducted. The results indicated that when the RH500 was increased from 0.1% to 2% (w/w) in Aksu soil, the Kd value relative to the control group increased by 1.20 to 3.82 times. Finally, a mathematical model was developed for predicting FLU concentrations in SPW from RH500-containing soil. The predicted values closely aligned with the experimental data (slope = 1.27, $R^2 > 0.9$, and mean absolute percentage error = 24.2%), indicating that the model yields predictions with a reasonable accuracy. In conclusion, we have developed an effective approach to establish a phytotoxicity threshold for residual herbicides in rotation crop systems, and we propose an RH500-based strategy to mitigate damage caused by residual FLU in soil.

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFASs) pose an increasing environmental as well as financial and legal concern for agricultural lands where wastewater and sludges have been used to irrigate fields and amend soils. A significant proportion of non-industrial wastewater and sludge has historically been applied to agricultural land. In addition to benefits for plant growth and soil restoration, reuse of wastewater and sludges provides an alternative to expensive treatment or disposal. Wastewater and sludges from industrial sources, including textile mills and paper processing facilities, have also been applied to agricultural lands in some areas due to the lack of disposal options and a shortage of clean water for crop irrigation. Regulatory controls have traditionally focused on metals that could pose a toxicity risk to plants or adverse uptake into food crops, including livestock feed, and general soil and water quality parameters such as pH and salinity. Consideration or organic contaminants in early, draft regulations was dropped after the ban of organochlorine pesticides such as DDT, toxaphene and chlordane in the 1970s and 1980s.

The identification of PFASs in both industrial and non-industrial wastewater and sludges has called into question the continued reuse of these media for agricultural operations as well as the continued use of affected fields for the cultivation of food crops. The anionic form of PFASs are normally found in the environment. Toxicity studies suggest that long-chain compounds, such as perfluorooctanoate ($PFOA^-$), perfluorooctane sulfonate ($PFOS^-$) and perfluorohexane sulfonate ($PFHxS^-$) are potentially more toxic than legacy contaminants such as polychlorinated biphenyls (PCBs). These compounds are considered "terminal" in that they are resistant to further degradation in the environment. Although less toxic in comparison, studies suggest that ultrashort and short-chain compounds such as perfluoroethanoic acid ($PFEtA^-$ or "trifluoroacetate") and perfluorobutane sulfonate ($PFBS^-$) are similar in toxicity to contaminants such as naphthalene, arsenic and cadmium. Uptake of long-chain compounds such as $PFOA^-$ into the stems and leaves of plants used for food is well documented. Uptake of ultrashort and short-chain compounds into food crops is less well studied but likely of even greater concern, due to their increased abundance in wastewater and sludges and increased mobility in the environment. Risks posed by the myriad of precursor compounds and related breakdown products that can dominate the makeup of PFASs in wastewater and sludges is even less well researched and understood. The inability of laboratories to comprehensively report all PFAS-related compounds in a sample as well as the lack of toxicity factors for the majority of precursor compounds and their metabolites necessitates development of an alternative method to assess risk.

Accurate assessment of the risk posed by PFAS-impacted agricultural lands and food crops requires careful, systematic planning and data collection, including: 1) Designation of risk-based "Decision Unit (DU)" areas and volumes of water, soil and/or crops for testing, 2) Use of risk-based methods to collect samples that are reliably representative of the targeted DU volumes of media of concern, 3) Processing and collection of a subsample (test portion) at the laboratory in a manner that retains the representativeness of the sample submitted, 4) Utilization of Total Oxidizable Precursors (TOPs) processing and Total Organic Fluorine (TOF) analysis of the test portion to identify the full scope of PFAS-related compounds and 5) Quantitative assessment of the data in a manner that focuses on systemic health risk to developing children and women of child bearing age generates a single, cumulative Hazard Index for the mixture of PFAS-related compounds as a whole.

Investigations are initiated by the preparation of well-thought-out, risk-based questions. Example questions include: 1) "Does the makeup and mean concentration of PFASs in the upper 50cm of the subject field indicative of the application of industrial sludges?"; 2) "Does the makeup and mean concentration of PFASs in the upper 50cm of the subject field exceed screening levels for potential adverse uptake into food crops?" and 3) "Does the cumulative risk posed by consumption of food crops cultivated in the subject field exceed an acceptable limit for PFASs?"

Well-thought-out DU areas and volumes of specified media of concern are subsequently designated for sample collection based on factors such as historical records, interviews with farmers and industry representatives, available sample data, observations in the field, current or planned use of areas for cultivation of food crops and consignment orders from purchasers of existing or planned crops. A single, representative sample of media is then prepared for each DU using Multi Increment® collection methods. Examples of risk-based sampling methods include:

- Use of a "compositor" to collection a sample of wastewater over 24-hour or longer period of time;
- Collection and combination of 50 or more "increments" of biosolids from a stockpile proposed for use as a soil amendment;
- Collection and combination of 50 or more "increments" of soil from a targeted field area and depth and
- *In situ* or *ex situ* collection and combination of 50 or more "increments" of a crop cultivated from a field suspected to be impacted by PFASs.

Sample collection methods are "risk-based" in that the objective of the investigation is to assess long-term, chronic health risk associated with continuous exposure to PFASs in the targeted media over many years or uptake of the PFASs into the edible portions of food crops. The use of Multi Increment sampling methods significantly and increases the applicability and reliability of the resulting data and dramatically decreases the number of samples collected and submitted for analysis. Independent, replicate samples (minimum two) are collected from at least 10% of DUs and used to test the precision of the overall sampling and analysis method. Samples are processed and subsampled at the laboratory in a manner that ensures the test portion(s) to be analyzed is representative of the sample provided. Replicate test portions (minimum two) are collected from 10% of the samples submitted in order to test the precision of the sample processing and subsampling method.

Analysis of samples is carried out in a manner that reports complex mixtures of PFASs in terms of three, risk-based groups: 1) "Primary Terminal PFASs" originally present in the samples and identified using methods such as USEPA 537M and 1633 or SGS method MLA110; 2) "Secondary Terminal PFASs" associated with precursor compounds and identified by TOPs processing of the sample prior to analysis and 3) "Excess Fluorine PFASs" associated with additional terminal PFASs present in the sample identified based on a comparison of the concentration of organic fluorine predicted by reported concentrations of Primary and Secondary Terminal PFASs to TOF actually measured by the laboratory.

Data for identified Primary and Secondary Terminal PFASs are compared to risk-based screening levels for the media and exposure pathway of interest and used to generate a cumulative Hazard Index for each group of compounds. Non-targeted analysis suggests that much if not most "excess" organic fluorine identified in samples is associated with unidentified, ultrashort PFAS compounds. As a default, the concentration of excess organic fluorine calculated is conservatively converted into an equivalent concentration of the ultrashort compound perfluoropropanoate ($PFPrA^-$) due to its higher toxicity in comparison to ultrashort compounds such as perfluorethanoate ($PFEtA^-$; aka trifluoroacetate). The resulting concentration is compared to risk-based screening levels for this compound and used to calculate a Hazard Quotient for "Excess Fluorine PFASs." Cumulative or "Total" PFAS risk is subsequently calculated as the sum of the Hazard Indices calculated for Primary Terminal PFASs and Secondary Terminal PFASs and the Hazard Quotient calculated for Excess Fluorine PFASs. A resulting, cumulative Hazard Index greater than "1" indicates a potential risk that requires additional review and action.

The approach described significantly improves the quality of sample data collected reliability of estimates of risk posed by complex mixtures of PFASs. Although focused on PFASs, the concepts and methodologies described are applicable to organic and inorganic contaminants in general. Risk-based sampling methods and comprehensive testing of samples is critical for development of reliable bioaccumulation factors and soil and water screening levels that can ultimately be used to identify high-risk fields or irrigation water prior to the cultivation of crops.

**ABSTRACT**

Geological variation in soil selenium (Se) concentrations determines both the nutritional composition and potential toxic element co-occurrence in food crops. In Se-deficient regions, agronomic biofortification, particularly via Se application, has been widely studied to enhance dietary Se intake. Conversely, crops cultivated in seleniferous soils may acquire high Se levels naturally, but this process can also promote the co-accumulation of arsenic (As), a toxic metalloid with partially overlapping uptake pathways. This study evaluated Se and As concentrations, processing losses, and gastrointestinal bioaccessibility in biofortified rice cultivated in Brazil and a range of naturally enriched food products, including polished rice, rice noodles, maize noodles, teas, dried meats, and dietary supplements sourced from seleniferous regions of China. Total elemental concentrations were quantified using inductively coupled plasma mass spectrometry (ICP-MS). Bioaccessibility was assessed using a standardized static in vitro digestion model. Foliar application increased Se concentrations in Brazilian rice between 174 and 9,000 µg/kg, with As concentrations below 1 µg/kg. In contrast, naturally enriched rice showed a broader Se range (76–995 µg/kg) and substantially higher As content (48–321 µg/kg). Cooking retained approximately 35% of Se and reduced As concentrations by 43–71%, depending on the matrix. Based on modelled consumption scenarios, biofortified rice provided between 11% and 433% of the Se recommended dietary allowance (RDA), while naturally enriched cereals contributed 55–62%, supplements up to 161%, dried meats 12%, and teas ≤2%. All Se exposures remained below established tolerable upper intake levels (ULs); however, As exposure from certain naturally enriched rice samples exceeded the European Food Safety Authority (EFSA) chronic benchmark dose, with hazard quotients (HQs) exceeding 3. Se bioaccessibility averaged 24% in cereal products and 49–57% in teas and supplements, while As bioaccessibility ranged from 56% to 80% across all matrices. These results demonstrate that while biofortification via foliar application provide a controlled and low-risk strategy to enhance Se intake, reliance on geogenically enriched foods may pose unintended toxicological risks due to elevated As content and high bioaccessibility. The findings highlight the necessity of integrated nutrient–toxicant assessments when evaluating Se-enrichment strategies, particularly in regions where soil geochemistry contributes to simultaneous exposure to beneficial and harmful elements.

# Effects of Calcination Temperature on the Chemical Properties of Natural and Commercial Diatomites

**Wanpen Buamuang[1*], Daojarus Ketrot[1], Saowanuch Tawornpruek[1], Timtong Darunsontaya[1] and Wittaya Jindaluang[1]**

[1] *Department of Soil Science, Faculty of Agriculture, Kasetsart University, Bangkok 10900, Thailand*

*E-mail Address of Presenting Author: Wanpen.buam@ku.th

**ABSTRACT**

Diatomite is a siliceous, highly porous material increasingly used in soil improvement and environmental applications, although its effectiveness depends strongly on both geological origin and post-treatment modification. This study evaluated three diatomite samples—one commercial product and two natural deposits from northern Thailand collected at depths of 10 m and 15 m—before and after calcination at 600, 800, and 1000 °C for 6 h. All samples were analyzed for pH (1:2 $H_2O$), electrical conductivity ($EC_{1:5}$ $H_2O$), total carbon (TC) by carbon–sulfur analyzer, organic carbon (OC) by the Walkley and Black method, cation-exchange capacity (CEC) using 1 M $NH_4OAc$, and elemental composition (Si, Al, Fe, K, Mg) by X-ray fluorescence (XRF).

Calcination, a simple, rapid, and acid-free modification method, produced clear and systematic changes. $pH_{1:2}$ increased progressively with temperature, rising from 4.72–5.47 in the unheated samples to 6.66–8.24 at 1000 °C, reflecting dehydroxylation and mineral transformation. $EC_{1:5}$ values did not show a consistent decreasing trend after calcination (0.03–0.41 to 0.03–0.38 dS/m). TC and OC were markedly reduced (TC from 3.36–4.05 to 1.51–2.24 g/kg, and OC from 0.99–1.08 to 0.06–0.50 g/kg), confirming efficient removal of organic components. CEC decreased substantially with increasing temperature, particularly at 800 and 1000 °C—from 5.50–27.0 to 3.25–18.5 $cmol_c/kg$—likely due to the loss of exchange sites caused by structural collapse, sintering, and the reduction of surface functional groups during high-temperature treatment (El Ouardi et al., 2020). Si increased noticeably after calcination (from 64.6–73.0 to 74.2–77.4%), while Al showed a slight increase (10.5–13.9 to 11.5–16.8%). Fe decreased sharply across all temperatures (4.98–18.8 to 2.11–10.1%), and K exhibited a similar decline (2.73–5.73 to 1.30–2.81%). Mg varied only slightly among samples (0.71–0.93 to 0.78–0.90%), reflecting source-dependent mineral differences and thermal-stability contrasts.

Overall, calcination markedly altered the chemical properties of both commercial and natural diatomite, increasing pH and modifying elemental composition while reducing TC, OC, and CEC. To optimize its applicability in soil and environmental systems, further work should investigate specific surface area, mineralogical transformations, and sorption behavior, as well as evaluate shorter holding times at high temperatures to minimize structural degradation while preserving functional performance.

# Soil Cadmium Immobilization and Selenium Activation: A Strategy to Enhance Health in High Geological Background Areas

**JiaWen Zhang [1], JianMing Xu [2], Xingmei Liu***

*State Key Laboratory of Soil Pollution Control and Safety, Zhejiang Provincial Key Laboratory of Agricultural Resources and Environment, College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, 310058, China.*

**ABSTRACT**

High geological background areas are frequently characterized by the coexistence of cadmium (Cd) contamination and selenium (Se) deficiency, which poses substantial threats to food safety and human health. This study integrated multiple technical approaches and risk assessment methodologies to clarify the pivotal role of soil Cd immobilization and Se activation in enhancing regional health levels. From the technical perspective, hydroxyapatite-modified biochar (PBC) derived from Se-enriched straw enhanced soil available Se through synergistic mechanisms including intrinsic Se release, adsorption suppression, and soil Se activation. This treatment increased grain Se content by 55.6% and achieved a net benefit of US$18,301 per hectare. Meanwhile, the alkalizing bacterium *Stenotrophomonas* sp. H225 (SH225) reduced Cd accumulation in edible tissues by 44.7% and increased Se accumulation by nearly 4-fold by secreting piperidine to elevate rhizosphere pH and generating hydrogen sulfide for Cd precipitation. In terms of risk assessment, a novel benefit-risk-value (BRV) criterion was established. Combined with bioaccessibility analysis, the results revealed that traditional single-element assessment overestimated Cd-related health risks, while obvious Se deficiency was identified in adults and the elderly. Collectively, the Cd immobilization and Se activation technologies can simultaneously address Cd contamination and Se deficiency issues, providing technical support and assessment basis for improving health levels in high geological background areas.

# Arbuscular mycorrhizal fungi suffer from perfluorooctanoic acid in soil but ameliorate negative effects on plant performance

**Han Yan[1,2†], Tingting Zhao[1,2†], Baile Xu[1,2], Anika Lehmann[1,2], Matthias C. Rillig[1,2]**

[1] *Freie Universität Berlin, Institut für Biologie, 14195 Berlin, Germany*

[2] *Berlin-Brandenburg Institute of Advanced Biodiversity Research, 14195 Berlin, Germany*

**ABSTRACT**

*Per*- and polyfluoroalkyl substances (PFAS) can impact plant growth, while how the symbiosis of arbuscular mycorrhizal fungi (AMF) would affect the response of plant performance to PFAS contamination remains entirely unknown. To address this gap, we conducted an eight-week pot experiment to investigate the function of AMF in plant response to perfluorooctanoic acid (PFOA) using spring onion (*Allium cepa*) as phytometer. At harvest, we measured whole-plant performance (including growth, root morphology and mycorrhizal association) and soil parameters (pH and litter decomposition rate) as affected by PFOA and AMF inoculation. Our results showed that PFOA reduced the AMF colonization rate, frequency of arbuscules and vesicles. It also negatively affected root traits including root biomass, total length, average diameter, and root tissue density, while positively affecting specific root length and surface area. Moreover, PFOA significantly decreased leaf biomass, maximum height, and total biomass, but did not affect root/shoot ratio, soil pH, and litter decomposition. The inoculation of AMF reduced the negative effect of PFOA on root diameter and the positive effects on specific root length and surface area. It also increased the total root length, but this effect was neutralized by PFOA. Our results suggest that AMF inoculation alters the resource allocation strategies of plants under PFOA stress, favoring shoot growth at the expense of roots. This study provides evidence that AMF inoculation enhances plant resistance to environmental stressors and highlights the need to explore its interactions with plants and pollutants like PFAS.

## ABSTRACT

Biochar is a carbon material that can be produced from renewable biomass and has been primarily used in soil remediation and regarded as a functional carbon material due to its cost-effective and environmentally friendly characteristics. Aside from the primary aim of pollution remediation, biochar in this study was prepared using the invasive plant *Leucaena leucocephala* to achieve the forest conservation goal. Biochar was sequentially modified by acid washing followed by iron loading. The textural properties were enhanced, raising the BET surface area from 68 to 102 $m^2/g$ and improving pore volume 266%. Magnetically iron-modified biochar (Fe-ATB) achieved efficient phosphate recovery, exhibiting a 17-fold increase in binding affinity over pristine biochar. Magnetite formation (~ 31% Fe oxide) enabled high magnetic recovery efficiencies in both aqueous (96.0%) and soil (91.2%) systems, supporting its economic viability for reusable adsorption cycles. Looking at the promising potential of Fe-ATB for pollution remediation, further research will be conducted on an emerging contaminant, Ibuprofen (IBP), where additional modification of microbe loading will be applied to the biochar. Out of 27 bacterial strains tested, six strains including *Cellulosimicrobium funkei, Promicromonospora thailandica, Serratia marcescens, Bacillus aryabhattai, Sphingorhabdus buctiana, and Gordonia terrae* showed high IBP tolerance up to 500 mg $kg^{-1}$. Therefore, applying iron-modified and microbe-loaded biochar is expected to improve IBP degradation, adsorption, and removal, as well as facilitate magnetic separation and circular utilization.

**ABSTRACT**

Simultaneously improving micronutrient nutrition and minimizing toxic metal exposure from rice is a global food-safety challenge in many monsoon influenced or geogenically enriched agricultural regions, where naturally seleniferous paddy targeted for Se biofortification often co-occur with cadmium (Cd) contamination. Here, we conducted a multi-site field investigation in Guangxi, China, sampling soils and porewater across four cultivation stages (July, August, September, and December 2024) spanning alternating flooded and drained conditions. Porewater chemistry was characterized alongside size-resolved Se and Cd partitioning (ionic and colloidal) using asymmetric flow field-flow fractionation (AF4) coupled with ICP-MS/TOC analysis, Se speciation by HPLC-ICP-MS, organic matter characterization by FT-ICR-MS, and particle-scale imaging by TEM/STEM-EDS. Across flood-drainage transitions, both Se and Cd shifted systematically between ionic and colloid-associated pools: flooding decreased ionic Se from 78.5% to 55.2% while increasing mineral-sized colloidal Se (130 kDa-150 nm) from 0% to 42.8%, and decreased ionic Cd from 94.5% to 54.3% while increasing small colloidal Cd (1-40 kDa) from 22.3% to 35.5%. Critically, direct Se-Cd immobilization via CdSe was not supported: CdS signals were consistently detected whereas CdSe was absent, indicating that Se and Cd are not controlled by a single coupled precipitation pathway in paddy. Mechanistically, Cd speciation was dominated by ionic Cd during drainage and by labile complexes with low molecular weight protein-like colloids during flooding, consistent with oxidative weakening of protein binding and release of ionic Cd during the drainage stage. In contrast to the common assumption of inorganic Se dominance in seleniferous soils, porewater Se was overwhelmingly dominated by L-Se-methylselenocysteine, peaking at 75.3% during flooding and decreasing to 55.2% during drainage, when minor but more plant available selenite (20.1%) and selenate (14.1%) emerged during drainage. These findings identify drainage as a critical window where Se activation and heightened ionic Cd risk co-occur, providing a mechanistic basis for water-management optimization and targeted amendments to reconcile Se biofortification with Cd-safe rice production.

## ABSTRACT

Heavy metal (HMs) contamination has emerged as a global environmental challenge threatening farmland ecological security and agricultural product quality. In regions characterized by high geochemical background levels in combination with intensive anthropogenic activities, toxic metals such as mercury (Hg), cadmium (Cd), and arsenic (As) tend to accumulate continuously along the soil–crop–human continuum, thereby substantially increasing dietary exposure and associated health risks. Mitigating HMs contamination while maintaining agricultural productivity and nutritional security remains a critical challenge for farmland remediation and risk management.

To address the major challenges of unclear health risks, poorly understood process mechanisms, and the lack of green remediation technologies associated with soil HMs pollution in China, this study systematically elucidates the key regulatory roles of selenium (Se) in environments co-contaminated with Hg, Cd, and As. The results demonstrate that Se effectively suppresses the migration, transformation, and bioaccumulation of HMs in soil–crop systems through multiple pathways, including complexation and precipitation, enhancement of antioxidant defenses, regulation of metal-related gene expression, and maintenance of nutritional homeostasis. On this basis, a dual-regulation concept termed “Se enhancement for pollution mitigation” was proposed, and an integrated remediation framework incorporating microbe–plant interactions, agronomic management, and functional materials was established. This framework successfully achieved the synergistic reduction of HMs risks and enhancement of Se nutrition in rice cultivated in typical high-geochemical-background regions, such as Tongren, known as the "Hg Capital of the China". Furthermore, from the perspective of human health risk management, a novel Benefit–Risk Value (BRV) assessment method based on Se-HMs antagonistic interactions was developed. This method overcomes the limitations of conventional risk assessment frameworks that focus exclusively on metal toxicity while neglecting the protective nutritional role of Se, enabling an integrated evaluation of food safety and nutritional benefits.

Collectively, these outcomes have led to the development of a suite of remediation technologies and soil conditioners, and to the establishment of the “Tongren model” for risk control and safe utilization, providing scientific evidence and technical support for the sustainable management and green remediation of farmland contaminated by HMs in high geochemical background regions.

## ABSTRACT

Heavy metal contamination in farmland poses a critical threat to global food security, particularly in densely populated regions of East Asia where arable land is scarce. Conventional remediation techniques (e.g., chemical immobilization, phytoremediation) often fail to achieve complete metal removal or disrupt agricultural production, making them unsuitable for areas requiring continuous land use. To address this challenge, we developed a series of lignin hydrogel-loaded nanoparticle composites enabling in-situ metal removal while maintaining crop cultivation. We synthesized multiple nanocomposites by embedding nanoparticles (e.g., FeS, $Fe_3O_4$, $Fe_2O_3$) into a lignin-based hydrogel network, whose three-dimensional porous structure ensures high loading capacity and uniform dispersion of nanoparticles, preventing aggregation and enhancing reactivity. Among these, the FeS-loaded lignin hydrogel (FeS@LH) demonstrated exceptional performance, with a maximum cadmium (Cd) adsorption capacity of 833.3 mg/g via chemical precipitation (CdS formation) and ion exchange. Recently, we optimized the synthesis process using a one-pot method to produce $Fe_3O_4$@LH and $Fe_2O_3$@LH, simplifying preparation and reducing costs for scalable application. Field trials validated the efficacy of FeS@LH under real farming conditions: in a water spinach plot, application of FeS@LH (30 g/m²) for 30 days reduced bioavailable soil Cd by 37.6% and vegetable Cd by 34.5%; in a rice paddy system, a single application reduced soil Cd by 0.42–31.72% and grain Cd by 1.52–49.11% after 94–103 days, and continuous remediation over multiple seasons showed sustained Cd reduction without compromising yield. The composite also improved soil quality (total nitrogen increased by 16.1%; organic matter increased by 13.8%) and exhibited high biosafety (zebrafish survival rate >98%) and recoverability (>88%). This study demonstrates that lignin hydrogel nanocomposites achieve efficient heavy metal removal through synergistic synthesis optimization, interface behavior control, and field-scale validation, offering a sustainable "remediation-while-farming" solution for contaminated farmland in land-stressed regions, which aligns with the conference's focus on innovative soil composites for environmental applications.

**ABSTRACT**

Selenium (Se) is an essential trace element for both plants and humans. It often exhibits a co-enrichment characteristic with the toxic element cadmium (Cd) in soil, and this phenomenon is particularly pronounced in karst areas with the superposition of high geological background values and mining-smelting activities. At present, systematic research on the distribution patterns and driving mechanisms of soil Se and Cd co-enrichment remains relatively scarce. In this study, a total of 1,528 topsoil samples were systematically collected from a typical area with the superposition of high geological background values and historical indigenous zinc smelting activities in Southwest China. Combined with multivariate statistical analysis, geostatistical methods and random forest models, the spatial distribution patterns and co-enrichment driving factors of Se and Cd in the soil were investigated. The results showed that the soil Se content in the study area ranged from 0.09 to 1.79 mg/kg, with a mean value of 0.65 mg/kg, which was significantly higher than the soil Se background values of the world and China. In contrast, the soil Cd content exhibited a wide variation range of 0.38 to 15.10 mg/kg and a mean value of 4.22 mg/kg. In terms of spatial distribution, the high-value areas of Se and Cd co-enrichment are concentrated in the northern pastureland region as well as the central region characterized by the superposition of carbonate rocks and historical indigenous zinc smelting activities. Results from correlation analysis and random forest models showed that soil organic matter (SOM), lithological distribution (LIT), distance to mining-smelting sites (DTM), and soil nitrogen (N) content were the core driving factors regulating the spatial distribution of Se and Cd in the study area. Furthermore, bivariate local Moran's I was employed to construct a spatial correlation model between Se and Cd enrichment characteristics and key driving factors, thus identifying the dominant factors affecting the enrichment and distribution of Se and Cd in different enrichment areas: In the central region, the weathering of carbonate rocks combined with the exogenous input from indigenous zinc smelting activities has jointly intensified the co-enrichment of Se and Cd. In the northern pastureland region, high contents of SOM and N are important factors controlling the enrichment and distribution of Se and Cd. In conclusion, mining-smelting activities and land use changes are important factors affecting the synergistic enrichment and spatial differentiation pattern of Se and Cd in regional soils. This study reveals the multi-factor driving mechanism of Se and Cd co-enrichment in the compound-impacted area, which can provide theoretical support and practical guidance for the rational development of Se-rich soil resources as well as the precise prevention, control and remediation of Cd pollution.

# Cell-level Toxicological and Biodegradation Responses of Pure Bacterial Cultures to Per- and Polyfluoroalkyl Substances (PFAS)

**Gayeon Jang[1*], Minjoo Lee[1], Wonsik Nam[1], Yeeun Kim[1], Yuhun Bak[1], Joonhong Park[1]**

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFAS), characterized by strong carbon–fluorine (C–F) bonds, have been widely recognized as "almost forever chemicals" due to their extreme persistence and pronounced toxicity to microorganisms. Despite increasing concern regarding their environmental accumulation, the quantitative impacts of structurally diverse PFAS on bacterial growth, viability, and pollutant degradation at the cellular level remain poorly understood. In this study, we systematically investigated the growth, survival, and degradation responses of pure bacterial cultures exposed to representative PFAS, including perfluorobutanoic acid (PFBA), perfluorooctanoic acid (PFOA), and 6:2 fluorotelomer alcohol (6:2-FTOH). *Escherichia coli* K-12 BD792 was employed as a non-degrading control, while four known aerobic PFAS-degrading isolates (*Pseudomonas aeruginosa* Migula 1900, *Pseudomonas fluorescens* DSM 50090, *Delftia acidovorans* DSM 39, and *Rhodococcus jostii* DSM 44719) were selected to evaluate degradation-associated toxicity. In addition, two toluene-degrading isolates (*Pseudomonas putida* F1, *Burkholderia cepacia* G4), and one biphenyl-degrading isolate *Burkholderia xenovorans* LB400 were included to assess the potential interference of PFAS with the biodegradation of co-occurring organic pollutants. Across a total of eight bacterial isolates, growth kinetics, resting-cell viability, and PFOA degradation rates were quantitatively examined under PFAS exposure. PFAS attenuation was monitored using liquid chromatography–mass spectrometry (LC–MS), while fluoride release, as direct evidence of defluorination, was determined by ion chromatography and a fluoride ion-selective electrode. Furthermore, flow cytometry was applied to examine cell-to-cell heterogeneity in a pure culture, including changes in cell size, cellular complexity, and live/dead cell ratios. The results provide insight into cell-level responses to a toxicant, which may differ from population-level averaged observations, and implications for the applicability of single-cell sorting of PFAS-degrading and/or PFAS-tolerant bacterial cells in accelerating selective enrichment of PFAS-degrading microbes.

**ABSTRACT**

Selenium (Se) is a trace element with a narrow threshold between essentiality and toxicity in ecological and agricultural systems, particularly in seleniferous soils of northwestern India. This study evaluated the effects of organic (biochar, farmyard manure [FYM], crop residue straw) and inorganic (gypsum) amendments on selenium fractionation and speciation in seleniferous soils. Laboratory experiments were conducted with graded amendment levels. Soil pH, electrical conductivity (EC), organic carbon (OC), total and available Se, Se fractions (water-soluble, exchangeable, organic-bound, residual), and Se species [selenite (Se(IV)), selenate (Se(VI)), selenide (Se(-II)), elemental Se (Se(0))] were quantified. Results showed that organic amendments significantly shifted selenium from more labile forms (water-soluble and exchangeable) toward less mobile organic-bound and residual fractions, indicating enhanced Se immobilization. This effect was attributed to increased microbial activity and organic matter interactions that drive reduction and complexation processes, consistent with recent observations that soil microbial communities and dissolved organic carbon regulate Se bioavailability under organic amendment regimes (Zhang et al., 2022). Biochar influenced Se speciation by altering soil redox conditions and organo-mineral interactions, reducing available Se, in line with mechanistic insights into biochar–Se interactions (Yao et al., 2020). Inorganic gypsum affected soil chemical properties, moderately reducing soluble Se forms through ionic interactions (Etteieb et al., 2024). Collectively, amendment-induced changes in Se fractionation and speciation reduced its mobility and potential toxicity, demonstrating that integrated use of organic and inorganic amendments can sustainably manage selenium-rich soils by regulating Se transformations and minimizing environmental risk.

**ABSTRACT**

Microplastics (MPs) in groundwater exhibit complex surface properties and generate MP-derived dissolved organic matter (MP-DOM), which exerts a strong regulatory effect on elemental cycling within aquifers. DOM can alter the metabolic activities of microbial communities, thereby enhancing microbially mediated arsenic (As) biogeochemical processes. However, the influence of MPs and MP-DOM on the migration and transformation of As in alluvial aquifers remains poorly understood to date. To address this knowledge gap, we selected high-As alluvial aquifer systems in the middle reaches of the Yangtze River basins and used Fluorescence excitation-emission matrices (EEMs) spectra, Ultra high-resolution Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS), 16S rRNA and groundwater chemistry to reveal the potential cycling behavior of As in alluvial aquifers under MPs-containing groundwater conditions. Results indicated severe As pollution (14.05-240.03 μg/L) in confined groundwater (CG) with relatively lower MPs values. By contrast, significantly higher MPs concentrations (3940 to 17130 items/m³) with lower As values (0.27-11.19 μg/L) were detected in unconfined groundwater (UG). EEMs and FT-ICR-MS analysis revealed abundant lignins and specific molecular formulas with higher H/C ratios (>1.5) and lower O/C ratios (<0.50), which are the distinctive traits of MP-DOM. This unique MP-DOM can sequester As through the formation of As-Fe-DOM ternary complexes. Hydrogen bond interaction and/or surface complexation serve as another important way for arsenic immobilization by MPs. Moreover, the ultimately higher diversity and abundance of bacteria with As tolerance and As metabolic capabilities (e.g., *Methylomonas*, *Azospira* and *Acinetobacter*) in CG likely drive the reductive dissolution of Fe(III) oxides/oxyhydroxides, consequently promoting the release of As adsorbed onto these minerals, with MP-DOM serving as electron donors. This research provides new insights into the roles of MPs and MP-DOM in regulating the mobilization and enrichment of As in alluvial aquifers, thereby advancing our understanding of the genesis of geogenic As-contaminated alluvial aquifer systems.

## ABSTRACT

Cadmium (Cd) contamination in paddy soils severely threatens food security and human health. Globally, 14%-17% of arable land (242 million hectares) is contaminated by toxic heavy metals, with China's farmland soil showing a 7% Cd over-standard rate. Zhejiang Province faces a more severe challenge with a 15.6% over-standard rate (≈1.38 million mu). As rice is the staple food for over half of China's population, with ~10% of grains exceeding Cd limits, this study develops efficient Cd control technologies aligned with the national strategy of "Putting People's Life and Health First".

Three core technical directions were explored: arbuscular mycorrhizal fungi (AMF)-rice symbiosis, calcium (Ca)-based amendments, and rice-Sesbania cannabina intercropping. For AMF symbiosis, Glomus etunicatum was applied in seedling trays, achieving a 30% colonization rate without affecting rice growth and reducing Cd absorption by over 50%. AMF alleviated Cd-induced cell damage, enhanced photosynthetic performance, reduced Cd flow velocity in root xylem by ~50%, and regulated key transporter genes (e.g., NRAMP1 upregulated by 2.9-fold, ABCG48 by 4.7-fold). Validation with OsNRAMP5-deficient mutants confirmed AMF's role in inhibiting Cd translocation to grains.

Regarding Ca-based amendments, lime (CaO, $Ca(OH)_2$, $CaCO_3$) was selected for its low cost and effectiveness. In alkaline coastal fluvo-aquic soil (pH=8.17, Ca=0.36%), $CaCO_3$performed best by continuously releasing $Ca^{2+}$, increasing soil pH and Ca concentration, and reducing Cd bioavailability. When the Ca/Cd ratio reached 20, Cd adsorption on rice root iron plaque decreased by ~70%. High-throughput sequencing showed $CaCO_3$ altered soil bacterial community structure, reducing richness by ~4 times.

In the rice-Sesbania cannabina intercropping system (1 row Sesbania + 5 rows rice, 25cm spacing), field and pot experiments demonstrated a ~50% reduction in grain Cd content. Sesbania's superior biomass promoted rice root growth and iron plaque formation; when plaque thickness exceeded 15-25 mg/kg, Cd migration to roots was inhibited. Additionally, Sesbania's shading reduced rice transpiration rate by 25% during the booting stage, suppressing Cd transport to grains with only a 10% yield reduction.

Based on these findings, an integrated "One Mixing, Two Applications, Three Intercroppings" model was established: mixing AMF inoculant with substrate (0.5% volume), applying $CaCO_3$ (200-300 kg/mu), and intercropping rice with Sesbania (5:1 row ratio). This model integrates biological, chemical, and agronomic measures, enabling safe rice production in Cd-contaminated soils and providing a practical solution for "production-while-repair".

**ABSTRACT**

Per- and polyfluoroalkyl substances (PFAS) have attracted increasing global concern owing to their extreme environmental persistence, bioaccumulative potential, and associated human health risks. Landfills are recognized as major point sources of PFAS release, particularly in rapidly urbanizing regions where many landfills are located in close proximity to agricultural land. This spatial configuration creates a direct exposure pathway linking "landfill–water–soil–crop–human," thereby elevating the potential for agricultural and dietary risks. Following international restrictions on legacy long-chain PFAS such as perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), industrial production has progressively shifted toward short-chain homologues and fluoroether-based alternatives.This transition, however, introduces a dual and underappreciated environmental challenge. On the one hand, many emerging PFAS alternatives exhibit higher aqueous solubility and mobility, facilitating their migration through landfill liners and vadose zones and enhancing their transport along groundwater–soil continua into crop root zones. On the other hand, their widespread introduction has substantially reshaped the compositional profiles of PFAS in surrounding environments. When these emerging compounds coexist with legacy long- and short-chain PFAS in complex mixtures, their bioavailability, competitive interactions, and influence on the environmental behavior of existing PFAS remain poorly understood. Such complexity challenges conventional assessment frameworks, thereby contributing to delays and inadequacies in current agricultural environmental regulations.

To address these knowledge gaps, this study investigated an agricultural system surrounding three representative landfill in southern China. By integrating field surveys with laboratory-based interaction simulations, we systematically characterized the occurrence of PFAS in farmland irrigation water and elucidated differential root accumulation behaviors under multi-PFAS coexistence conditions.Field investigations revealed widespread mixed PFAS contamination with pronounced spatial heterogeneity. Irrigation water adjacent to simple landfills exhibited a composite pollution profile dominated by the fluoroether substitute GenX (1005.94 ±398.37 ng/L), accompanied by elevated concentrations of short-chain PFAS (e.g., PFBA and PFBS) and detectable residues of long-chain compounds. In contrast, areas influenced by properly managed sanitary landfills showed markedly reduced GenX levels but comparatively higher residual concentrations of legacy PFAS. This clear divergence in compositional profiles indicates that crop roots in different regions are subjected to fundamentally distinct PFAS stress environments, characterized by chemically crowded mixtures encompassing diverse chain lengths and functional groups.

To further evaluate how PFAS composition regulates bioavailability, root accumulation behaviors were compared under single-compound and mixed-exposure conditions. The results demonstrated that, in mixed systems, the accumulation of most legacy perfluoroalkyl acids was significantly inhibited. This suppression exhibited strong structure dependence: with increasing carbon chain length and molecular volume, competitive disadvantage became increasingly pronounced (e.g., PFNA accumulation decreased by 49%, whereas PFBA decreased by only 13%). In contrast, GenX accumulation was largely unaffected by coexisting PFAS, despite sharing a fluorinated backbone with legacy compounds. This distinctive behavior suggests that the incorporation of an ether linkage may enable GenX to access root tissues via alternative uptake pathways—such as nonspecific diffusion or independent carrier-mediated transport—thereby circumventing the competitive inhibition observed among conventional PFAAs.

In summary, this study underscores the urgency of incorporating emerging alternatives and interactions between PFAS compounds for plant uptake into the prediction of soil-plant transfer and human health risk assessment of vegetable fields receiving PFAS-contaminated irrigation water.

# Removal Performance and Mechanism of MOF-Based Iron-Carbon Composite Materials for PFOA and PFOS Electron Transfer Mediated by Iron Sites

**Aonan Nie[1,2*], Mengfang Chen[1], and Lei Yang[1]**

[1] *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

[2] *China University of Geosciences (Wuhan), Wuhan, China*

* annie@issas.ac.cn

**ABSTRACT**

This study developed a metal–organic-framework-derived iron–carbon composite (Fe-NC-0.1) for the efficient removal of mixed PFOA/PFOS contamination from water. Using ZIF-8 as the structural template and FePc as the iron source, iron–carbon materials with tunable pore structures and active sites were synthesized through a solution-based reaction followed by pyrolysis. Among the materials with different Fe loadings, Fe-NC-0.1 retained a well-defined polyhedral morphology, exhibited the largest specific surface area (561.56 m2/g), and contained abundant single-atom Fe sites. Batch adsorption experiments demonstrated that Fe-NC-0.1 rapidly removed PFOA and PFOS, achieving 90% removal within 2 min in single-PFOA/PFOS systems and maintaining high performance under mixed PFOA/PFOS contamination. Fe-NC-0.1 showed strong resistance to interference across a wide pH range (3-11) and in the presence of common groundwater ions. Compared with commercial activated carbon, Fe-NC-0.1 exhibited faster adsorption and higher efficiency at low dosage and maintained >99% removal efficiency over five regeneration cycles.

The adsorption mechanism involves electron transfer and hydrophobic interactions, in which adsorption is primarily governed by the interaction between the PFAS tail functional groups and the Fe–N coordination sites, accompanied by electron transfer from the single-atom Fe to the central functional groups of PFOA/PFOS. XPS, FT-IR, Raman spectroscopy, and DFT calculations all confirmed Fe-centered chemisorption, with stronger affinity toward PFOS than PFOA, consistent with the experimental observations. Dynamic column experiments further validated effective removal under flow conditions. Overall, Fe-NC-0.1 integrates high adsorption capacity, rapid kinetics, regenerability, and magnetic recoverability, demonstrating strong potential for PFAS remediation in groundwater treatment systems.

# Remediation of oxytetracycline-contaminated calcareous soil by a novel Zinc oxide/Schwertmannite composite: interface behavior and plant synergy

**Yingxuan Fan[1], Jian Zhang[2*], Fenwu Liu[3*] and Wenlong Bi[4]**

[1] *Affiliation of the Yingxuan Fan, Jian Zhang, Fenwu Liu and Wenlong Bi (College of Resource and Environment, Shanxi Agricultural University, Taigu, 030801, Shanxi, China)*

*E-mail Address of Jian Zhang and Fenwu Liu: zhangjian82@126.com; lfwlfw2008@163.com

## ABSTRACT

**Introduction:** The land application of livestock manure exacerbates the accumulation and migration risks of oxytetracycline in calcareous soils of northern China. The characteristics of such soils—high pH, high calcium, and low organic matter—not only severely restrict the soil's intrinsic immobilization capacity but also render sole phytoremediation inefficient. To address this dual challenge, this study developed a novel composite, Zinc oxide/Schwertmannite composite, aiming to construct an efficient "material-assisted phytoextraction" synergistic remediation strategy.

**Methodology & Results:** Zinc oxide/Schwertmannite composite was synthesized via biosynthesis and co-precipitation[1-2]. Adsorption tests in aqueous systems demonstrated that the material possesses excellent adsorption performance (35.98 mg/g) and solar photocatalytic potential. Through 56-day soil incubation and pot experiments, it was found that Zinc oxide/Schwertmannite composite acts as a "dynamic reservoir" in the soil, actively competing to immobilize oxytetracycline, effectively buffering phytotoxicity, and creating an enrichment interface for plant extraction. Zinc oxide/Schwertmannite composite not only increased the biomass of *Sedum plumbizincicola* but also optimized the rhizosphere microenvironment, enhancing the oxytetracycline extraction efficiency of the plant by 4.71 times, thereby achieving high-efficiency removal via "material immobilization–plant extraction". Meanwhile, the recovery of inhibited soil catalase activity confirmed the restoration of metabolic functions.

**Conclusion**: This study confirms that, targeting the migration risk of oxytetracycline in alkaline soils, the synergy between Zinc oxide/Schwertmannite composite and the hyperaccumulator successfully couples the "immobilization" and "extraction" processes. This "detoxification-enhancement" strategy offers an innovative and green solution for managing antibiotic contamination in agricultural soils with similar properties.

**ABSTRACT**

Salt-affected soils in Northeast Thailand represent a major constraint to rice production. Spatial information on soil properties is essential for effective soil and fertilizer management. This study aimed to develop digital maps predicting the spatial distribution of organic matter (OM), available phosphorus (P), and available potassium (K) using Quantile Random Forest (QRF) models and to analyze relationships among OM, P, K and salinity levels to provide soil management recommendations for rice cultivation in Muang Phia subdistrict, Ban Phai district, Khon Kaen province, covering 35,255 rai (approximately 5,640 hectares). Data from 107 soil samples collected at a 0–30 cm depth were combined with remote sensing indices and environmental covariates derived from Landsat 9 OLI imagery, NASA SRTM digital elevation model, and existing soil, geological, and land use maps. Results showed that key variables influencing OM and K were spectral reflectance indices and salinity indices, while P was primarily influenced by topography and geology. The QRF algorithm achieved satisfactory prediction performance with Nash-Sutcliffe efficiency (NSE) values of 0.66 for OM, 0.47 for P, and 0.63 for K. Based on the OM, P, and K maps, the study area was classified into 7 soil and fertilizer management zones for rice cultivation, with the zone having low levels of all three nutrients (L-L-L) being the most predominant (42.86%). The resulting maps can support site-specific soil and fertilizer management planning, thereby reducing production costs and improving rice productivity in salt-affected areas sustainably.

**ABSTRACT**

Heavy metals and excessive inorganic salts in soil can degrade soil physicochemical properties, reduce soil quality, and result in human health risks.Currently, most conventional soil washing equipment adopts mineral processing production line configurations, which suffer from several limitations: lengthy processing lines, narrow applicability (restricted to sandy soils only), prolonged installation cycles, high water consumption, and substantial energy consumption.

To address the need for efficient remediation of diverse contaminated soil types, particularly clayey soils, it is essential to thoroughly investigate the occurrence forms and migration/transformation mechanisms of heavy metals and inorganic salt ions in clayey soils. Simultaneously, soil remediation equipment must be updated and optimized to enhance the removal efficiency of heavy metal ions and salt ions, thereby achieving the sustainable remediation objectives of water and energy conservation.

The soil washing equipment developed in this study adopts a modular integrated design, dividing the entire contaminated soil treatment process into five sequential stages: (1) feed pretreatment, (2) scrubbing and screening, (3) efficient classification and concentration, (4) sludge pressure filtration, and (5) water circulation treatment and reuse. This design establishes a complete closed-loop water circulation system. The equipment offers several advantages: convenient transportation, significantly shortened installation and commissioning cycle (reduced from 1–2 months for conventional equipment to less than 10 days), and high degree of automation enabling linked operation across modules, which effectively minimizes manual intervention and ensures continuous and stable operation.

Furthermore, by incorporating key technologies such as cylindrical scrubbers equipped with wear-resistant liners and high-efficiency deep cone thickeners with overflow functionality, the equipment can effectively achieve synergistic reduction, hazard elimination, and resource utilization of various contaminated soil types, including clayey soils..

## ABSTRACT

In order to address the issues such as the deteriorating ecological environment, low water and fertilizer use efficiency, and intensified non-point source pollution in salinized farmlands along the Yellow River, this study investigated the effects of organic materials on soil nitrification in saline-alkali cropland. Experimental treatments included combined application of organic materials (corn straw (C1), biochar (B1)) and nitrogen fertilizer at three levels (N0, N, N2), with no organic material and no nitrogen fertilizer as the control (B0N0, C0N0). The results showed that compared with C0N0, the C1N0 treatment generally alleviated nitrogen mineralization and nitrification processes in saline soil, whereas the C1N2 treatment increased the nitrogen mineralization rate and nitrification rate in saline soil. Straw returning and reduced nitrogen fertilizer application can retain more ammonium nitrogen, thereby inhibiting nitrification of soil nitrogen, reducing the environmental pollution risk of nitrate leaching, and mitigating soil nitrogen loss in saline soils. In addition, corn straw and biochar treatments increased the relative abundance of Actinobacteriota, Bacteroidota and Firmicutes in the soil, while decreasing the relative abundance of Gemmatimonadota, Chloroflexi, Acidobacteria, Planctomycetes and Patescibacteria. Biochar significantly altered the fungal community structure in moderately saline soil, and the addition of corn straw significantly increased beneficial fungal groups in moderately saline soil. Ammonium nitrogen, nitrate nitrogen and nitrate reductase were the main environmental factors affecting the bacterial community in moderately saline soil. Ammonium nitrogen and nitrate reductase mainly influenced the bacterial community, and nitrate nitrogen also predominantly affected the bacterial community. Soil nitrate reductase and ammonium nitrogen were the dominant environmental factors shaping the fungal community in moderately saline soil, followed by nitrate nitrogen, electrical conductivity and nitrite reductase. The results of this study provide a theoretical basis for establishing a reasonable and efficient regulation model of organic materials in salinized farmlands, improving nitrogen uptake and utilization efficiency as well as soil nitrogen transformation capacity. They are also of great significance for guiding the formulation of efficient nitrogen fertilizer management strategies for salinized land and reducing environmental pollution caused by nitrogen loss.

# "Reshaping soil structure": A systems engineering mode for ecological management of Salt-Affected Land

**Shuwen Hu**

**ABSTRACT**

Confronting the central challenge in reclaiming salt-affected soils, namely structural degradation that suppresses water infiltration and leaching efficiency, this work presents a ecological framework that prioritizes rebuilding soil aggregate structure to catalyze efficient desalinization. A series of bio-based amendments was innovated to accelerate micro-aggregation and enlarge capillary porosity, increasing leaching efficacy five- to thirteen-fold. In parallel, salt-tolerant controlled-release fertilizers were devised to modulate rhizosphere nutrient delivery and optimize crop habitat. Hydraulic interventions, including gated embankments and groundwater regulation, sever salt-return pathways. The integrated mode thus orchestrates structure reconstruction, high-efficiency desalinization, microbial community rehabilitation, nutrient cycling, and ecological restoration. Tailored for the arid region, a pioneering water-soluble amendment combined with functional fertilizers enables a unified regime of drip irrigation, fertilization, and soil improvement, reducing costs by 80 percent relative to conventional practices. Over a decade of validation across five representative saline and sodic landscapes and deployment in 28 counties of 11 provinces has reclaimed 1.95 million mu of saline farmland, markedly boosting yields and generating 17.6 billion yuan in economic benefit. The paradigm offers a replicable, systems-level solution for converting salt-impaired soils into productive and resilient agroecosystems.

# Reclamation of saline-alkali soils using fulvic acid: mechanisms and field effects

**Wentai Zhang*, and Guiqing Hu**

*College of Resources and Environment, Xinjiang Agricultural University, Urumqi, China*

*E-mail zwt@xjau.edu.cn

**ABSTRACT**

Fulvic acid is one of organic soil amendments used to ameliorate saline-alkali soils and to alleviate the negative effects of salt-affected soils on crops. However, scientific tests of many fulvic acid products have given very mixed results. A meta-analysis of 16 study cases on field application of fulvic acid was conducted. Results showed that fulvic acid could increase the average particle size of soil aggregates, but had a weak effect on the improvement of capillary porosity. Compared with control, application of fulvic acid can generally reduce soil electrical conductivity by 0.15 dS $m^{-1}$. However, for field with high groundwater level and poor discharge, the effect of fulvic acid on promoting salt leaching downward is not good. Fulvic acid treatment reduced soil pH from 8.48 to 8.38, a decrease of 0.1, yet for fields with high $[CO_3^{2-}]+[HCO_3^-]$ content, soil pH may increase after fulvic acid application. The mechanisms of fulvic acid on reducing soil electrical conductivity and pH was mainly though colloid absorption and ion exchange. Fulvic acid can promote the absorption of nutrients such as nitrogen and phosphorus by crops, and increase crop yield by 40.5%. Fulvic acid had a better effect on amelioration of moderate saline-alkali land.

# Salinity management when irrigating with non-conventional water sources

**Alon Ben-Gal**[1*]

[1] *Soil, Water and Environmental Sciences, Agricultural Research Organization – Volcani Institute, Gilat Research Center, Israel*

*bengal@volcani.agri.gov.il

**ABSTRACT**

Water scarcity and climate change threaten irrigated agriculture, particularly in dry locations. Semi-arid and arid regions are typically the first to utilize non-conventional, often low-quality (high salinity) sources of water for irrigation. The need for leaching salts out of the root zone mobilizes contaminants and pollutants, including but not exclusive to the salts themselves, to deep soils and groundwater. In many cases of arid regions where there is no natural hydrological flow to the sea, strategies built on the utilization of low- or marginal-quality water are, in the long term, not environmentally sustainable.

Treated wastewater brings potentially positive additions of plant nutrients along with risks to crops, the environment, and human health, including salinity, disease agents, and numerous other contaminants of concern. Desalination offers an opportunity to reduce the leaching-contamination cycle, decrease water requirements, and increase the sustainability of irrigated arid-region agriculture. But, desalination comes at a relatively high price due to energy and facility costs. Inland desalination of brackish water and desalination of wastewater are additionally challenged with the question of brine disposal.

The Israeli experience can be used to demonstrate the costs and management challenges when irrigating with water containing relatively high concentrations of salts (brackish groundwater and recycled municipal wastewater) and how large-scale desalination of seawater can influence dry-region irrigated agriculture via both direct and indirect (via recycled wastewater) use. A decision support tool (ANSWERapp: https://app.agri.gov.il/AnswerApp/) that considers crop response to environmental conditions, including water and salt balance calculations in the root zone, is used to demonstrate agronomic and environmental repercussions of irrigation as a function of water salinity while considering processes specific to soil, weather, and crop. The app couples crop response prediction to farm and water costs and benefits, and thus allows calculation of the water required to minimize negative environmental effects and maximize profits.

# Enhancement of Organic Matter in Saline-Alkali Soils: Mechanisms and Technologies

## ABSTRACT

Saline-alkali lands represent vital land resources and potential grain baskets, yet their productivity enhancement faces multiple constraints: high salinity levels resistant to reduction, low organic carbon content with slow accumulation rates, and nutrient deficiencies with low use efficiency. Among these, organic matter improvement serves as the foundation for productivity enhancement and nutrient retention, while also providing an effective pathway for salinity mitigation. This report synthesizes theories and technologies related to organic matter enhancement in saline-alkali soils, addressing: the mechanisms behind slow organic matter accumulation, the role of microorganisms in soil organic carbon sequestration, and differences in carbon stabilization mechanisms between lightly and moderately saline-alkali soils. It further outlines strategic pathways for carbon enhancement and stabilization, introduces technologies including multi-source organic amendment for rapid carbon increase, negative priming-induced carbon conservation, and microbial assimilation for carbon sequestration, while proposing future research priorities for organic matter improvement in degraded saline-alkali landscapes.

# Escaping Salinity, Cyclone and other Coastal Hazards for Crop Production through Early Sowing in Wet Soils with Strip Tillage

**Mohammad Asadul Haque[1*], and M Jahiruddin[2]**

[1]Department of Soil Science, Patuakhali Science and Technology University, Patuakhali-8602, Bangladesh

[2]Department of Soil Science, Bangladesh Agricultural University, Mymensingh-2202, Bangladesh

*E-mail Address: masadulh@pstu.ac.bd

## ABSTRACT

Salinity, cyclone, early tidal water flooding and many other coastal calamities are increasingly threatening crop production in the Ganges delta coastal ecosystem; furthermore conventional (traditional) full tillage practices worsen the situation through delayed sowing of dry season crops until January. The aim of the study was to evaluate strip tillage technology for enabling early sowing of dry season crops in wet soil condition immediately after monsoon (*Aman)* rice harvest, allowing dry season crops to escape salinity and other coastal hazards. Field studies were conducted during the 2022-2024 dry seasons using maize and wheat as the test crops where strip tillage was compared with conventional full tillage under different doses of phosphorus fertilizer application. Conventional tillage was done after soils became dry during 5-10 January, and strip tillage was imposed immediately after harvesting of previous *Aman* rice during 10-15 December in moist soil condition. Strip tillage advanced sowing date by 20-25 days over conventional tillage. Salinity starts to build up from early February and it reached a peak in March-April; with onset of monsoon rain and it gets declined from late May. Results revealed that the grain yield of maize varied from 9.88 to11.2 t $ha^{-1}$ in strip tillage and 9.28 to 10.7 t $ha^{-1}$ in conventional full tillage endorsing consistently increased maize yield in strip tillage by 5-12% over conventional tillage. The wheat yield under strip tillage was 3.84-4.26 t $ha^{-1}$ while the conventional tillage method yielded only 1.51-2.09 t $ha^{-1}$, which was two-three times higher than the conventional tillage. Strip tillage had allowed harvesting of wheat crop by the 3$^{rd}$ week of March and maize crop by the 1$^{st}$ week of May; whereas in conventional tillage crop harvesting was done in the first week of April and the last week of May, respectively. This result indicates that reproductive stage of crop (wheat) was complete before peak time of salinity. In maize, cob initiation and reproductive stage ended before mid-March which otherwise facilitates overcoming salt stress in grain filling stage. Moreover, strip tillage also helps escape crop damage caused by extreme cyclone events in May. Early sowing through strip tillage thus not only improved crop yield and also reduced the risk of crop loss due to salinity, cyclone and other coastal calamities. Therefore, early sowing with strip tillage can sustainably intensify dry season crops in the coastal fallow lands and enhance resilience in climate-vulnerable agro-ecosystems.

# Sustainable Management of Saline and Sodic Black Soils in the Lowlands of Eastern Georgia

**Teo Urushadze[1], Tamari Kvrivishvili[1], Giorgi Ghambashidze[1*], Amiran Tkhelidze[1], Diana Khomasuridze[1]**

[1] *Agricultural University of Georgia, School of Agronomy and Landscape Management, Tbilisi, Georgia*

*g.ghambashidze@agruni.edu.ge

**ABSTRACT**

Soil salinisation and sodification are the primary forms of land degradation in the dry subtropical zones of Eastern Georgia, particularly in the arid lowlands of Kakheti. This study aims to characterise the properties of saline and sodic black soils developed under agricultural use in the Sighnaghi Municipality and to determine parameters describing the degree of sodicity using the sodium adsorption ratio and the exchangeable sodium percentage.

Soil samples were examined for pH, $CaCO_3$, humus, soluble salts, texture and exchangeable cations. The studied soils were characterised by alkaline pH, moderate carbonate content and medium to high humus content. The soluble salts content did not exceed 0.75 dS/m in most cases suggesting non-saline conditions.

Exchangeable calcium dominates in the CEC, while exchangeable sodium accounts for 3–39% of it. According to the ESP, most topsoil layers are slightly sodic (3–10%), subsoils are moderately sodic (10–25%), and occasional samples show strong sodicity (>25%). Correspondingly, SAR values range from 2.6 to 37.5 meq/100 g and show a positive correlation with ESP.

A direct correlation was also observed between alkalinity (pH >8.5) and exchangeable $Na^+$, confirming the predominance of sodification. Textural analysis shows a high clay content unfavourable for crop production and promoting physical degradation.

The study concludes that the black soils of Sighnaghi lowlands are variably affected by sodification, mainly in subsoil layers, under arid climatic conditions.

Sustainable agricultural use of these soils requires integrated reclamation measures, including gypsum application, leaching with fresh water, drainage improvement and crop rotation with salt-tolerant species. These measures are essential to restore soil structure, enhance fertility and prevent further degradation.

This research provides a scientific basis for developing site-specific management practices for saline and sodic soils in the Eastern Georgian lowlands, thereby contributing to sustainable agricultural use and long-term preservation of soil fertility.

**ABSTRACT**

Climate change is resulting in severe decline in crop yields around the world due to enhanced soil salinity, heat and drought stress. Quinoa (*Chenopodium quinoa* Willd) has been regarded as an important crop for food security under the changing climatic conditions. The combined effects of soil salinity, drought and heat stress on two genotypes of quinoa (Titicaca, Puno) were explored during a field experiment conducted on salt affected soil under dryland conditions. The joint stress of salinity, high-temperature and drought was more detrimental for plant growth and grain yield in contrast to individual stresses. The combined stresses caused 36, 41%, and 35 and 43% decline in plant biomass and grain yield Puno and Titicaca, respectively. Likewise, relative water contents and stomatal conductance in both genotypes also declined in the same way. Plants accumulated the highest K and lowest Na in the shoot when heat and drought stress were imposed along with salt stress. The mineral contents in grains such as Zn, Ca, Fe, Mg, K, Mn and Cu) also reduced more under the combined stresses of salinity, drought and heat. The contents of carbohydrates, proteins and lipids in grain were not affected by salinity alone but declined when salinity was combined with heat and drought. Plant growth, grain yield and quality was better in case of Puno compared to Titicaca. Henceforth, Puno genotype should be cultivated on salt affected soils under dry land farming systems prune to heat stress.

**ABSTRACT**

Soil salinity is a major constraint to sustainable agriculture, impairing soil chemical balance, nutrient availability, and crop productivity in arid and semi-arid regions. Barley (Hordeum vulgare L.), a moderately salt-tolerant cereal, offers potential for cultivation on saline soils if tolerant genotypes are identified and effectively managed. This study aimed to identify salt-tolerant barley genotypes and evaluate their phosphorus (P) accumulation and nutritional performance under salinity stress. Twenty-one barley genotypes with contrasting salinity tolerance were grown under controlled glasshouse conditions at the University of Western Australia between May and July 2024. Treatments consisted of two salinity levels (0 and 200 mM NaCl) and two phosphorus levels (low and high) arranged in a randomized complete block design with four replicates. Growth parameters, chlorophyll content (SPAD), photosystem II efficiency (Fv/Fm), and P concentrations in shoots and roots were measured after 10–12 weeks. Statistical analyses confirmed significant effects of treatments and genotypes ($P < 0.05$). Salinity stress markedly reduced shoot and root P content, with shoot P declining from 0.24% under high P and low salinity to 0.09% under low P and high salinity. Genotypes G-6, G-7, and G-17 maintained superior P accumulation and biomass under salinity stress, reflecting higher nutrient-use efficiency and physiological resilience. Enhanced P uptake under saline conditions suggests improved ion balance and reduced $Na^+$ toxicity in the root–soil interface. These findings advance genotype-based soil management strategies that enhance nutrient resilience and support sustainable agricultural productivity in saline-affected regions

2. Soil and Water Resources Institute, Hellenic Agricultural Organization – DIMITRA, 57001, Thermi-Thessaloniki, Greece

*tiziana.danise@unicampania.it

**ABSTRACT**

The Mediterranean region, one of the world's most important biodiversity hotspots, hosts numerous plant species naturally adapted to dry, non-fertile and saline environments. Once integral to traditional rural practices, these species, known as neglected and underutilized species (NUS), are now gaining attention for their nutritional and pharmaceutical/cosmeceutical value, as well as for their role in supporting key ecological processes. Compared with conventional crops, such as cereals and horticultural species, NUS exhibit remarkable tolerance to environmental stress and can enhance soil functionality by improving moisture retention, organic carbon accumulation, salt removal, and soil cover.

Although NUS have a negligible participation in the global agricultural market, they offer a promising opportunity to rehabilitate degraded lands, providing farmers with alternative income sources while promoting the sustainable use of natural resources.

This research aims to assess the environmental impact of introducing low-input, drought- and salt-tolerant NUS such as, *Salicornia europaea*, and *Atriplex* spp into Mediterranean farming systems affected by salinization, nutrient depletion, and desertification processes.

The study was conducted in the context of the VENUS project (https://venus-project.org/), in a reclaimed lowland area in the south of the Venice Lagoon (Italy) characterized by land subsidence, soil and groundwater salinization. Two marginal grassland pilot sites (Zennare and Gesia; total area ≈1.8 ha) managed by the Consorzio di Bonifica Adige Euganeo (CONSAE) were selected, exhibiting contrasting soil features in terms of organic matter, salinity, and acidity.

A multidisciplinary assessment was carried out, combining chemical and physical indicators (organic carbon, total nitrogen, pH, electrical conductivity) with biological metrics (soil enzymatic activity, microbial activity and biomass, nematode community structure and abundance). The results highlight the potential of NUS cultivation to foster slight yet meaningful improvements in the ecological performance, such as high biodiversity of marginal soils, supporting their progressive functional restoration, and to provide measurable agronomic benefits, reinforcing their role as a sustainable tool for climate-resilient land management in the Mediterranean region.

## ABSTRACT

Saline and alkaline soils represent a global issue that compromises agricultural productivity, particularly in arid and semi-arid regions, where limited rainfall and high evapotranspiration exacerbate salt accumulation and nutrient imbalances. Among essential nutrients, phosphorus (P) plays a crucial role in plant growth and soil fertility. However, its availability in dryland soils is often limited due to its association with apatite and other refractory mineral phases. Therefore, understanding the processes that control P dynamics under such conditions is essential for improving nutrient management and promoting sustainable agriculture, even in salt-affected soils. This study examined the distribution and fractionation of P in cultivated and uncultivated soils developed from different parent materials across two regions of the United Arab Emirates. Sequential extraction revealed that P predominantly occurs in moderately or poorly available forms, regardless of land use. Nevertheless, both the mineralogical composition of the parent material and the irrigation regime affected P fractionation and mobility. In soils derived from gypsum-rich aeolian sands, P precipitation is mainly governed by $Ca^{2+}$ ions released through gypsum dissolution, whereas irrigation with brackish water containing sodium chloride (NaCl) and $Mg^{2+}$ salts increases P solubility through the formation of Na–P compounds. In contrast, in alluvial soils, the weathering of Fe-bearing minerals such as hornblende and chamosite under irrigation conditions promotes P coprecipitation with Fe oxides and hydroxides through ligands exchange. These findings demonstrate that P availability in arid ecosystems results from a complex interaction among parent material, mineralogy, and agricultural management. A deeper understanding of P dynamics in dryland soils is therefore essential to support sustainable soil management in these challenging environments.

# Managing saline soil to boost crop yield and halve nitrogen losses

**Wen Wen[1*] and Baojing Gu[1]**

[1] *College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, China*

*viviwen@zju.edu.cn

**ABSTRACT**

Global soil salinity, exacerbated by climate change, unsustainable irrigation, and excessive fertilizer use, is an escalating challenge for agricultural systems. While its negative effects on crop growth are recognized, the dual challenges of yield reduction and elevated reactive nitrogen ($N_r$) losses remain poorly quantified at the global scale. Existing studies are fragmented and largely confined to local mechanisms, leaving a critical gap in understanding how salinity shapes both crop productivity and nitrogen cycling across global croplands.

To address this gap, we developed the first global nitrogen budget for saline croplands by integrating the Integrated Model to Assess the Global Environment (IMAGE) with the Coupled Human and Natural Systems (CHANS) model. Using a spatially explicit pairwise comparison framework, we quantified salinity-induced changes in nitrogen inputs, yields, and $N_r$ fluxes. We further compiled and systematically evaluated ten categories of mitigation strategies for saline croplands and conducted a global cost–benefit analysis to assess their effectiveness and regional applicability, providing actionable insights for sustainable and climate-resilient management of saline croplands.

Our results show that salinity increases nitrogen inputs by 13% (over 1 million tonnes annually), reduces nitrogen harvest by 7%, and amplifies $N_r$ losses by 61%. We further demonstrate that mitigation measures can cut $N_r$ losses by 58% (1.9 million tonnes annually), enhance yields, and generate net global benefits of US$12.6 ± 6.5 billion US dollars per year. China, Pakistan, and Indonesia emerge as hotspot regions where targeted interventions could deliver the greatest gains. These findings highlight salinity management as a critical and scalable strategy for enhancing agricultural productivity and mitigating nitrogen pollution within climate-smart agriculture frameworks.

# Sustainability of Using Salt Affected Lands in Saline Agriculture

**Leila Jahanbazi[1*], Mohammad Hossein Mohammadi[2], and Ahmad Heidari[2]**

[1] *Department of Agroecology, Aarhus university, Aarhus, Denmark*

[2] *Department of Soil Science and Engineering, Tehran, Iran*

*Leila.Jahanbazii@gmail.com

**ABSTRACT**

Soil salinization and its associated consequence, soil degradation, is a serious threat to sustainable use of salt-affected soils in arid and semi-arid regions. As saline soils are the most dominant type of soil in arid and semi-arid regions, farmers' lives are dependent on saline agriculture in these unsustainable soil resources.

This study was conducted with the aim of tracking soil salinity changes in saline agriculture areas to investigate sustainability of using salt affected soil for agricultural use.

The study area located in the Semnan province in central Iran and cultivated crops were pistachio, wheat, and maize. Soil moisture and temperature regimes were identified as Aridic and Thermic, respectively. Laboratory analysis of soil samples taken from study areas was done in various years 2002, 2008 and 2018 to monitor temporal salinity changes.

Study area is in arid and semiarid part of Iran where producing crops without irrigation is impossible. Agricultural use of salt affected soils increased the need for irrigation and because of the arid climate in study area it is mainly supplied by groundwater from deep wells. Using deep groundwater due to saline parent material and rock-water reaction caused salinity to increase and therefore decrease irrigation water quality. EC of irrigation water sample from 2018 was 7.08 ds/m, which increased 15% in comparison to the year 2002. To assess the sustainability of agriculture in the study area, we compared data obtained in 2018 with data from soil analyses over the past 16 years. Long term use of saline irrigation water led to further accumulation of salt in soils and accelerating degradation of salt-affected soils in study area. Comparison of the mean values of the measured ECe (in 2018) with those of 2002 indicated that it increased by at least two to more than eight times. The main mechanism involved in salt accumulation in the study area was using saline irrigation water and irrelevant irrigation methods. During these years saline agriculture has caused soil resources to degrade, and present land use is not sustainable. The consequences of increasing salinity are reduced yields and soil and water quality in the study area. Pistachio orchards' yield decreased from 2000 kg/ha to less than 500 kg/ha per year.

The results indicated that it is not possible to use salt-affected soils for agriculture without considering sustainability and the salt balance in the root zone. The hot and arid climate combined with other environmental parameters demonstrates the unsuitability of the study area for agricultural purposes. Changing land use in the study area is very difficult due to farmers' heavy dependence on their lands to meet their needs and, indeed, their very survival. Due to the high sensitivity of the economic and social conditions in the study area, special management is needed to sustain agriculture.

# Hybrid CNN-LSTM Model for Predicting Nitrogen, Phosphorus, and Potassium (NPK) Fertilization Requirements: Integrating Satellite Spectral Indices with Field Microclimate Data

**Abdellatif Moussaid[1*], Yousra Gamoussi[1], and Hamza Briak[1]**

*[1] Center for Sustainable Soil Sciences (C3S), College of Agriculture and Environmental Sciences (CAES), University Mohammed VI Polytechnic (UM6P), 660 Lot, Ben Guerir 43150, Morocco*

**ABSTRACT**

Optimizing the application of Nitrogen (N), Phosphorus (P), and Potassium (K) fertilizers is a cornerstone of precision agriculture, essential for maximizing crop yield while minimizing environmental impact. Accurately predicting crop nutrient requirements remains a complex challenge due to the dynamic interplay of spatial vegetation characteristics and temporal climatic conditions. This study proposes a novel deep learning approach to predict NPK fertilization needs by integrating freely available satellite data with field-level climate measurements. We developed a hybrid Convolutional Neural Network-Long Short-Term Memory (CNN-LSTM) model designed to process multi-modal data. The architecture features parallel branches to extract spatial features from Sentinel-2 spectral indices—Modified Soil Adjusted Vegetation Index (MSAVI), Normalized Difference Red Edge Index (NDRE), Normalized Difference Vegetation Index (NDVI), and Red Edge Chlorophyll Index (RECI)—and to model temporal dependencies from daily climate variables (temperature, humidity, precipitation, wind speed, solar radiation). Tabular data on parcel size and observation date are also integrated. The model was trained and evaluated on a comprehensive dataset of 3,208 samples from a citrus orchard in Morocco, with a strict chronological split reserving the final five months for testing. The model demonstrated exceptional predictive performance on normalized test data. For Nitrogen, the Mean Squared Error (MSE) was 0.0208, Mean Absolute Error (MAE) was 0.1132, and the coefficient of determination ($R^2$) was 0.9542. For Phosphorus, MSE was 0.0281, MAE was 0.1313, and $R^2$ was 0.9480. For Potassium, MSE was 0.0225, MAE was 0.1154, and $R^2$ was 0.9474. An ablation study confirmed the critical importance of both data modalities, revealing that the removal of climate data caused a significantly larger performance degradation than the removal of satellite data. Furthermore, the model maintained stable and accurate multi-step forecasts for up to four months ahead without retraining. This work confirms that a hybrid CNN-LSTM model can effectively capture complex spatio-temporal patterns to provide accurate, near-term forecasts of NPK requirements. By leveraging free satellite data and common climate sensors, this approach offers a practical, cost-effective, and crop-agnostic decision-support tool, empowering farmers to optimize fertilization strategies, enhance productivity, and promote environmental sustainability, particularly in data-scarce regions.

# Synergistic Control of Soil Salinity via Ridge–Furrow Cultivation, Straw Mulching, and Mechanical Desalination in the Yellow River Delta

**Tan Lili[1,2], Pan Yinghua[1*], Sun Kaixiao[1], Han Xing[1], Ma Yingpei[1], Zhao Ying[1]**

*E-mail tanll@ldu.edu.cn

**ABSTRACT**

Soil salinization in the Yellow River Delta, driven by shallow groundwater and intense evaporation, threatens agricultural productivity. This study investigates the synergistic effects of ridge tillage morphology (base widths: 60/90/120 cm), straw mulching (0/5 cm), and mechanical desalination (0–3 cm scraping) on salt regulation through a 2-year field experiment (2022–2023). The study results indicated that large ridges (120 cm base width) enhanced subsurface water retention by 14.2% in the furrow layer (30–50 cm) through gravitational potential energy redistribution but amplified crest salinity (peak EC = 3.21 dS/m); straw mulching (5 cm) reduced surface evaporation by 32%, maintained soil moisture at 22.87% (vs. 17.87% in controls), and lowered electrical conductivity (EC) by 67% (0.53 vs. 1.58 mS/cm); mechanical scraping (0–3 cm) removed 2.1 kg/m²salt from the topsoil, reducing surface EC from 26.77 to 8.72 mS/cm. Integrated management (large ridge configuration + straw mulching+ mechanical desalination) achieved a root-zone desalination rate of 61.3% (0-80 cm depth) over conventional practices. This provides a viable solution for saline soil management in arid regions through morphology-mulch-desalination synergy regulation.

**Keywords:** Ridge tillage morphology; Straw mulching; Mechanical desalination; Synergistic salt control; Yellow River Delta

# GeoAI-Informed Inversion: A Hierarchical Environmental Embedding Transformer (HEET) for Interpretable Soil Heavy Metal Mapping

**Guo Tianhao[1], Zhao Zhongqiu[1*], and Wu Kening[1]**

[1] *School of Land Science and Technology, China University of Geosciences (Beijing), Beijing 100083, China*

*13583330109@163.com

**ABSTRACT**

Accurate estimation of soil heavy metal concentrations is essential for human health protection, ecological risk assessment, and soil pollution control. However, the spatial heterogeneity across diverse climatic zones, soil types, and land-use conditions poses a substantial challenge. Existing methods typically treat multi-source features as flattened inputs, thereby ignoring the hierarchical dependencies inherent in Earth surface systems, which limits their ability to generalize across heterogeneous environments. To address this limitation, we propose a Hierarchical Environmental Embedding Transformer (HEET) model for large-scale inversion of soil heavy metal concentrations. The model integrates dynamic geospatial features and static environmental priors as inputs. Specifically, a hierarchical embedding module is utilized to explicitly encode the multi-level environmental priors into a structured representation. The Transformer backbone employs this hierarchical representation within its self-attention mechanism to dynamically adjust feature importance under varying environmental conditions, thereby more accurately capturing the complex response relationships among spectra, environment, and soil heavy metal variables. Experimental results demonstrate that the proposed model consistently outperforms existing methods across diverse climatic, soil, and land-use conditions, exhibiting superior performance in widely used metrics such as R2, RMSE, and MAE. Furthermore, this study provides a novel approach for integrating geoscientific hierarchy into artificial intelligence models, enhancing both generalization and physical interpretability in remote sensing applications.

## ABSTRACT

Saline land holds significant potential for carbon sequestration and serves as a crucial reserve of arable land to address global climate change and food security. However, the impact of reclaiming saline land by using *Tamarix chinensis* (*T. chinensis*) and *Suaeda salsa* (S. salsa) as pioneer plants on soil structure and soil organic carbon (SOC) storage remains unclear. To clarify the effects of these two halophytes on the physicochemical properties, aggregation structure, and SOC storage of saline land, this study conducted a field experiment on plots of *T. chinensis* and *S. salsa* land that had been cultivated for five years along the coast of the Yellow Sea, with saline bare land as the control. Compared to bare land, *T. chinensis* was found to decrease the soil bulk density by 0.19, 0.27, and 0.1 g $cm^{-3}$ in the 0–10, 10–20, and 20–40 cm soil depths, respectively. Furthermore, both *T. chinensis* and *S. salsa* also increased soil porosity by 18.95 % and 28.63 % in the 0–10 cm soil depth, and by 14.54 % and 23.66 % in the 10–20 cm soil depth, respectively. Both halophytes also significantly enhanced saturated hydraulic conductivity in the 0–20 cm depth. A significant negative correlation was observed between saturated hydraulic conductivity and total soil salt content, this correlation likely facilitated salt leaching, which in turn reduced soil sodium absorption ratio (SAR). Compared to bare land, *T. chinensis* and *S. salsa* significantly reduced the soil SAR by 217.01, 122.44, and 83.35 mmol $L^{-1}$, and 114.90, 68.63, and 25.39 mmol $L^{-1}$, in the 0–10, 10–20 and 20–40 cm soil depths, respectively. They also significantly increased macroaggregates percentage (> 0.25 mm), with *T. chinensis* exerting the most pronounced effects. Most SOC storage was concentrated in the 0–10 and 10–20 cm soil depths, and *T. chinensis* induced the greatest increase-2.44 and 1.97 times higher than that of bare land in these two depths, respectively. Structural equation modeling (SEM) analysis revealed that halophytes primarily promote SOC storage in saline land by increasing the soil carbon-to-nitrogen (C/N) ratio and the proportion of macroaggregates. This study provides a theoretical basis for the improvement engineering of saline land using T. chinensis and S. salsa as pioneer plants.

**ABSTRACT**

The coastal plain of the Parnaíba Delta, located in northeastern Brazil, constitutes a complex macro-geosystem formed during the Quaternary. This landscape represents a dynamic mosaic of fluvial (Qfa), fluvio-marine (Qpm), and eolian (Qe) sediments. The region's geomorphology, characterized by low elevation, predominantly flat relief (<3% slope), and the strong influence of the tidal saline wedge, creates ideal conditions for the development of intense halomorphic processes. This study aimed to characterize the pedogenesis, major chemical properties, and classification of these salt-affected soils, based on a comprehensive analytical dataset from 40 soil profiles collected within the Parnaíba Delta Environmental Protection Area (APA Delta do Parnaíba), in the State of Piauí, Brazil. The analytical results revealed two dominant pedogenetic pathways leading to halomorphism. The first, sodification, primarily identified within fluvio-alluvial deposits (Qfa), leads to the formation of Solonetz. Profile PD03 exemplifies this pathway, presenting a diagnostic natric horizon characterized by an abrupt textural discontinuity (a loam A horizon with 213 g $kg^{-1}$ clay transitioning to a Btv1 horizon with 548 g $kg^{-1}$ clay), an Exchangeable Sodium Percentage (ESP) far exceeding the 15% threshold (15.57% in Btv1), and high Electrical Conductivity (EC) in the subsurface (15.57 dS $m^{-1}$). According to WRB (2022), PD03 is classified as a Gleyic, Salic Solonetz. The second pathway, salinization, results in the formation of Gleysols in widespread hydromorphic settings. Profile PD24, classified as a Salic, Sodic Gleysol, exhibits extreme primary salinity, with an EC of 209.1 dS $m^{-1}$ and an ESP of 49.4% in the 0–10 cm surface layer. This condition contrasts sharply with adjacent non-saline Arenosols developed on stable eolian deposits. The distribution of these halomorphic soils is controlled by landscape position—which permits the capillary rise of brackish groundwater—and by the sedimentary parent material. The flat topography is the main determining factor driving these processes. The accurate identification and classification of this complex soil mosaic—which also includes Cambisols (e.g., PD15, a Salic, Sodic, Fluvic Cambisol) and Vertisols (e.g., PD12, a Sodic Vertisol) and is marked by combined physical constraints (sodium-induced compaction) and chemical toxicity (salinity and sodicity)—are essential for environmental zoning, agricultural management, and the conservation of mangrove ecosystems within this Environmental Protection Area.

**ABSTRACT**

Saline–alkaline land represents a substantial reserve of potential arable soil, and its restoration could greatly enhance global crop production and food security. Although soil salinization is known to impair soil fertility and reduce crop yield in local experiments, large-scale patterns of belowground ecosystem multifunctionality (EMF) and crop productivity along salinity gradients remain poorly understood. Here, we collected saline soil samples and associated crop-yield data and assessed EMF using multiple approaches based on diverse indicators representing key belowground ecosystem functions.

We found that both soil salinization and land abandonment markedly decreased belowground EMF—by up to 61%—and machine-learning analyses identified the most influential predictors across different salinity levels. Crop yield in saline cropland could be reliably predicted using EMF, and predictive performance improved further when EMF was integrated with geographic variables. Moreover, substantial yield gains may be achievable by narrowing the yield gap between current yield and the saturated yield through improvements in EMF combined with targeted agricultural practices. These findings underscore the importance of comprehensive assessment of belowground EMF for ecosystem sustainability and food security, and they offer new insights and practical guidance for the amelioration and utilization of saline–alkaline land.

# Formation Mechanism of Salt Patches and Quantitative Relationship Between Water and Salt in Coastal Salinized Farmland

**Wei Zhu[1,2*], Xin Zhang[1], Yu Xuan[1] and Rongjiang Yao[1]**

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China*

## ABSTRACT

Saline-alkali soil is a typical restrictive soil type distributed extensively across the globe. Its amelioration and utilization are of great significance for safeguarding food security and maintaining soil ecological health. In China, substantial research and amelioration efforts have been carried out targeting coastal saline-alkali soils. At present, a variety of improvement measures have generally achieved the comprehensive remediation and utilization of saline-alkali lands. Nevertheless, salt patches still scatter sporadically in the form of plaques across farmland plots. However, the formation mechanism of salt patches and their quantitative water-salt relationship remain unclear.

Therefore, based on a long-term in-situ experiment conducted in the coastal saline-alkali land of the Tiaozini Reclamation Area, Yancheng Economic and Technological Development Zone, Dongtai City, Jiangsu Province, combined with the Hydrus model, this study systematically analyzed the variations in water and salt fluxes at the boundary of salinized farmland. The results showed that the variation in water flux at the upper boundary could be roughly divided into three stages: a prolonged drought stage, an intense rainfall stage, and a moderate continuous rainfall stage. During the initial phase of prolonged drought, soil moisture decreased rapidly; subsequently, it remained stable at a relatively low level due to groundwater recharge, while surface soil salinity generally exhibited an accumulating trend. Intense rainfall events could reduce salinity content, whereas the impact of moderate rainfall was relatively weak.

Salt patch formation was most pronounced during the prolonged drought stage. Intense rainfall alleviated salt patch formation to a certain extent, but moderate rainfall failed to prevent it. Film mulching only controlled the fluctuation range of soil salinity. During the formation process of salt patches, the relative variation in soil moisture and that in soil salinity showed an overall negative correlation. Moreover, the longer the duration of prolonged drought, the more significant the correlation between soil moisture and salinity became. The variation trend of soil salinity in the 0–30 cm surface layer was consistent with the variation trend of actual boundary water flux, indicating that the characteristics of salt patch variation could be inferred from the actual boundary water flux.

Overall, salt patch formation is closely related to the variation in boundary water flux. Regulating boundary water flux can effectively mitigate the persistent salt patches in coastal salinized farmland.

**ABSTRACT**

Saline-sodic soils are concentrated in the western part of the Songnen Plain in Northeast China, covering an area of 3.73 million hectares. Although this soil has strong alkalinity, serious physical and chemical barriers, and is difficult to treat, due to the suitable climate and relatively abundant available water resources in this region, saline-sodic soil has become the most promising reserve arable land resource for development. After long-term production practice, planting rice has been proven to be the most feasible and successful way to develop and utilize saline-sodic land. In recent years, our group has been committed to addressing the scientific problem of poor rice growth and yield caused by salt alkali barriers and low soil fertility during the development of rice cultivation in saline-sodic land. Through long-term field experiments, we aim to reveal the mechanism of alkaline barriers on rice growth and yield improvement, analyze the interaction between salinity and soil nutrients, and clarify the coupling mechanism between salinity, nutrient and yield. Our goal is to answer the question of how to scientifically reduce salt barriers and increase fertilizer efficiency during rice cultivation in saline-sodic land, and provide theoretical basis and technical support for the establishment of scientific regulation methods in the development of rice cultivation in saline-sodic land.

**ABSTRACT**

The accurate quantification of soil volumetric water content (VWC) and electrical conductivity (EC) in saline vadose zones remains a critical challenge for precision agricultural water management. This study presents a comprehensive laboratory evaluation of the Campbell Scientific SoilVUE10, a profile sensor utilizing TrueWave™ Time Domain Reflectometry (TDR), compared against the Campbell Scientific CS655 (Time Domain Reflectometry) and the Beijing Truwel SM926 (Standing Wave Ratio, 50 MHz). Experiments were conducted in large-scale glass chambers (130 cm height, 50 cm × 50 cm cross-section) packed with homogeneous and stratified profiles containing expansive clay, subjected to wetting and drying cycles with salinity levels ranging from 0.01 to 19.05 dS/m. Results demonstrate that the measurement principle dictates performance stability under saline conditions. The SoilVUE10 exhibited superior resilience to bulk EC attenuation compared to frequency-domain alternatives, maintaining the lowest Root Mean Square Error (RMSE) in high-salinity treatments provided that soil-sensor contact was optimal. However, the study identified a critical vulnerability in the SoilVUE10's rigid, threaded design during drying cycles in expansive silty clays, where soil shrinkage generated air gaps that caused significant VWC underestimation. The CS655 displayed a predictable positive bias in conductive soils—correctable via soil-specific calibration—though its larger integration volume failed to resolve sharp wetting fronts in layered profiles. The SM926, operating at a fixed 50 MHz, demonstrated high sensitivity to dielectric relaxation in saline silty clays, contradicting manufacturer claims of salinity insensitivity. We conclude that while the SoilVUE10 offers the high-resolution vertical profiling necessary for stratified soils, its deployment in expansive saline soils requires modified installation protocols, such as slurry backfilling, to mitigate contact resistance errors.

## ABSTRACT

Saline–alkali soils, serving as the reserve resources of arable land for food security, require remediation to relieve salinization indicators and improve agricultural potential yield. Although previous studies have quantified potential yield gains on saline–alkali soils at the field scale, a systematic evaluation across regions, salinization levels, amendment measures, and crop types is still lacking, and the overall potential production and the spatial heterogeneity of yield improvement across these soils remain uncharacterized.

To address this gap, we conducted a meta-analysis of 243 peer-reviewed publications from 2000 to 2024 to quantify the effects of amendment measures on saline-alkali soil properties and crop yield in China. Then, we present a framework that integrates the Global Agro–Ecological Zones (GAEZ) model with remediation-adjusted soil salinization indicators derived from the above field-scale meta–analysis. We applied this framework to simulate wheat potential yield improvement of saline–alkali soils in a typical region with saline–alkali soils — the Huang–Huai–Hai Region (HHHR), China from 2011 to 2020, considering both perspectives of remediation measures (chemical, biological, and integrated measures) and administrative units (Shandong, Hebei+Beijing, Tianjin, Henan+Anhui, and Jiangsu).

The results demonstrated that amendments significantly improved soil properties, reducing electrical conductivity (EC) by 8.44% and salt content by 17.34%, while increasing soil organic carbon (SOC), total nitrogen (TN), available nitrogen (AN), and available phosphorus (AP) by 28.15%, 39.24%, 33.29%, and 51.05%, respectively. These improvements contributed to an average crop yield increase of 41.66%, with the most substantial effects in northeast China (76.9%) and severely saline-alkali soils (80.39%). Amendment efficacy varied by type: biological measures, primarily through organic matter input and microbial activity, were most effective in enhancing SOC, TN, AN, and AP; hydraulic measures, such as leaching and drainage, best reduced salt content; and chemical amendments, through ion exchange mechanisms, most effectively lowered exchangeable sodium percentage (ESP) and sodium adsorption ratio (SAR). Crop responses also differed: cash crops exhibited greater salt stress alleviation, whereas grain crops like rice and barley achieved higher yields and nutrient uptake. Structural equation modeling (SEM) quantified that the yield increase was primarily mediated through enhanced soil nutrients and reduced salinity, which indirectly promoted crop growth.

Spatially explicit assessment of wheat yield improvement potential in saline–alkali soils demonstrated strong consistency in potential yield improvement compared to observed field data (R2=0.7, RMSE=630 kg/ha). The soil electrical conductivity, exchangeable sodium percentage, and pH of saline–alkali soils under remediation decreased by 10.31%, 22.92% and 1.2%, respectively, in the entire region. The maximum improvement of wheat potential production under remediation in saline–alkali soils of HHHR could reach 1.26 million tons (1.03-1.79 million tons), could meet the annual wheat demand for 15.85 to 27.54 million people. Among the approaches assessed for enhancing the potential yield of saline-alkali soils, integrated measures demonstrated the better effective results. From the perspective of administrative units, the potential yield of improved saline-alkali soils in Henan and Anhui increased to 1.22 times the pre-remediation. These findings provide a mechanistic basis for designing targeted and integrated strategies for saline-alkali soil amendment in China. Our new framework for spatially explicit assessment of wheat potential yield improvement in saline–alkali soils provides a scientific basis for the sustainable development and utilization of saline–alkali soils.

**ABSTRACT**

This study investigates saline surface soils, particularly sabkha soils—defined as coastal or continental mudflats characterized by high salinity, groundwater discharge, and evaporative mineralization—as a non-conventional source for lithium, a critical strategic metal for energy storage technologies. While salinity degrades land, it also drives the mobilization and surface accumulation of highly soluble elements. We hypothesize that elements like lithium (Li), sodium (Na), and strontium (Sr) are transported from depth via capillary action and evaporation, forming detectable geochemical anomalies in surface layers.

To test this, a refined aqueous extraction protocol was developed to enhance the recovery of these mobile elements from challenging arid substrates. The method was applied to 36 samples from the Arabian Peninsula and analyzed via ICP-OES, with all data normalized to a dry-weight basis.

Our results identified significant lithium anomalies, with concentrations in some samples reaching 258% of the background mean. Strong positive correlations between Li-K (r=0.83) and Li-Mg (r=0.84) suggest their co-migration via saline groundwater. Crucially, lithium concentrations in sabkha soils were found to be up to twenty times higher than in typical aridisols, underscoring the critical role of this specific saline environment in element enrichment.

The findings confirm that the surface geochemistry of salt-affected soils can serve as an effective exploration indicator. The presented extraction technique offers a rapid tool for early-stage lithium prospecting. Consequently, the desalination of sabkha soils could be re-envisioned not just for land reclamation, but also as a promising frontier for sourcing strategic metals, adding a new dimension to the global status and management of these problematic lands.

*ntkimphuong@ctu.edu.vn

**ABSTRACT**

Freshwater scarcity and increasing salinity in the Vietnamese Mekong Delta have caused substantial crop losses, highlighting the urgent need to diversify cropping systems toward appropriate upland crops and to develop agronomic practices that enhance crop performance under severe conditions. This study evaluated the effects of rice straw mulching and biochar application on soil nitrogen transformation, biochemical properties, and cowpea performance in salt-affected areas of the Vietnamese Mekong Delta. Field experiments were conducted from 2021 to 2023 at Long Phu and Lieu Tu districts, Soc Trang province, where salinity intrusion and freshwater shortages occur during the dry season, within a cowpea-rice–rice cropping sequence. A two-factor factorial design was applied, consisting of rice straw mulching at rates of 0, 3.5, and 7 t $ha^{-1}$ and biochar application at 0 and 5 t $ha^{-1}$, with three replicates per treatment. Soil and plant samples from the 2023 cowpea crop were collected, and post-harvest soils were used for laboratory nitrogen mineralization experiments. The results showed that straw mulching and biochar influenced plant growth, soil properties, and nitrogen mineralization processes. Ammonium ($NH_4^+$) release during incubation was higher with biochar application at the Lieu Tu site and increased with increasing rice straw mulching rates at the Long Phu site, whereas nitrate ($NO_3^-$) release was not significantly affected by biochar, indicating its role in soil $NH_4^+$ retention. Urease activity varied between sites and was affected by both straw mulching and biochar, with the combined application of 7 t $ha^{-1}$ rice straw mulch and 5 t $ha^{-1}$ biochar resulting in the highest urease activity. Soil microbial activity, assessed by soil respiration, increased with increasing rice straw mulching rates and was further enhanced by biochar application. Cowpea SPAD values increased with higher rice straw mulching rates and were also higher with biochar application. Improvements in soil chemical properties, including increased organic matter content, enhanced cation exchange capacity, increased potassium availability, and reduced sodium concentrations, contributed to a yield increase of up to 70% under straw mulching at 3.5 and 7 t $ha^{-1}$ compared with no mulching, whereas biochar application at 5 t $ha^{-1}$ did not show a clear yield effect over the three-year period. Overall, organic residue management improved soil quality and regulated nitrogen transformation pathways, providing a basis for developing sustainable nitrogen management strategies in salt-affected soils in the Vietnamese Mekong Delta.

**Keywords:** Biochar, cowpea, rice straw mulching

We acknowledge ACIAR for funding this work, SLAM/2018/144. Much appreciation goes to the farmers at the experimental sites, without their care-taking, monitoring soil moisture and watering, the crops would not be grown successfully.

# Spatial Synergies and Trade-offs between Soil Salinity and Organic Carbon in the Yellow River Delta

**Xinyu Liu[1]*,Xiaobing Chen[1],and Wenping Xie[2]**

[1] *Yantai Institute of Coastal Zone Research, Chinese Academy of Sciences (CAS), Yantai 264003, China*

**ABSTRACT**

The transition zone between terrestrial "Green Carbon" and coastal "Blue Carbon" in the Yellow River Delta is a hotspot of anthropogenic conflict. Intensive land reclamation often severs natural land-sea connectivity, replacing saline wetlands with desalinized agro-ecosystems. Does this artificial removal of salinity—a key abiotic stressor—unintentionally dismantle the biogeochemical "locks" preserving millennia-old carbon pools? The spatial divergence between crop-driven inputs and salt-mediated sequestration mechanisms remains poorly quantified, hindering precise planning.

To bridge this knowledge gap, we used Google Earth Engine and Random Forest regression to map Soil Salinity (EC) and Organic Carbon (SOC). Integrating spectral features with field surveys, we spatially quantified EC-SOC interactions. Results reveal a distinct divergence governed by hydrological connectivity: agro-ecosystems exhibit a significant trade-off, where artificial desalination lowers decomposer metabolic costs, likely triggering "rhizosphere priming" and accelerating mineralization. Conversely, natural wetlands show a synergy above specific thresholds. This challenges the "salinity is purely detrimental" paradigm, identifying salinity as a "bioenergetic preservation mechanism" that increases decomposition activation energy, effectively "pickling" organic matter.

Practically, this study provides a pedological basis for scientifically delineating "Red Lines" (cultivated) and "Blue Lines" (ecological). We propose a dual strategy: supporting precision desalination for the "Bohai Granary" initiative, while restoring the "salinity-carbon synergy" in wetlands via re-establishing hydrological connectivity. This harmonizes regional food security with carbon neutrality, ensuring the pursuit of fertility does not compromise stability.

## ABSTRACT

**Purpose**

Coastal salt-affected soils are a crucial resource for agriculture and ecosystems, but they are highly sensitive to seawater intrusion and land-use changes. This study investigates and compares soil quality across different land-use types and soil depths at varying distances from the coastline in the former Go Cong Dong area (Vietnam), to identify the land-use types and soil layers most strongly affected, thereby providing a basis for proposing sustainable soil restoration and management strategies.

**Methods**

Soil quality was assessed using the Soil Quality Index (SQI) for 180 soil samples collected from two soil layers (0-30 and 30-60 cm) across three land-use types (upland soil - US, paddy soil - PS, and natural soil - NS). The effects of land-use type, soil layer, and their interaction were analyzed using two-way ANOVA, while the relationship between SQI and distance from the coastline was described using a linear model. In addition, contributive percentage analysis was applied to determine differences in the dominant roles of soil properties in controlling SQI across distances from the coastline (group I - less than 4 km and group II - greater than 4 km) and between soil layers.

**Results**

The highest SQI was observed in US (0.57 in the 0-30 cm layer and 0.55 in the 30-60 cm layer), followed by NS (0.53 in both layers), while the lowest values occurred in PS (0.51-0.52), with statistically significant differences among land-use types. The SQI of US increased markedly with increasing distance from the coastline, particularly within group I, showing a significant linear relationship in the 0-30 cm layer, indicating an improvement in soil quality toward inland areas. For PS, SQI also increased with distance, but with a weaker explanatory power and significance only in the 30-60 cm layer, reflecting greater variability among sampling points. In contrast, no clear relationship between SQI and distance was observed for NS. Contributive percentage analysis further indicated that the dominant controls on SQI varied with distance and soil depth: within group I, US dominated SQI variation in the surface layer (31.01%), whereas PS dominated in the subsoil (19.71%). In group II, SQI variation was mainly governed by factors other than land-use type.

**Conclusions**

PS are mainly affected by salinity, US maintains higher exchangeable cations and surface P, whereas NS preserves higher OC in the subsoil. Near the coast, SQI is depth-dependently dominated by US in the surface layer and by PS in the subsoil; farther inland, SQI variation is less strongly controlled by land-use type. These findings highlight the need for multi-layer soil assessments and for prioritizing integrated management strategies in coastal areas, while future studies should expand hydrological monitoring and ion speciation analyses.

# Spatial Distribution, Underlying Mechanisms, and Management Strategies of Soil Salinity in North China Cultivated land: A Soil Profile Perspective

**Enyi Xie[1], Xiangbin Kong[2*]**

[1] *College ofLand Science and Technology, China Agricultural University, Beijing 100193, China*

[2] *School of Public Administration, South China Agricultural University, Guangzhou 510640, China*

*xieenyi2000@163.com

**ABSTRACT**

Soil salinization under global climate warming has become a critical challenge worldwide. Intensive agricultural activities contribute to the uncertainty of soil salinity distribution. This study focused on cultivated land in North China, where 519 whole-profile soil samples (0–120 cm, collected at 20 cm intervals) were systematically collected and analyzed. Based on these data, an integrated assessment framework was developed to accurately determine the spatial distribution patterns of whole-profile soil salinity. Furthermore, the effects of climate, topography, soil properties and cultivation practices on soil salinity were explored, with the response mechanism of whole-profile soil salinity in cultivated land to the coupled effects of climate warming and intensive agricultural activities being quantitatively revealed. The results indicated the following. (1) The spatial distribution of whole-profile soil salinity followed a northwest-low to southeast-high pattern. Based on vertical differentiation characteristics, four types of salinity distribution profiles were identified: surface aggregation profile (SAP), bottom aggregation profile (BAP), uniform distribution profile (UDP) and vibration distribution profile (VDP), with UDP (36.14%) and BAP (33.04%) predominating. (2) The ratio of evaporation to precipitation, elevation, slope, soil texture, soil pH and cultivation practices significantly affected whole-profile soil salinity, while cultivation practices primarily influenced salinity distribution in the 0–40 cm soil layer. (3) The structural equation model (SEM) results indicated that climate (Direct Path Coefficient, DPC = 0.19 to 0.36) and soil properties (DPC = 0.39 to 0.65) positively affected soil salinity, whereas topography (DPC = –0.54 to – 0.69) had a negative effect. The influence of cultivation factors on soil salinity shifted from a negative effect to a positive effect at a depth of 40 cm (DPC = –0.23 to 0.14). Overall, intensive agricultural activities did not lead to surface soil salinity accumulation. Instead, irrigation counteracted the salinity accumulation effect that was intensified by climate warming, effectively reducing surface soil salinity in the cultivated land profile. This study underscores the importance of a whole-profile perspective in managing soil salinity under the combined influence of climate warming and intensive agricultural activities. This study provides a scientific basis for developing and optimizing sustainable cultivation management strategies across scales from individual fields to regions.

**ABSTRACT**

To investigate the effects of different amendment measures on the reclamation of coastal saline-alkali soil and crop growth, a field experiment was conducted in the saline-alkali land of the Yellow River Delta. The experiment comprised six treatments: a control group (CK, no fertilization), conventional nitrogen, phosphorus, and potassium (NPK) fertilization (T1), slow-release fertilizer (T2), NPK fertilization with soil compaction (T3), NPK fertilization with ridge-furrow cultivation (T4, including the furrow bottom, T4-1, and the ridge top, T4-2), and NPK fertilization with biochar (T5). The effects of these different amendment measures on soil moisture, salinity, nutrient dynamics, and cotton growth were analyzed. The results indicated that fertilization significantly increased soil nutrient content, with the T2 treatment providing the most stable nitrogen supply throughout the cotton growth period. The T5 treatment significantly increased the soil organic carbon (SOC) content; by the boll-opening stage, the SOC content in the 0–10 cm soil layer had doubled compared to that of the control group. The T3 treatment inhibited salt leaching, leading to a maximum increase in surface soil salinity of 15.2% compared to the control. The ridge-furrow treatment (T4) induced salt redistribution, decreasing surface salinity in the furrow bottom (T4-1) while causing salt accumulation on the ridge top (T4-2) due to evaporation. Furthermore, compared to the CK treatment, all amendment measures significantly increased cotton plant height, the number of established plants, single boll weight, and seed cotton yield. Specifically, treatments T1 and T2 significantly increased the number of established plants, while treatments T2, T3, and T4 significantly increased single boll weight. Correlation analysis revealed that seed cotton yield was positively correlated with planting density and boll weight, and negatively correlated with soil salinity. A close relationship was found between cotton plant traits and soil physicochemical properties. In conclusion, each amendment measure exhibits unique advantages and limitations for the reclamation of saline-alkali soil. This study provides a valuable References for developing reclamation strategies for coastal saline-alkali land.

# Aquaculture impoundment reduces salt leaching efficiency of subsurface drainage systems in neighboring farms

## ABSTRACT

Subsurface drainage is widely used to mitigate soil salinization in coastal agricultural systems by regulating groundwater tables. However, adjacent surface water bodies may alter regional groundwater flow and thereby affect salt leaching efficiency. In this study, subsurface drainage systems were installed at a coastal farm comprising both rice (*Oryza sativa* L.) fields and adjacent bare soil patches. Field monitoring over one year showed that soil apparent electrical conductivity decreased by 49.5% following subsurface drainage installation. Groundwater dynamics were strongly influenced by a nearby freshwater aquaculture pond. When the pond was impounded, groundwater table control by subsurface drainage became ineffective, leading to reduced salt leaching efficiency. A two-dimensional HydroGeoSphere model was employed to simulate coupled groundwater flow and salinity transport under subsurface drainage conditions, incorporating the hydraulic influence of the aquaculture pond. Model simulations reproduced the observed groundwater responses and soil salinity trends, supporting field observations. Our results indicate a shift in the dominant drivers of soil salinity dynamics: groundwater table regulation dominated salt leaching before pond impoundment, whereas rainfall became the primary control after impoundment. These findings highlight the importance of accounting for nearby surface water bodies, such as land-based aquaculture ponds, when designing subsurface drainage strategies for coastal farmland salinity management.

**ABSTRACT**

The mechanisms by which soil salinity impacts on water vapor sorption behaviors are not completely clear. The study aimed to investigate the effects of natural salts on soil water vapor sorption and associated hysteresis under different water activity ($a_w$) levels, and to elucidate the role of salt crystals in the water vapor adsorption and desorption process. We measured the water vapor sorption isotherms (WSIs) and physicochemical properties of seven soils with salt content ($Q$) ranging from 0.5 to 22.7 g kg$^{-1}$ before and after salt removal. The WSIs of low-salinity soils ($Q$ < 9.0 g kg$^{-1}$) exhibited classical Type II isotherm, but the WSIs of high-salinity soils ($Q$ > 15.7 g kg$^{-1}$) displayed atypical linear adsorption ($a_w$ = ~0.7 to ~0.85) and desorption ($a_w$ = ~0.5 to ~0.75) trends, deviating from Type II behavior. The presence of salts had little effect on water content at low $a_w$ levels ($a_w$ < ~0.4), but significantly increased water content at high $a_w$ levels (adsorption: $a_w$ > ~0.6; desorption: $a_w$ > ~0.5). The presence of salts increased local hysteresis ($H$) across all $a_w$ levels, with untreated soils exhibiting 1.3 to 6.2 times higher average $H$ values than salt-removed counterparts. The maximum $H$ differences for soils with $Q$ < 15.7 g kg$^{-1}$ occurred at $a_w$ > 0.8, while for the soil with $Q$ = 22.7 g kg$^{-1}$, it occurred at $a_w$ = 0.7. Water vapor sorption in saline and non-saline soils at low $a_w$ levels was mainly through hydration interactions. The effects of salts on soil WSIs at high $a_w$ levels were mainly attributed to the deliquescence of salts (sulfates and chlorides), increased electrostatic forces, and the osmotic potential generated by salt dissolution. The presence of salts amplified $H$ primarily through cation hydration-dehydration asymmetry at low $a_w$ levels, pore-throat blockage via capillary condensation at high $a_w$ levels, and asymmetric deliquescence-crystallization thresholds in high-salinity soils.

# Integrating Hydrological Modeling and Explainable Machine Learning to Reveal the Key Drivers of Soil Salinization in the Huolin River Basin

**Peng Guo[1]*, Puyu Feng[1], and Baoguo Li[1]**

*[1] College of Land Science and Technology, China Agricultural University; Key Laboratory of Arable Land Conservation (North China), Ministry of Agriculture and Rural Affairs, Beijing, China*

*E-mail Address of Presenting Author:gp1997er@163.com

**ABSTRACT**

This study focuses on soda saline–alkali soils in the Huolin River Basin, where scarce precipitation, seasonal flow cessation, and imbalanced irrigation–drainage have led to persistent salt accumulation, while the basin-scale driving mechanisms remain poorly understood. We integrate the SWAT hydrological model with an XGBoost–SHAP framework to quantitatively identify the key controls on soil EC and ESP at the sub-watershed scale. A total of 95 sub-watersheds were delineated from a high-resolution DEM, and SWAT was calibrated to obtain sub-watershed-level runoff, baseflow, percolation, evapotranspiration, and soil water content. These hydrological variables, together with PLAND and other landscape metrics, were combined with a global EC/ESP mapping product to build regression models. The results show that hydrological and landscape factors can accurately reproduce the spatial patterns of EC and ESP (with $R^2$ for EC up to 0.94), indicating that, at the sub-watershed scale, soil salinization is no longer controlled solely by local soil and climate conditions but is dominantly driven by the joint effects of surface runoff, groundwater discharge, deep percolation, evapotranspiration, and land-use configuration. Seasonal flow interruption and irrigation–drainage imbalance markedly enhance salt accumulation in the root zone and shallow groundwater. SHAP-based composite indices of soil salinization (SSA), landscape configuration (LAN), and hydrological conditions (HYD) exhibit stable cointegration and mutual Granger causality, revealing strong bidirectional coupling and temporal lags between hydro-salinity processes and landscape evolution. These findings provide a methodological framework and quantitative basis for optimizing water diversion and drainage regimes and cropland configuration, thereby enabling basin-scale macro-control of soil salinization under different levels of water-resource security.

## ABSTRACT

At present, the situation regarding global farmland protection and food security remains severe. The existing farmland is mostly under high-intensity utilization, and the potential for increasing high-yield farmland is narrowing. Soil salinization is seriously threatening the productivity of global arable land, becoming a major environmental issue restricting the sustainable development of agriculture. Particularly in arid regions, severely saline-alkaline soils, due to high salt accumulation, deteriorated structure, and low nutrient availability, severely limit crop growth and sustainable land use. According to statistics, the area of land affected by salinity worldwide is approximately 950 million hectares, mainly distributed in arid and semi-arid climate zones. These regions have intense evaporation, scarce precipitation, high groundwater levels, and abundant soluble salts, making them prone to salt accumulation on the surface and the formation of secondary or primary saline-alkaline soils. In China's northwest region, a typical inland arid area, it has long been under the control of a continental climate, with evaporation several times that of precipitation. Coupled with historically unreasonable flood irrigation and the absence of drainage systems, a large amount of farmland and potential arable land has degraded into severely saline-alkaline land. Severely saline-alkaline soil is characterized by highly concentrated salts, deteriorated physical structure, imbalanced chemical properties, and reduced biological activity.

The stress caused by saline-alkaline environments on plants includes osmotic stress, ion toxicity, oxidative stress, and nutrient imbalance, significantly inhibiting seed germination, root development, photosynthesis, and dry matter accumulation, leading to reduced crop yields or even total crop failure. Traditional single improvement measures, such as simple leaching, single application of organic materials, or relying solely on drainage, are often difficult to achieve sustained and efficient salt removal and soil fertility improvement in arid regions. They have problems such as easy rebound of improvement effects, high costs, and uncontrollable ecological risks. Therefore, it is urgent to establish a systematic technical model that can simultaneously address crop stress resistance, soil modification, and salt drainage to achieve a balance between short-term benefits and long-term sustainability.

Based on the above background, this study proposed and implemented the "Top Promotion - Middle Modification - Bottom Drainage" comprehensive improvement technology model in a typical arid and severely saline-alkaline area in northwest China. It starts from the three-dimensional coordination of the crop layer, soil layer, and water-salt transport layer, aiming to break the vicious cycle of salt accumulation and soil degradation.

The overall goals of the research are:

1. To clarify the improvement mechanism of severely saline-alkaline land in arid areas under the three-layer coupling effect of "Top Promotion - Middle Modification - Bottom Drainage";
2. To verify the comprehensive effectiveness of this model in reducing soil salinity, improving physical and chemical properties, increasing crop yields, and enhancing ecological functions;
3. To provide a replicable and scalable technical model for regional agricultural ecological restoration and sustainable land use.

The theoretical framework is centered on the coupling theory of soil-plant-water systems, implementing improvement measures in a vertical layering manner: Top Promotion: In the crop layer, through agronomic and microbial measures, enhance the salt tolerance and growth potential of plants, buffering the impact of saline-alkaline stress on key life processes; Middle Modification: In the rhizosphere and plow layer, through the coordinated application of organic-inorganic-biological amendments, regulate soil physical and chemical properties, breaking the cycle of salt accumulation; Bottom Drainage: In the lower part of the soil profile, construct controllable salt transport channels, and use hydraulic conditions to guide soluble salts out of the plow layer, preventing salt from rising and flowing back. The three measures can be implemented simultaneously in time, form vertical linkage in space, and achieve a closed loop of "salt suppression - soil modification - growth promotion - salt drainage" in mechanism, thereby overcoming the limitations of single measures.

The study area is located in the southern part of Xinjiang Uygur Autonomous Region, China, in the alluvial plain between the northern part of the Tarim Basin, the southern foot of the Tianshan Mountains, and the northern edge of the Taklimakan Desert. It has a typical temperate continental arid climate, with an average annual precipitation of less than 100 millimeters and an evaporation of 2000-2500 millimeters, about 20-25 times that of precipitation. The average annual sunshine duration is 2556-2991 hours, with up to 8-9 hours in summer and about 6-7 hours in winter. The soil texture is sandy loam, with an initial salt content of 17.43 g $kg^{-1}$, pH = 8.66, organic matter of 3.71 g $kg^{-1}$, and bulk density of 1.48 g $cm^{-3}$. The experimental plots were designed in a randomized block layout, with four treatments: CK (conventional tillage as the control), T1 (upper promotion treatment), T2 (upper promotion + middle modification treatment), and T3 (upper promotion + middle modification + lower drainage (comprehensive mode)). Each treatment was replicated three times, and intervals were set between treatments to eliminate the influence of lateral water movement. The upper promotion measures included the use of mulched drip irrigation, the selection of the cotton variety "Tahe 2" and the planting of salt-tolerant crops; the application of salt-resistant and growth-promoting compound fertilizer (N-$P_2O_5$-$K_2O$ = 12-10-18) as base fertilizer; seed treatment with salt-tolerant bacteria before sowing; and drip irrigation with small amounts of water in multiple applications to keep the root zone moist without waterlogging. The middle modification measures included the incorporation of biochar (1 t/acre) and vinegar residue (1 t/acre) before plowing; the application of straw humic acid (5 kg/acre) and mineral humic acid (5 kg/acre), followed by rotary tillage to a depth of 30 cm; the inoculation of a compound microbial agent (2 kg/acre); and the spraying of a new phospholipid-based lipid preparation before sowing. The lower drainage measures involved the installation of corrugated PE plastic perforated pipes (diameter 110 mm, spacing 10 m, buried depth 120 cm), connected to a water collection well and a pump drainage system.

After one season of improvement, the physical and chemical properties of the soil changed. In the 0-20 cm soil layer of the T3 treatment, the salt content decreased from 17.43 g $kg^{-1}$ to 4.61 g $kg^{-1}$, a reduction of 73%, $EC_{1:5}$ decreased from 13.5 ms/cm to 3.15 ms/cm, and pH decreased from 8.9 to 8.3; the organic matter increased to 7.6 g $kg^{-1}$. The emergence rate of wheat in the T3 treatment increased to 80%, while that of CK was 30%. The plant height at maturity increased by 35% in the T3 treatment, and the seed cotton yield reached 378.68 kg/acre, an increase of 211.5% compared to CK. The characteristics of water and salt movement showed that the average daily drainage volume of the underground drainage system during the leaching period was 120 $m^3$ $ha^{-1}$, and the salt drainage volume was approximately 180 kg $ha^{-1}$·time, effectively preventing the capillary rise of salt. The microbial community response indicated that the Shannon index of the root zone bacteria in the T3 treatment was significantly higher than that of CK ($P < 0.05$), with the dominant phyla being Ascomycota and Basidiomycota. The abundance of salt-tolerant functional bacterial groups increased, suggesting that the amendments and microbial agents promoted the colonization and functional expression of beneficial microorganisms.

The upper promotion measures enhance the salt tolerance and stress resistance of crops through agronomic and microbial pathways. Salt-alkali stress mainly manifests as osmotic stress, $Na^+/Cl^-$ ion toxicity, and oxidative stress, which inhibit water absorption by roots, nutrient uptake, and photosynthesis. Selecting salt-tolerant varieties and combining them with salt-resistant and growth-promoting fertilizers can increase the osmotic adjustment substances and antioxidant enzyme activities in cells, alleviating ion imbalance. Inoculating salt-tolerant functional bacteria can secrete plant hormones, promote root development, and induce systemic resistance. Drip irrigation with small amounts of water in multiple applications maintains an appropriate water potential in the root zone, reducing surface salt accumulation and water waste. These measures work together to increase the salt tolerance threshold and resource utilization efficiency of crops, ensuring the accumulation of photosynthetic products and grain filling during the critical growth stages. The middle modification measures utilize the synergistic effects of organic, inorganic, and biological components to break the salt accumulation cycle. Biochar, with its porous structure and rich functional groups, can adsorb and fix $Na^+$, reduce salt activity, and improve soil porosity and infiltration performance. Vinegar residue, rich in organic acids and readily available carbon, promotes microbial activity and reduces pH, activating insoluble nutrients. Straw humic acid and mineral humic acid can fix $Na^+$ through ion exchange and complexation, improve aggregate stability and cation exchange capacity, and enhance fertilizer retention capacity. The compound microbial agent can secrete extracellular polysaccharides to promote aggregate formation, and the desalination bacteria can reduce the $Na^+$ activity in the rhizosphere. Nitrogen-fixing and phosphorus-solubilizing bacteria can enhance the availability of nitrogen and phosphorus. New lipids participate in cell membrane repair, reducing the increase in membrane permeability and ion leakage caused by salt, and stabilizing the intracellular ion homeostasis. The four types of soil amendments, namely organic, mineral, biological and lipid, work in synergy to improve the soil from physical structure, chemical properties and biological activity, breaking the positive feedback loop of salt accumulation - soil structure deterioration - biological decline. The lower layer is equipped with underground drainage pipes and leaching systems to establish a stable salt transport channel. The pipes are buried below the root zone and can collect and discharge the salt-laden water during irrigation and leaching periods, preventing capillary action from bringing salt from the lower layer back to the surface. Quantitative freshwater leaching combined with water level control can replace the high-salt water in the plow layer and lock in the salt drainage effect. This design avoids the direct discharge of high-concentration salt water into sensitive environments, achieving environmentally friendly salt management. The three-layer coupling is characterized by temporal synchronization, spatial coverage and complementary mechanisms: enhanced crop stress resistance reduces the pressure on soil improvement, the optimization of soil physical and biological properties provides a high-quality growth medium for crops, and the drainage system prevents salt backflow and locks in the results. This three-dimensional improvement based on the soil-plant-water system coupling theory significantly enhances the synergy of salt drainage, soil improvement and yield increase, verifying the scientificity and feasibility of the integrated model in the management of severely saline-alkali land in arid areas.

The "top promotion - middle improvement - bottom drainage" integrated improvement technology model has achieved significant goals of salt drainage, quality improvement, yield increase and ecological restoration under the severe saline-alkali conditions in arid areas. The core lies in promoting crop stress resistance and growth, systematically optimizing the physical and biological properties of the rhizosphere and plow layer, and ensuring the stable operation of the salt drainage channel. This model provides a replicable and scalable technical paradigm for the management of saline-alkali land in arid areas and offers empirical support for the theory of integrated management of the soil-plant-water system. In the future, our research will focus on: ① long-term effect assessment under different climate and management scenarios; ② precise optimization of amendment ratios and application methods; ③ resource utilization and environmental impact control of drainage water; ④ construction of a smart monitoring and decision support system based on remote sensing and the Internet of Things, to achieve digital and intelligent management of saline-alkali land improvement.

## ABSTRACT

We have presented a new scheme, “optimized irrigation”, in which irrigation depth is determined such that net income considering the price of water and weather forecasts during each interval is maximized using WASH_1D/2D which are numerical simulation models of water flow and solute transport in soils and crop growth. To evaluate whether the optimized irrigation is also able to restrict salinity stress and avoid salinization without any intentional leaching, we carried out an irrigation experiment.

A variety of Tomato was grown on a sandy loam soil in a greenhouse in Tropical Agriculture Research Front of Japan International Research Center for Agricultural Sciences using a drip irrigation system whose emitter distance was 20 cm and lateral spacing was 100 cm. On November 21, seedlings were transplanted below each emitter after exposing natural rain for six months. Two treatments were established: C: irrigated with saline water containing 2 g/L NaCl using an automated irrigation system using two soil moisture sensors, ARP WD5-WET-SDI, installed below 10 cm and leaching was carried out twice and O: irrigation depth was determined with the scheme and 2 g/L NaCl solution was used for the irrigation. Each treatment had three replicates. To evaluate if WASH_2D can predict water flow and solute movement under such condition, soil moisture and salinity sensors, ARP WD5-WET-SDI, were installed at the depths of 10 and 40 cm below emitter. The same amount of liquid fertilizer was applied to each treatment at a constant daily rate. As a result, total yield and applied water were almost the same, giving the non-significant difference in net income. If we consider depreciation expenses for the sensors, solenoid valves and controllers, net income for the proposed scheme was higher. Regarding the accuracy of simulation, fair agreement between observed and simulated water contents were obtained. These results may demonstrate the effectiveness of the proposed scheme even in saline conditions.

# Bio-Organo Silicon Granules: A Strategy for Salinity Tolerance in Tomato

**Selvi Duraisamy[1*], Manimaran Gajendiran[1], Thiyageshwari Subramanium[1] and Anandham Rangasamy [2]**

*[1,2 &3]Department of Soil Science & Agricultural Chemistry, Tamil Nadu Agricultural University, Coimbatore, India*

*Email:selvi.d@tnau.ac.in

**ABSTRACT**

Silicon (Si) amendments are well known to mitigate salinity stress in tomato (*Solanum lycopersicum*), but higher doses can result in soil fixation and associated environmental concerns. To address these challenges, we developed and evaluated a bio-organo silicon granule (BOSG) strategy that integrates silicate-solubilizing bacteria (SSB), a chemical source, and an organic carrier to alleviate salt stress. Adsorption–desorption assays in a characterized saline soil revealed a substantial Si fixation, once solution concentrations exceeded 100 ppm, with pronounced hysteresis, indicating low reversibility and minimal carryover from soluble sources. Preliminary pot screening (0-200 ppm) identified 75 ppm solution Si as an operationally efficient dose, with diminishing physiological benefits at higher levels, consistent with fixation constraints. Soil incubation over 80 days showed sustained Si delivery for approximately 60 days, followed by a gradual decline; a Weibull nonlinear model provided the best kinetic fit (median $R^2 = 0.95–0.98$; $\Delta AIC \geq 12$ vs. zero- or first-order models). In saline pot trials, BOSG 1@100 kg Si $ha^{-1}$ significantly outperformed NPK-only controls: soil-solution Si increased by 20–35%, leaf $Na^+$ content decreased by 10–18 %, and physiological indices improved (chlorophyll +8–15%, photosynthetic rate + 10–14 %, membrane stability +6–12 %), leading to biomass and marketable yield gains of 12–22 %. Overall, these findings demonstrate that saline soils strongly immobilize Si above -100 ppm, that -75 ppm solution Si maximizes efficiency in this soil–crop system, and that SSB-enabled BOSG 1 @100 kg Si $ha^{-1}$ offers a lower-input, sustained-release strategy to mitigate salinity stress in tomato, meriting field-scale evaluation.

# Saltwater intrusion impact on coastal agricultural soils of Los Lagos Region, Chile

**Osvaldo Salazar[1*], Alejandro Martiniello[1], Michelle Moscoso[1], Oscar Seguel[1], Marco Pfeiffer[1] and Yasna Tapia[1]**

[1] *Universidad de Chile (Departmento de Ingeniería y Suelos, Facultad de Ciencias Agronómicas, Santiago, Chile)*

*E-mail: osalazar@uchile.cl

**ABSTRACT**

A comprehensive soil survey program is urgently needed to evaluate the impact of saltwater intrusion on the salinity of coastal agricultural soils in Chile, particularly in communes projected to experience intensified issues due to climate change. This study aims to investigate changes in soil salinity along a gradient of saltwater intrusion in coastal agricultural soils. The study sites are located in three distinct hydric soils with varying soil properties: the Maullín estuary, characterized by beach ridges with sandy materials classified as Inceptisols; the Calbuco coastal area, a marine terrace comprised of a mix of materials including surface volcanic deposits, beach sands, marine fossils, and fluvioglacial materials, also classified as Inceptisols; and Chiloé Island, featuring volcanic and fluvioglacial materials classified as Andisols. These three sites have been identified as highly vulnerable to saltwater intrusion due to their low-lying topography and inadequate coastal protection. The area exhibits a temperate-oceanic climate (Cfb), with average annual precipitation ranging from 2000 to 2500 mm and annual temperatures between 13.6 and 6.3 °C. Soil samples were collected to a depth of approximately 150 cm using a bucket auger at each site along three intrusion transects (1, 2, and 3 masl), with cores segmented into five depth increments: 0-15, 15-30, 30-60, 60-100, and 100-150 cm for chemical analysis (n=5). The sampling process occurred in September 2024, during the winter season. Moreover, each experimental site was equipped with an environmental monitoring station, including sensors for measuring soil temperature, electrical conductivity (EC), and soil moisture; and a piezometer (up to 1.5 m depth) was employed at each transect to monitor water level fluctuations, as well as water EC and temperature between July 2024 and September 2025. All collected soil samples underwent standardized chemical characterization, assessing parameters such as pH, ECe, sulfate, boron, carbonate, bicarbonate, chloride, $Ca^{2+}$, $Mg^{2+}$, $K^{+}$, and $Na^{+}$. Analyses revealed that soil pH increased from moderately acidic values at the surface (pH: 5.5-6.1) to moderately alkaline values at greater depths (pH: 7.1-8.1). Similarly, ECe and salt concentrations were higher in subsurface soils (ECe: 0.41-1.92 dS/m) compared to surface soils (ECe: 0.27-0.36 dS/m). The sensor data indicated that EC levels rose as the water table fell, suggesting potential seawater intrusion or increasing salt concentrations. In groundwater, the highest EC values (2.6 dS/m) were recorded during low rainfall periods, particularly at the end of summer (March 2025). In conclusion, there is significant evidence of saline intrusion phenomena leading to the alkalinization and salinization of deeper horizons in coastal soils.

# Mechanisms of Ammonia Volatilization Mitigation in Saline-Alkali Soils Amended with Biochar-Compost: Linking Reduced pH and Enhanced Aggregate Stability to Microbial Shifts

**XIE WENPING[1*], LIU JUNYAO[1], JI YAHUI[2],YAO RONGJIANG[1], YANG JINGSONG[1], WANG XIANGPING[1], FENG YANFANG[2]**

## ABSTRACT

Ammonia ($NH_3$) volatilization is a major nitrogen (N) loss pathway, accounting for over 30% of the applied N in salt-affected soils. $NH_3$ emissions pose a dual environmental threat by contributing to the formation of $PM_{2.5}$ and promoting eutrophication. Nevertheless, there is a lack of research on effective control of $NH_3$ volatilization in saline-alkali soils, as well as the mechanisms by which amendments synergistically inhibit $NH_3$ volatilization through the regulation of soil physicochemical properties and microbial communities. A soil column experiment was conducted with a saline-alkali soil from the Ningxia Hetao Irrigation District to assess the impact of biochar-compost on $NH_3$ volatilization, soil properties, and microbial community. Compared to conventional fertilization (CKU), the 1% biochar-compost treatment (BCOFL) resulted in a 30.82% reduction in cumulative $NH_3$ volatilization and a 35.24% decrease in $NH_3$ flux per unit biomass. High-throughput sequencing revealed significant shifts in microbial communities under compost-based amendments: BCOFL exhibited a higher relative abundance of Firmicutes compared to the 1% compost-only treatment (OFL), with Firmicutes showing positive correlations with soil mean weight diameter (MWD) and total N ($P < 0.05$). FAPROTAX annotation indicated that N-fixing functional groups in BCOFL were 57.28% and 85.52% more abundant than those in OFL and CKU, respectively. Structural equation modeling identified reduced soil pH and increased MWD as key drivers of $NH_3$ volatilization suppression. These findings suggest that biochar-compost effectively mitigates $NH_3$ emissions by lowering soil pH, enhancing aggregate stability, and promoting N-fixing microbes, thereby demonstrating potential for improving N use efficiency and reducing N loss-related environmental risks in saline-alkali soils.

**ABSTRACT**

In arid and semi-arid regions with shallow groundwater, soil salinization, water scarcity, and deterioration water quality are major constraints to regional agricultural development. Determining optimal groundwater depth (GWD) is essential for conserving water resources, controlling resalinization, and sustaining crop yields. However, it is not feasible to evaluate the results under various scenarios solely through field experiments. This study addresses this gap by integrating field experiments (2023-2024) with the agro-hydrological & chemical and systems simulator (AHC) to optimize GWD for sunflower cultivation under varying hydrological years and groundwater salinity in the Hetao Irrigation District (HID), China. The calibrated model simulated root zone water-salt dynamics and crop responses across scenarios, with multi-objective optimization (NSGA-II) deriving Pareto-optimal solutions for yield and salinity control. The results indicated that root zone bottom flux decreases with rising GWD, with upward water flux approaching zero at about 3 m depth and upward salt flux approaching zero at 1.5-1.9 m depth, respectively. The final yield of sunflowers was negatively correlated with groundwater mineralization, though this dependence weakens at deeper GWD (>1.8 m). The optimal GWDs for sunflower growth under dry, normal, and wet hydrological years with pre-sowing spring irrigation and rainfed conditions during the growth period were approximately 1.18-1.28 m, 1.23-1.32 m, and 1.37-1.45 m, respectively. These results demonstrate GWD's pivotal role in regulating farmland water-salt distribution, with derived thresholds enabling sunflower production while reducing root-zone salt accumulation.

## ABSTRACT

Quantifying soil health is crucial for evaluating and guiding soil management strategies. Soil salinization has become one of the main threats to soil health. However, the effects of biochar application on the improvement of saline soils and greenhouse gas emissions remain controversial. This study focused on spring maize fields in the Hetao Irrigation District and conducted a two-year field experiment from 2021 to 2022. Biochar derived from maize stalks at a pyrolysis temperature of 400℃ was a evenly spread over the soil surface, manually incorporated, and then rotary tilled to ensure thorough mixing within the 0–30 cm soil layer. Five field treatments were set up: CK (no fertilizer), BC0 (0 t $ha^{-1}$ biochar), BC7.5 (7.5 t $ha^{-1}$ biochar), BC15 (15.0 t $ha^{-1}$ biochar), and BC22.5 (22.5 t $ha^{-1}$ biochar). The results showed that appropriate biochar (15.0 t $ha^{-1}$) addition increased soil profile nitrate nitrogen content, 0–40 cm soil organic carbon and total nitrogen, 0–120 cm soil water storage (SWS) and electrical conductivity, as well as maize plant height, leaf area index, dry matter accumulation, grains per row, 100-grain weight, yield, and water use efficiency (WUE). However, excessive biochar application (22.5 t $ha^{-1}$) reduced the effectiveness of soil water storage, led to salt accumulation, decreased soil profile nitrate nitrogen content, and increased maize water consumption. Additionally, biochar application reduced $N_2O$ emission peaks, $N_2O$ emission factors, and cumulative emissions, while promoting soil $CH_4$ absorption. Biochar reduced cumulative soil $CO_2$ emissions, but excessive application (22.5 t $ha^{-1}$) increased $CO_2$ cumulative emissions. Sole nitrogen fertilizer application significantly increased global warming potential (GWP) and greenhouse gas emission intensity (GHGI), but the combination of nitrogen fertilizer and biochar significantly reduced GWP and GHGI. These findings provide a theoretical basis for improving the health of saline soils and mitigating climate change.

# The Construction of a Soil Profile Image Segmentation Dataset（SPISD） Based on Typical Soil Series Profile Photos from 13 Provinces in China

## ABSTRACT

A major bottleneck restricting the widespread application of artificial intelligence in soil science is the lack of high-quality soil image datasets comparable to ImageNet in the field of computer vision. Soil profiles serve as the foundation for soil classification. By analyzing the characteristics of soil profiles, we can understand soil formation processes and predict some soil properties. Currently, the Third National Soil Census is being conducted in China, involving the excavation of tens of thousands of soil profiles and photographing them with digital cameras. However, the construction of high-quality soil profile image datasets has not yet garnered sufficient attention from soil scientists. To address this, this paper proposes a method for constructing a soil profile image segmentation dataset based on soil profile photographs using an interactive segmentation annotation tool. The aim is to initiate further efforts and encourage more soil science researchers to build soil profile image datasets, thereby providing foundational data support for applying artificial intelligence to advance the field of soil science.

We collected the provincial volumes of the *China Soil Series Records*, totaling 12 books [1-12]. From these books, we identified typical soil series profile photographs from 13 provinces (municipalities directly under the central government), including Anhui, Beijing, Fujian, Guangdong, Hainan, Hebei, Henan, Hubei, Jiangsu, Jilin, Shanghai, Tianjin, and Zhejiang. Using the scanner integrated in the MFC-7450 Brother printer, we scanned the typical soil series color photographs from the aforementioned books. The scanning parameters were set as follows: horizontal and vertical resolutions both at 96 dpi, bit depth of 32, and file type as JPG. During scanning, we ensured that the photographs in the book pages were placed straight and flat against the scanner panel to guarantee image clarity. After scanning, the scanned image files were cleaned and organized. The JPG files were loaded into the Windows Paint software to crop out the soil profile photograph sections, including the soil profile color photographs (primarily featuring three types of objects: the surface area of the profile point, the profile scale, and the main soil profile body, i.e., the soil mass) and the text indicating the soil series name below them (Figure 1).

Figure 1. Typical soil series profile photo[12] (a),EISeg software labeled soil section (b), and segmented and labeled soil profile image (c)

We used the high-performance interactive segmentation automatic annotation tool, EISeg (https://github.com/PaddlePaddle/PaddleSeg/tree/release/2.2/contrib/EISeg), developed by the Baidu PaddleSeg team, to perform interactive segmentation annotation on the pure soil body parts within the soil profile images. The segmentation annotation mode was set, and a high-precision image annotation model suitable for general scenarios was selected. The network (model) structure and loaded parameters were static_hrnet18_ocr64_cocolvis.pdiparams. Based on the soil series profile scale, we segmented and annotated the soil body part within the 0–1 meter depth of the soil profile. For soil series profiles with depths less than 1 meter, we segmented and annotated the soil body part corresponding to the actual depth. The annotation results consisted of PNG files of the pure soil body parts of the soil profiles and their corresponding label files (CSV files). The first column of the label file is the soil profile serial number, such as 33-001 in Figure 1; the second and third columns are the latitude and longitude values of the profile point (in degrees); the fourth column is the name of the province where the profile point is located; the fifth column is the number of soil horizons, and the sixth to eleventh columns are the names of the soil taxonomy: order, suborder, great group, subgroup, family, and series.

We named this soil profile dataset the Soil Profile Image Segmentation Dataset (SPISD). It comprises 1,654 typical soil series photographs from 13 provinces in China, along with segmented annotation result images and label files. It encompasses 12 soil orders, 31 suborders, 89 soil great groups, 209 subgroups, 945 soil families, and 1,638 soil series.

The potential applications of SPISD mainly include: (1) utilizing artificial intelligence deep learning techniques for soil classification research; (2) qualitative and quantitative analysis of soil color, such as color space conversion and redness rate; and (3) assisting in the prediction of soil properties.

We will share the Soil Profile Image Segmentation Dataset (SPISD) on Science Data Bank (https://www.scidb.cn) or GitHub for scientific community access.

**ABSTRACT**

Salt-affected soils are widespread in arid and semiarid regions worldwide. It is estimated that about 955 × $10^6$ ha of land is affected by salinity and sodicity globally. Approximately 60% of the world salt affected soils are classified as sodic or saline/sodic soils. These soils suffer from severe structural degradation caused by certain physical processes (slaking, swelling and clay dispersion) and specific conditions (surface crusting and hardsetting). Consequently, water and air movement, plant-available water holding capacity, root penetration and tillage operations are adversely affected. In addition, osmotic stress, ion-specific toxicity and nutrient imbalances further constrain plant growth. In such cases, these combined physical and chemical stresses negatively affect plant root activity, soil microbial communities, and ultimately crop growth and yield.

It is estimated that about 20% of future increases in crop production will still result from land extensification. In such context, the development and effective utilization of the sodic and saline/sodic lands resource is essential for agricultural expansion to meet the food demands for the global population, which is expected to reach 9.1 billion by 2050. In such case, sodic and saline-sodic lands are not just a burden, but they are the last agricultural frontier. Resultantly, it is imperative to find ways to improve such land productivity of salt-affected soils.

From a land use perspective, the main current conversion pathways for sodic and saline/sodic soils include rice paddy fields, drylands, and grasslands, depending on water resources, technologies inputs, and economic conditions. As a moderately salinity-sensitive and sodicity-tolerant crop, rice is often recommended for desalinization and de-alkalization in salt-affected soils. Rice cultivation increases percolation rates, reduces soil exchangeable sodium percentage, and lowers soil pH through root activity. In practice, rice paddy fields are considered the most successful reclamation approach when reliable irrigation and drainage system can be guaranteed.

Correspondingly, recent advances in the amelioration processes of sodic and saline/sodic paddy fields, covering engineering, chemical, physical, biological, agronomic and integrated measures are reviewed. In particular, the contrasting effects on crop productivity following the reclamation of saline-sodic land using the "Da'an Model" as a 3G-integrated farming system including good soil, good variety and good agricultural management-implemented in the Songnen plain of northeast China are discussed. Furthermore, key priorities for rice paddy field amelioration technologies under emerging conditions are also proposed based on existing technical limitations and practical needs. These include the development and application of green long-term saline-alkali soil conditioners; high-efficiency desalination and alkali reduction technologies; saline-alkaline-tolerant, high-yielding, and high-quality rice varieties; specialized fertilizers for rice; water-saving irrigation practices; the cultivation and application of salt-tolerant and growth-promoting microorganisms; and green high-yield cultivation technologies. Collectively, this will provide theoretical and practical guidance for alleviating soil constraints, enhancing baseline soil fertility, and synergistically improving rice yield and grain quality.

## ABSTRACT

Rice cultivation is widely applied to reclaim saline-alkali soils, yet its long-term impacts on phosphorus (P) speciation, microbial functional organization, and ecosystem-level P balance remain insufficiently resolved. Here, we integrated two long-term field chronosequence datasets (0-51 years and 0-30 years of rice cultivation) to quantify how rice-based reclamation restructures soil P pools and microbial P cycling along a salinity-alkalinity relaxation gradient.

Rice cultivation significantly decreased soil salinity and pH while increasing soil organic matter, reactive Fe/Al oxides, total P, and Olsen-P. In early reclamation stages (0-10 years), inorganic P was dominated by Ca-bound fractions, representing 57-71% of total $P_i$. With prolonged cultivation (≥20 years), the proportion of moderately labile Fe-P and Al-P increased to 40-57% of $P_i$, coinciding with higher contents of poorly crystalline and organically complexed Fe oxides. These mineralogical shifts enhanced labile and moderately labile P pools, increased microbial biomass P and phospholipid fatty acid abundance, and promoted plant P uptake, while simultaneously reducing soil P mass balance relative to short-term cultivation.

Microbial functional responses tracked these soil chemical changes. The reduction of the abundance of salt tolerance genes encoding $Na^+/H^+$ antiporters (*mnhB, mrpB, mnhC, mrpC, mnhD, mrpD, mnhG, mrpG, mnhA, mrpA, mnhE, mrpE, mnhF, mrpF, yrbG*), following the decrease of soil salinity, and their network connectivity with P cycling genes weakened. In contrast, genes associated with inorganic P solubilization (*gcd*) and organic P mineralization (*phoD*) decreased in relative abundance under long-term cultivation, whereas genes encoding low-affinity phosphate transporters (*pit*) increased, indicating a functional shift from P acquisition under limitation toward P assimilation under increased availability. Phosphorus cycling gene network complexity increased at intermediate reclamation stages (about 10 years) but declined after 20-30 years, reflecting a transition from stress-induced functional diversification to a more streamlined and efficient microbial P utilization system.

Collectively, these results demonstrate that rice-based reclamation induces a coordinated cascade of soil chemical relaxation, mineral P redistribution, microbial functional reorganization, and ecosystem-level P rebalancing. This process enhances phosphorus availability and biological uptake while reducing P surplus accumulation, thereby improving P use efficiency and sustainability in reclaimed saline-alkali agroecosystems.

## ABSTRACT

To investigate the ameliorative effects of humic acid (HA), zeolite (Z), and phosphate rock (P) on coastal saline soil, a field experiment was conducted in a rice paddy at the Cixi Modern Agricultural Industrial Park, Ningbo, Zhejiang Province, during the 2022 growing season. Five treatments were established: control (CK), HA alone, Z alone, P alone, and a full combination (F) of all three amendments. Soil physicochemical properties, aggregate size distribution and rice yield were systematically analyzed. A soil quality index (SQI) was calculated, and principal component analysis (PCA) was used to identify key driving factors. The results showed that each amendments had certain ameliorative effects: Compared to CK, HA significantly increased soil organic matter, available nitrogen, and available potassium, resulting in a 33.2% yield increase; Z was most effective in reducing total salt content and electrical conductivity (EC); and P enhanced available phosphorus content. The combined treatment (F) integrated the advantages of the individual amendments. Compared to CK, the F treatment significantly reduced total salt content by 11.8% and EC by 6.5%, while significantly increasing available nitrogen by 27.6%, available phosphorus by 32.3%, available potassium by 19.2%, soil organic matter by 8.0%, and the the weight percentage of >0.25 mm macro-aggregates by 3.12 percentage points. PCA indicated that the combined treatment simultaneously optimized principal component 1 (PC1, loaded primarily with nutrient and structure properties, loading >0.73) and principal component 2 (PC2, loaded primarily with salinity characteristics, loading >0.92). Consequently, the SQI value of the F treatment reached 0.67, a 158% increase over the CK value (0.26). In summary, the combined application of humic acid, zeolite, and phosphate rock achieved the simultaneous goals of salinity reduction, fertility enhancement, and soil structure improvement, which are difficult to accomplish with single amendments. This synergistic effect is key to significantly improving coastal saline soil quality and rice productivity, providing an effective technical model for the amelioration of such soils.

**ABSTRACT**

Against freshwater scarcity, halophytes have demonstrated efficiency in rehabilitating saline-alkali soils and saline water resources. Studies on the growth, salt absorption characteristics, and the synergistic effects of irrigation leaching and salt absorption of *Suaeda salsa* under various saline drip irrigation strategies in crop fields remain limited. Therefore, this study selected *Suaeda salsa*, an annual Euhalophyte, as the research subject. Based on the groundwater salinity levels in Xinjiang, seven treatments were established considering both salinity (S, g/L) and quota (W, m³/ha) of irrigation water: $S_1W_1$, $S_1W_2$, $S_2W_1$, $S_2W_2$, $S_3W_1$, $S_3W_2$, ($S_1$: 0.40g/L (0.47 dS/m), $S_2$: 20g/L (33.60 dS/m), $S_3$: 40g/L (60.00 dS/m), $W_1$: 3415 m³/ha, $W_2$: 4854 m³/ha), and Control Group (CK, S: 0g/L (0 dS/m), W: full irrigation). Two years of field observations showed that the biomass, ash, $Na^+$ and $Cl^-$ in *Suaeda salsa* achieved the maximum values under the $S_2W_2$ treatment, the growth peaks all occurred at maturity stages; High salinity treatments ($S_3W_1$, $S_3W_2$, $S_2W_1$, $S_2W_2$) elevated soil salinity to levels that inhibited the growth or reduced the yield of glycophytes, the salt uptake from soil by *Suaeda salsa* accounted for 1.88~9.28% of the total salt brought in by irriagtion water after one growing season, indicating a negligible desalination effect; The salt removal from soil by *Suaeda salsa* under groundwater irrigation treatments ($S_1W_1$, $S_1W_2$) was up to 147~156% the salt content introduced by the irrigation water, and glycophytes would not experience significant yield reduction under this soil salinity levels. Under an irrigation quota of 3500–4854 m³/ha with water salinity of 0.81 dS/m, the model demonstrates that *Suaeda salsa* is capable of removing salts derived from both the previous and current years irrigation through rotation. The exponential model was found to better simulate and predict the normalized root length density (NRLD) distribution of *Suaeda salsa*. On one hand, the research findings provide a method for preventing and controlling secondary salinization of farmland-"Crop-halophyte rotation" can achieve the elimination of winter and spring irrigation while maintaining farmland water-salt balance, thereby conserving ecological water required for sustaining this equilibrium, On the other hand, due to their wide range of applications and high productivity in saline soils, the future development and utilization of severely saline-alkali lands should focus more on exploiting the direct economic benefits of halophytes rather than solely emphasizing their soil improvement function. Additionally, the continuous salt absorption by halophytes, and root model establish a data basis for developing root water-salt absorption and soil water-salt transport models.

**ABSTRACT**

Soil salinization and alkalization remain one of the major constraints on agricultural productivity and land sustainability worldwide. Existing reclamation practices are largely guided by empirical experience and manual interpretation of soil indicators, limiting their capacity to systematically integrate key soil-plant physicochemical and process-based parameters, including soil electrical conductivity (EC), exchangeable sodium percentage (ESP), sodicity, soil structure and aggregation, crop yield and nutrient availability into coherent decision-making frameworks. Moreover, fragmented soil knowledge and limited structured datasets have constrained the effective application of artificial intelligence in saline–alkali land reclamation.

To address these limitations, we developed *Wenyao*, a domain-specific large language model for saline–alkali land reclamation and soil amelioration. An automated pipeline was established to extract and structure saline–alkali land knowledge from the literature, explicitly linking "soil constraints–reclamation measures–amelioration effects–underlying mechanisms" to support structured cognition and causal inference. The training dataset for this model integrates more than 1,0000 peer-reviewed studies from Web of Science and CNKI together with multi-source public datasets, capturing regional heterogeneity in salinization mechanisms, soil texture, groundwater conditions, and baseline reclamation status. At the same time, we built a structured literature-derived database was constructed, comprising over 60 key parameters, including pre- and post-reclamation soil physicochemical properties (e.g., EC, pH, ESP, bulk density, aggregation, and nutrient availability) and associated plant physiological and yield responses. Finally, based on the collected data, we used low-rank adaptation (LoRA), the model was fine-tuned to enhance reasoning over soil water–salt dynamics, sodicity-driven structural degradation, reclamation measures, and yield–cost trade-offs. By optimizing the inference architecture, Wenyao enables integrated outputs that jointly consider reclamation effectiveness and economic feasibility, including soil constraint diagnosis, strategy recommendation, and outcome prediction.

Evaluations across multiple professional benchmarks show that Wenyao outperforms advanced general-purpose models, including Qwen3-Max and DeepSeek, in saline–alkali land question answering and decision-support tasks. Expert assessments based on over 200 questionnaires from more than 30 practitioners further confirm its strengths in constraint recognition, strategy optimization, and yield response prediction. Wenyao V1.0 provides a soil-process informed AI framework to support intelligent and precision-oriented reclamation of saline–alkali land.

**ABSTRACT**

Soil salinization, a growing global challenge, is a dynamic and multifaceted process shaped by the intricate interplay of natural environmental drivers and anthropogenic activities. Accurately predicting future trajectories of soil salinization poses a significant scientific challenge, as the underlying mechanisms driving its spatiotemporal evolution are not yet fully understood. This knowledge gap primarily arises from the complex nonlinear feedback mechanisms inherent in coupled human-environment systems. To address this challenge, we developed a multi-scale analytical framework integrating machine learning algorithms with causal inference approach to disentangle the complex interactions within these coupled systems. This comprehensive methodology was applied to a multi-source dataset encompassing climatic, topographic, edaphic, land-use, and remote sensing variables across varying spatial and temporal scales. From 1980 to 2100, our analysis reveals a pronounced global upward trend in soil salinization, with particularly accelerated rates observed across Asian and European regions. Notably, Russia and China have emerged as hotspots exhibiting the most substantial increases in salinization intensity. Our findings demonstrate that precipitation patterns and agricultural land-use changes constitute the dominant drivers shaping the future trajectory of global soil salinization dynamics. Current anthropogenic efforts to mitigate climate change appear insufficient to effectively counteract the accelerating global soil salinization process, suggesting a potential decoupling between climate change mitigation strategies and soil salinity control measures.

# Research on Salt-Alkali Tolerance Mechanisms of Characteristic Plants and Saline-Alkali Land Agriculture in Hetao-Ningxia Irrigation District

**XU Xing**

College of Forestry and Grassland Science, Ningxia University

**ABSTRACT**

As a strategic reserve resource for China in alleviating cultivated land shortage and bridging the food gap, saline-alkali land demonstrates immense potential for improvement and utilization. The saline-alkali areas in Hetao-Ningxia irrigation district are rich in halophytic plant resources, where Inner Mongolia and Ningxia account for 38.02% and 23.42% of China's total halophytic plant species, respectively. Therefore, studying the salt-alkali tolerance mechanisms of characteristic plants in Hetao-Ningxia irrigation district and saline-alkali land agriculture is crucial for exploiting the potential of saline-alkali land development and utilization, ensuring food security, and safeguarding regional ecological security. This study selected characteristic halophytic (salt-tolerant) plants in Ningxia, including *Lycium barbarum* L., sorghum, alfalfa, *Echinochloa crusgalli* var. frumentacea, *Glycyrrhiza uralensis* and *Suaeda salsa*, and adopted multidisciplinary approaches involving stress physiology, plant nutrition, molecular biology, ecology and geographic information science to carry out research encompassing the salt-alkali tolerance characteristics and biological improvement effects of different plants, the excavation and spatiotemporal expression of alkali-tolerant genes, the screening of salt-alkali-tolerant plant varieties and development of water-saving and salt-controlling cultivation techniques, as well as the spatial pattern configuration of salt-tolerant plants and construction of characteristic industrial models for saline-alkali land. The study elucidated the salt tolerance mechanisms, salt tolerance thresholds and biological improvement effects of different salt-tolerant plants, clarified the relationship between soil salt-alkali stress and crop quality, established a comprehensive evaluation method and a multi-dimensional precise identification technology system for plant salt tolerance, and proposed methods and schemes for the spatial pattern configuration of salt-tolerant crops in different types of saline-alkali land. It also analyzed the physiological and molecular mechanisms underlying drought and salt-alkali tolerance of different crops such as *Lycium barbarum* L., sorghum, alfalfa and *Glycyrrhiza uralensis*, identified 16 key drought and salt-tolerant genes with important application value including AT1, IPT and LcWRKY5, and elucidated their spatiotemporal expression mechanisms. In addition, the study screened a batch of suitable salt-tolerant crop varieties, put forward water-saving and salt-controlling cultivation techniques for different crops, constructed characteristic industrial models for the comprehensive utilization of different types of saline-alkali land, and conducted extensive demonstration and promotion of these models in Northwest China. The research findings provide a theoretical basis and practical guidance for saline-alkali land improvement and the development of characteristic industries in saline-alkali areas of Hetao-Ningxia irrigation district.

**ABSTRACT**

The use of coastal saline-alkali soils for soybean cultivation is crucial for global food security, yet high salinity severely inhibits soybean growth and production. The microbiome, often regarded as the plant's "second genome," plays a crucial role in enhancing stress resistance and fitness of plants. This study investigates how plant growth-promoting bacteria (PGPB), as functional components of this extended genome, improve soybean adaptation to saline soil. Native salt-tolerant PGPB strains were isolated from halophytes in a severely saline-alkali area along the Jiangsu coast. Among 488 salt-tolerant isolates, 35 produced IAA; 16 synthesized siderophores; and 5 secreted exopolysaccharides (EPS), with some exhibiting medium-to-high productivity levels comparable to literature reports. Using a soil-based screening system, six strains were identified that significantly alleviated salt stress in soybean seedlings, improving emergence rate, plant height, leaf area, and biomass accumulation. To elucidate the underlying mechanisms, metabolomics was employed to analyze the responses of metabolome in soybean roots inoculated with two representative strains, *Stutzerimonas kunmingensis* 246 and *Microbacterium algeriense* 266-2. The analysis revealed that both strains enhanced osmoregulation and activated the valine-leucine-isoleucine biosynthesis pathway. Strain 246 uniquely elevated antioxidant metabolites (citrerosein and 5-valerolactone) and the membrane-stabilizing compound Oleanane-2H,+1O,1COOH,O-HexA-HexA, while enriching the alanine-aspartate-glutamate pathway. Strain 266-2 upregulated stress-related signaling molecules and ROS scavengers and modulated the pantothenate and CoA biosynthesis pathway, potentially supporting ion homeostasis, membrane integrity, and energy supply. Field trials confirmed that these strains promoted soybean growth, nodulation, and yield in saline soil. This study demonstrates that specifically tailored PGPB can significantly improve crop resistance under salt stress, thereby providing a viable microbial strategy for sustainable production in saline-alkali soils.

# Identification of the dominant constraint factors in sodic saline-alkali paddy soils

**First A. XueQing Meng**[1*]

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences*
mengqingxue24@mails.ucas.ac.cn

**ABSTRACT**

Globally, more than 800 million hectares of land are affected by salinity and sodicity. These soils are classified into acidic, neutral, and alkaline types, each exhibiting distinct chemical properties. As one of the three largest sodic saline-alkali soil distribution regions in the world, the Songnen Plain of Northeast China contains>3.73 million ha of land estimated to be affected by sodicity, which is characterized by high alkalinity (pH 8.5-10.5), high exchangeable sodium percentage, and poor permeability. Experience shows that rice culture combined with continuous flooding-drainage management is the most cost-effective way to leach salts, increase organic matter and inhibit surface alkalization. However, >90 % of newly reclaimed paddy fields in these regions are classified as moderate-strong sodic saline-alkali, rice yields in sodic saline-alkali soils have remained relatively low, typically ranging from 0.7 to 6.7 t $ha^{-1}$ during the initial years following amelioration. Sodic saline-alkali soils have coupled stresses of high $Na^{+}$, elevated $HCO_3^{-}$-$CO_3^{2-}$, low $Ca^{2+}/Mg^{2+}$ ratio, reductive toxicity, nutrient imbalance and osmotic stress, leading to poorly targeted amendments. Therefore, systematically identifying the dominant constraint factors in sodic saline-alkali paddy soils can provide a scientific basis for precisely selecting amendments, optimizing irrigation-drainage regimes, and formulating field management protocols-an endeavor essential for boosting the productivity of low-yield fields and safeguarding grain security in Northeast China and the northern japonica rice belt.

# Global Salt-affected Soils Crisis: FAO's Latest Report and Strategic Responses

**Peirou Zhen**[1*]

*1 State Key Laboratory of Black Soil Protection and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, China*

Zhenpeirou25@mails.ucas.ac.cn

**ABSTRACT**

Soil salinization constitutes a critical threat to global agricultural productivity, ecological stability, and long-term food security in the 21st century. The 2024 landmark report by the United Nations Food and Agriculture Organization, "The State of the Global Saline Soils," provides the first comprehensive global assessment on this issue in five decades. This ABSTRACT synthesizes its core findings: approximately 1.381 billion hectares of land worldwide are salt-affected, equating to roughly 10.7% of the global land area. Notably, about 10% of both irrigated and rain-fed croplands are impacted, underscoring the scale and urgency of the crisis. The report identifies climate change and unsustainable human practices as primary drivers exacerbating this process. In response, it outlines a multi-tiered strategic framework for sustainable management. At the prevention and control level, the focus is on optimized water governance—enhancing irrigation efficiency, improving drainage systems, and regulating groundwater to curb salt accumulation. At the remediation and restoration level, strategies target degraded soils through amendments (e.g., gypsum, organic matter) and bioremediation to detoxify and improve soil properties. At the system adaptation and transformation level, the report advocates for developing saline agriculture by breeding and promoting salt-tolerant (halophyte) crops and adapting farming systems to saline conditions. Finally, it stresses that reversing salinization trends and safeguarding food security demand strengthened global policy collaboration, increased investment in innovation, and enhanced worldwide monitoring and knowledge-sharing via platforms like the International Network on Saline Soils (INSAS).

## ABSTRACT

Soil carbon (C) is a significant regulator of atmospheric $CO_2$. However, the contribution of soil inorganic C (SIC), particularly carbonate minerals, to atmospheric $CO_2$ and its interaction with soil organic C (SOC) are neglected. We conducted a microcosm incubation experiment with 13C-labeled straw addition to investigate the mechanisms governing SOC and SIC dynamics in saline (EC = 0.75 dS $m^{-1}$) versus sodic soils (ESP = 16.8%). Saline soils stimulated straw degradation by 14.7% but exhibited 10.7% lower SOC-derived $CO_2$ versus sodic soils. This corresponded to higher microbial biomass and enzyme activity, promoting preferential degradation of straw-derived C in saline soils. Conversely, sodic soils amplified SOC priming by 8-fold due to Na+- induced aggregate collapse, elevating straw- and SOC-derived $CO_2$ in microaggregates by 13.7%–53.5%. This accelerated mineralization also intensified SIC dissolution, contributing > 60% of the total priming-induced $CO_2$ emissions. Despite C losses, straw increased C accrual in salt-affected soils via contrasting pathways: microbial assimilation into SOC (more than 74% of the new-formed C) and abiotic precipitation of pedogenic carbonates (more than 22.6% of the new-formed C). Collectively, these findings identify SIC as a dominant yet under-addressed $CO_2$ source and highlight microbial-aggregate interactions as critical for C management in salt-affected croplands.

Presenting author:Abdul Sami (aadi@gtbagtech.com)

## ABSTRACT

GreenTech (Shanghai) Agricultural Technology Co., Ltd. leverages its platform advantages to integrate a comprehensive soil bioactivation technology (SBT®) system designed for the restoration of arid and saline–alkali soils. This system combines SBT core materials with field-scale soil preparation, amendment application, and agronomic management practices to support soil assessment, improvement, and crop cultivation. SBT® has been successfully applied to more than 667 ha of desert land in Shache, Xinjiang, and has been demonstrated in Abu Dhabi, UAE, where it enabled standardized cultivation of maize, cotton, and alfalfa while significantly enhancing soil quality and agricultural productivity.

Saline–alkali soils represent a major constraint to agricultural production in arid regions, yet effective biological remediation strategies remain insufficiently understood. Field experiments were conducted in Gobi and desert soils of Xinjiang to evaluate the effects of SBT applied alone and in combination with different crops (maize, cotton, and alfalfa) on soil salinity, microbial activity, soil fertility, and plant growth. Treatments included a non-amended control (CK), SBT amendment, and combined SBT–crop systems. SBT application significantly reduced soil salinity, with markedly greater effects observed when combined with crops. In Gobi soils, total salt content declined by 28.6% under SBT alone and by 45.3–59.1% under SBT–crop treatments relative to CK. In desert soils, SBT–crop systems also significantly reduced the soil salinity, reflecting stronger physicochemical constraints.

Soil bacterial abundance increased by approximately 418-fold following SBT application and by 1,800–2,961-fold under SBT–crop treatments across both soil types. These increases were accompanied by significant enhancements in urease activity (38–76%), which was positively correlated with bacterial abundance, indicating improved nitrogen transformation and utilization. In parallel, SBT application substantially improved soil fertility. Compared with CK, soil organic matter increased by 32–68%, available nitrogen by 25–54%, available phosphorus by 18–41%, and available potassium by 15–36% under SBT–crop systems. Soil pH decreased by 0.4–0.9 units, alleviating alkaline stress and promoting microbial activity and nutrient availability. These improvements generated favorable conditions for salt leaching, microbial proliferation, and rhizosphere processes. Enhanced soil biological and chemical properties under SBT only and SBT–crop treatments translated into significantly improved crop growth performance, including greater above ground biomass, root development, and overall vigor compared with CK. Rather than operating as a discrete assemblage of materials, SBT is designed as a comprehensive technology that integrates functional bio-materials with standardized application and management processes. Implemented as an integrated technology suite, this approach enhances the efficiency, stability, and reproducibility of remediation outcomes and establishes a robust foundation for the development of a comprehensive, system-level solution for saline–alkali soil restoration. Overall, the results demonstrate the effectiveness of SBT-based cropping systems as a sustainable strategy for restoring saline–alkali soils and improving agricultural productivity in arid regions.

# ON THE POSSIBILITIES OF USING NIR SPECTROSCOPY TO ESTABLISH THE GENETIC TYPE OF SOILS

**M. Stsepaniuk*, A. Khokh**

*Scientific and Practical Center of the State Forensic Examination Committee of the Republic of Belarus*

*[3]Affiliation of the C. Author (Department, Institute, City, Country)*

* mike-stepa@yandex.by

**ABSTRACT**

In the framework of this paper, the potential possibilities of using near-infrared spectroscopy to determine the genetic type of soils were studied (using the example of alluvial marshy, soddy-calcareous and brown forest soils).

For the study, soil samples were used in the form of "tablets" 0.5 g formed on a special mould, which were taken from the collection of soil samples. Later they were dried in an oven at temperature of 40-45 °C to an air-dry state. NIR spectra were recorded on a MicroNIR OnSite spectrometer (VIAVI, USA) in the range of 950–1650 nm. For each sample, 10 consecutive measurements were performed on each side of the "tablet".

Before using chemometric algorithms, the NIR spectra were subjected to preliminary processing – the calculation of 2nd derivatives according to Savitzky-Golay t. Statistical processing of the obtained second-order derivatives of the NIR spectra was performed using the Unscrambler X v.10.4.1 (CAMO, USA). To build a classification model, formal independent modelling of class analogies (SIMCA) was applied.

At the first stage, two sets were formed from the existing sample set. One of them later served to train the model (gauging set: 270 spectra for each soil type), the second was used to test the calculated model (validation set: 30 spectra for each soil type). Abnormal samples (8 pcs.) were previously excluded from each set, since their inclusion in any of the sets directly affects the values of statistical characteristics calculated when testing the model. Subsequently, for the gauging sets, preliminary classification models were built using the principal component method (hereinafter, PCA) for each of the 3 studied soil types. The purpose of the PCA is to extract the useful and noise components from a given data array. In other words, PCA reveals hidden data patterns.

Further, based on the calculated confidence intervals around each class, using SIMCA, the final classification model was built for the 3 studied classes, which had a 93% prediction accuracy within the gauging set. Next, the distances between the studied classes (soil types) were calculated; the obtained values are from 214.9 to 6519.4, which is considered suitable for reliable differentiation of the studied objects.

The practical possibilities of using the obtained classification model were tested on 90 samples of the variational set, each of which was projected onto the PC space corresponding to each class, based on the Euclidean distance, it was concluded about its belonging to the class. As a result, it was found that the accuracy of the classification model on the validation set is 91.1 %. At the same time, 2 out of 30 studied samples were not classified for alluvial marshy soils, 3 for soddy-calcareous soils, and one sample for brown forest soils, respectively; one sample for soddy-calcareous and brown forest soils was assigned to another class.

# Differentiation of Urban Lawn Soils on the Basis of a Combination of Physico-Chemical Methods(for Forensic Purposes)

**A. Khokh*, M. Stsepaniuk**

*Scientific and Practical Center of the State Forensic Examination Committee of the Republic of Belarus*

*1ann1hoh@gmail.com

**ABSTRACT**

Urban soils of Minsk are subject to intense man-made environmental impact from emissions from stationary and mobile sources of pollution. Currently, more than 300 industrial enterprises are functioning within the city, contributing their emissions to the air basin. The majority of atmospheric emissions come from large industrial facilities and heating enterprises. The cumulative impact of pollution sources causes varying intensity of input and heterogeneity in the composition of soil-contaminating substances. Furthermore, vehicle emissions directly impact the formation of soil properties of lawns located along highways.

Lawn soils are artificially created anthropogenic soils formed by mixing mineral soil (loamy sand, sand) and peat. Their chemical and agrochemical composition is determined primarily by the composition of the mixed soils and their ratios. Meanwhile, the man-made environmental impact (including the use of winter de-icing agents, and emissions from traffic and industry) results in soil salinization, heavy metal pollution, and the accumulation of solid anthropogenic particles. This results in the formation of soils having specific properties that differ from natural soil types.

In Belarus, lawn soils located along highways are frequently used in forensic soil studies, particularly in traffic accident cases. A comprehensive study of their physico-chemical properties was carried out to determine the possibility of differentiation. Soils from 14 lawn areas, located in different districts of Minsk along major highways with the most intensive traffic, were studied. Each area consisted of six 10x10m sites, spaced 50m apart. Four soil samples were collected from each site, from a depth of 0-5 cm.

The conducted research identified characteristics that can be used to differentiate urban lawn areas. Variations in urban lawn soil properties were studied in space and time.

It was established that differentiation is possible based on indicators such as granulometric composition, color, organic matter content, total and specific percentages of solid anthropogenic inclusions, chlorine, sodium, and potassium content, and heavy metal content (cadmium, lead, zinc, copper, and nickel). It was also found that the soils from 14 urban lawn areas differ from each other in their consistent variability in IR spectrometric parameters. The SIMCA classification model, developed using IR spectra, is capable of distinguishing between areas with an accuracy of 98.88±3.46 (%) for the training set and 97.32±4.92 (%) for the test set.

The obtained results form an informational and References database of indicators of soil-technogenic origin for assessing data from comprehensive forensic soil study of urban lawn areas, as well as other technogenically contaminated areas.

# Patterns of formation of the soil cover of historical urban parks (using the example of St. Petersburg, Russia)

**K. Bakhmatova[1*], A. Sheshukova[1], E. Gostintseva[1]**

[1] *Institute of Earth Sciences, Saint Petersburg State University, Saint Petersburg, Russia*

*E-mail: k.bahmatova@spbu.ru

**ABSTRACT**

The soil cover of cities is characterized by patchiness, associated with spatial neighborhood and alternation in time the different types of land use on the same spot. The goal of this study is to find soil cover patterns and predict them based on natural and anthropogenic factors of soil formation in urban parks with Saint Petersburg as an example.

Saint Petersburg is located in the northwestern part of Russia; total city area is 1439 $km^2$ (city center and suburbs). There are 90 parks and 136 gardens on this area. Saint Petersburg was built on terraced low plain; the historical center mean elevation is 5 m above sea level. Due to the prevalence of waterlogging processes, flat relief, high groundwater table and/or poor water permeability of sediments, the general tendency of soil cover transformation for urban greenery was to reduce excessive moisture and to provide fertile humus layer for plants. The soil cover of 3 urban gardens, 3 urban and 2 suburban parks were mapped on a scale 1:500 and 1:2000 to find patterns of its formation.

Analysis of large-scale and detailed soil maps have shown that the main type of soil transformation was caused by the drainage systems construction and surface filling. Other types of anthropogenic impacts reflected in the soil cover, both accidental and purposeful, are differentiated depending on specific locations. In parks, created on the site of a natural landscape, the soil cover patterns reflected the park layout and history of its formation, which allows predicting the localization of anthropogenic soils on its territory. The greatest degree of the soil cover transformation and its maximum taxonomic homogeneity were observed in small historical gardens of the city center, where natural soils are totally absent and soil cover consist from Urbic Technosols only. In large urban parks, along with anthropogenic soils, natural soils and their mildly transformed varieties are represented. The greatest diversity of soil cover components was found in spacious suburban parks, where the greater variability of natural factors combinations and wider range of anthropogenic impact varieties were observed. In large suburban and urban palace and park complexes the share of different anthropogenic soils and component diversity of soil cover is greater in areas adjacent to palace and estate buildings, due to both the specifics of park layout and a higher probability of soils accidental transformation and littering with construction debris there. Thus, the soil cover in suburban parks have been formed by superimposition of anthropogenic impact on natural regularities. To study the soil cover of such objects, it is necessary to consider the spatial confinement of different forms of purposeful anthropogenic impact, as well as the fact that a significant part of accidental soil disturbances associated with the vicinity of buildings, facilities and main roads within the park.

# Cultural layer in urban soils of Saint Petersburg, Russia

**A. Sheshukova[1*], K. Bakhmatova[1]**

[1] *Institute of Earth Sciences, Saint Petersburg State University, Saint Petersburg, Russia*

*E-mail a.sheshukova@spbu.ru

**ABSTRACT**

*Introduction.* Cultural layer in urban soils reflected historical specifics of the city and its certain areas. At the same time, cultural layer is the basis of surface soils formation. Moreover, deep strata of cultural layer could be surfaced during excavation works. Therefore, features of cultural layer are significant both in pedological and environmental aspects.

*Objects and methods*. Saint Petersburg is the second largest city of Russia, founded in 1703. The total urban area is 1439 $km^2$. The objects of this study are Saint Petersburg anthropogenic urban soils, located in parks, gardens and city streets. Totally 203 profiles were studied. pH, EC, C org., mobile P content in Olsen extraction, heavy metals (HM) –Cu, Pb and Zn (by ICP-MS, AAS and XRF methods) were determined in soil samples. Semi-quantitative phase composition of cultural layer was done with Rietveld method (desktop diffractometer Rigaku "MiniFlex II"). Past 3.12 was used for statistical data processing. The total content of artifacts (wt.%) was determined and then the artifacts were extracted by sieving, examined and photographed in 3D using a Leica stereo binocular and then studied using a scanning electron microscope with an X-ray probe Hitachi 3000 at the SPbSU Resource Center “Center for Microscopy and Microanalysis”.

*Results*. Total thickness of surface anthropogenic (cultural) layer in studied urban soils of Saint Petersburg is 0.5-2.0 m (up to 2.5-3.0 m). Cultural layer consists from fill (fine-grained material, matrix) and artifacts. Depending on the history of the city locality, the thickness of cultural layer and the artifacts content vary considerably. According to phase analysis, mineral matrix of studied cultural layer is similar with natural parent material except for calcite presence. Several types of anthropogenic inclusions were identified: 1) bricks; 2) lime mortar; 3) glass; 4) slag; 5) bones; 6) paint particles; 7) metal fragments; 8) fragments of ceramics, including tiles; 9) coal and charcoal; 10) solid food remains, except for bones - fish scales, egg shells. Construction debris quantitatively prevails. Less stable artifacts (mortar) undergo weathering with a decrease in particle size. The chemical composition of artifacts is characterized by high heterogeneity associated, among other factors, with the processes of their transformation in the soil. Artifacts in soils may contain HM (slag), but they may also serve as geochemical microbarriers where individual HMs are precipitated (bones, mortar, etc.).

Chemical properties of cultural layer are typical for urban soils: pH – 6.0-8.9; C org. is 2.5-3.5 % (up to 5-7 %), $CaCO_3$ – 0.3-35.6%. Mobile P content is high and very high. Maximum values of heavy metals (mg/kg): Zn - 1200, Pb - 1850 mg/kg, Cu - 680 mg/kg. These values are 15-90 times higher than background, i.e. inherited from natural parent materials.

# Carbon dioxide emissions from technogenic soils of the Central forest steppe

**Elena N. Tikhonova[1*], Polina V. Chernykh[2], Ella I. Treschevskaya[3] and Inna V. Golyadkina[4]**

*[1,2,4] Department of Landscape Architecture and Soil Science, Voronezh State University of Forestry and Technologies named after G.F. Morozov, Voronezh, Russian Federation*

*[3] Department of Forest planting, selection and melioration, Voronezh State University of Forestry and Technologies named after G.F. Morozov, Voronezh, Russian Federation*

*tichonova-9@mail.ru

**ABSTRACT**

In an era of intensive industrialization and increasing consumption of mineral resources, the problem of anthropogenic transformation of landscapes has taken on a global scale. Open pit mining is one of the most aggressive impacts on the natural environment: it leads to the formation of extensive post-technogenic landscapes with totally disrupted soil and vegetation, hydrological regime and biodiversity. In addition to the quarries, a huge area is occupied by waste rock dumps that have remained uncultivated for decades. Such areas become sources of erosion, dust, water and soil pollution, reduce the aesthetic and recreational value of the landscape. Reclamation is the main way to restore the damaged areas.

Disturbed lands contribute significantly to greenhouse emissions, with multiple emission mechanisms. Several studies have estimated that the $CO_2$ emissions from post-technogenic areas can be 2 to 5 times higher than the background values for natural landscapes of the same geographical zone. The long-term carbon footprint of mining areas is often not included in national greenhouse gas inventories.

The $CO_2$ emission on the waste rock dumps under forest recultivation was studied in the Central forest steppe zone of Russia, Voronezh region. The sand and sand-chalk mixtures occupy a leading position among overburden rocks in many mineral deposits. It is characterized by poor agrochemical and water-physical properties. The object of research is the dump area called the «Orlov log». It was created in 1972 by hydraulic washing of sand and chalk mixture. Later there were implemented a large-scale forest planting program, mainly of Scots pine (*Pínus sylvestris* L.).

The intensity of $CO_2$ emissions from soil was measured in forest recultivated sites on the growing season 2025 (from the first decade of June to October), using a closed chamber method with a portable gas measurement system LI-870SC ($CO_2/H_2O$) based on gas analyzer (LI-COR Biosciences Inc.). Measurements were carried out at a time when the $CO_2$ flows are close to the daily average emission values. During the measurements the layer of forest litter not removed. At each point, the $CO_2$ emissions were measured (in triplicates with calculation of average sizes and confidential intervals). The Stevens HydraProbe soil temperature and moisture sensor was placed in the soil directly near each point, recording the characteristics of the soil at the time of measurement. Data from field measurements of $CO_2$ emissions were processed in the specialized software SoilFluxPro v5.3.1 (LI-COR Biosciences Inc., 2024).

The average rate of $CO_2$ emission in technogenic soils covered with forests plantation was 2.68 ± 1.02 μmol $CO_2/m^2$ s, ranging from the lowest values in September - 1.56, to the highest values in July, reaching, in individual measurements - 7.68 μmol $CO_2/m^2$ s. The dynamics of carbon dioxide emissions in our studies have a gradually rising trend from the beginning of June, the maximum rate of $CO_2$ release from soil is observed at the end of July and then a gently declining trend towards the end of the growing season.

The reclamation of landscapes and soils in areas disturbed by mineral extraction is critical for reducing environmental stress and greenhouse gas emissions, for returning land to the economic and natural cycle. Without systematic scientific support, the recovery processes will remain fragmented and inefficient, and accumulated environmental damage will increase.

*E-mail korneykova.maria@mail.ru

**ABSTRACT**

Urbanization in the Arctic results in considerable and still poorly known environmental consequences. The effect of urbanization on soil microbiome – an ecosystem component highly sensitive to anthropogenic disturbance – remains overlooked for the Arctic region. The research compared chemical and microbial properties of the natural Podzol soils and urban soils of Arctic cities (Murmansk and Apatity), which located on Kola Peninsula. A particular attention was given to the profile distribution, which is almost completely ignored by most microbial studies. Soil microbiome was investigated by the quantitative indicators based on fluorescence microscopy (microbial biomass), PCR real-time methods (amount of rRNA genes copies of archaea, bacteria and fungi) and molecular genetic method (taxonomic and functional diversity). The principal changes in urban soils' properties compared to the natural References included a shift in pH and an increase in C and nutrients' contents, especially remarkable for the subsoil. The numbers of rRNA genes copies of archaea, bacteria, and fungi in urban topsoils were lower than in Podzol; however, the opposite pattern was shown for the subsoil. Similarly, the total microbial biomass in urban topsoils was lower compared to the Podzols, while urban subsoil microbial biomass was 2-2.5 times higher than in the natural conditions. Both for urban and natural soils and throughout the profiles, fungi were dominated by mycelium forms; however, the ratio of mycelium: spores were lower, and the amount of thin mycelium was higher in urban soils than in natural Podzols.

Functional richness of microbial communities was higher in natural Podzols, while the highest taxonomic diversity of bacteria and fungi occurred in the urban topsoil horizons. Aerobic chemoheterotrophs were universally dominant in bacterial communities in both urban soil and Podzol, with their abundance increasing in urban soils. Ectomycorrhizal fungi predominated in fungal communities in Podzol, with pathogenic and parasitic forms having minimal abundance; the contribution of saprotrophs increased in urban soils.

Urbanization in the Arctic altered soil morphological and chemical properties and created a new niche for microbial development in urban subsoils, which contribution to biodiversity and nutrient cycling will become increasingly important under projected climate change.

# Relationships between soil health and dynamics of soil potential pathogenic microbiota in functional domains of Xi'an urban greenspaces, China

**Yang Liu [1], Mengmeng Wen[2], Rong Hu[3], Jun Wang [4]**

*Shaanxi Key Laboratory of Earth Surface System and Environmental Carrying Capacity, College of Urban and Environmental Science, Northwest University, Xi'an, 710127, China.*

*E-mail: 527984479@qq.com and wangj@nwu.edu.cn

**ABSTRACT**

Soil potential pathogenic microbiota exacerbate the environment and human health through invading normal tissues of the human body, but their distributions and interactions across functional domains in urban greenspaces are poorly understood. Herein, we collected soil samples from parkland and residential land to explore the relationships between soil health and the dynamics of soil potential pathogenic microbiota. Soil organic matter-associated properties, soil multifunctionality and health were significantly about 30% higher in parkland, but soil stoichiometry including C/N, C/P, and C/N/P were lower in parkland. Alpha diversity of soil pathogenic bacterial communities was higher than for fungal communities in residential land. The relative abundances of the dominant genera *Mycobacterium*, *Metarhizium*, and *Cladosporium* that may cause chronic lung and gastrointestinal diseases in humans were greater for residential land. Potential connected networks including soil pathogenic bacterial and fungal phylotypes were more complicated and stable in residential land, based on higher total and positive connections and higher robustness. Meanwhile, bacterial phylotypes belonging to the genus *Shigella* were identified as keystone species in parkland network, all of which were chronic pathogens. Soil total nitrogen and phosphorus as dominant properties had greater total effects on soil health in parkland and residential land, respectively. In general, soil health was mostly affected by soil multifunctionality in parkland, but was subject to higher explanation in residential land. These findings underscore intimate relationships between soil health and the dynamics of soil potential pathogenic microbiota in urban greenspaces, which has implications for human daily outdoor routines and urban habitability.

## ABSTRACT

Anthropogenic soils in two cities of Southern European Russia were studied: the Rostov agglomeration, a major industrial center in the steppe zone, and the Federal Territory "Sirius" (FT Sirius), a recreational and tourist hub established on the Olympic legacy in the subtropical zone of the Black Sea coast. Monitoring in the Rostov agglomeration encompassed ten sites located in park and residential areas, whereas in Sirius, fifteen sites were examined within park-recreational zones and surrounding sports facilities.

Despite differences in their age and history, both cities are dominated by urbic technosols, a significant portion of which are artificially created soils – constructozems. A key unifying feature is that in both the steppe and subtropical zones, the surface recultivation layer was formed using the humus-accumulative horizons of Haplic Chernozems. These horizons are diagnostic for the Recultivation-Humus Horizons (RAT) typical for the southern European part of Russia. The study focused not only on the morphological features of constructozems under different climates but also on the transformation of various carbon forms during the early stages of their evolution. The selected monitoring sites represent the main variants of recultivated urban soils.

Despite being geographically remote from native Chernozem areas, the thickness of the RAT horizons of constructozems in FT Sirius varies widely, ranging from 5 to 55 cm, with an average of 26.4 ± 14.5 cm. In contrast, in the Rostov agglomeration, the maximum thickness of the RAT horizons does not exceed 40 cm, with an average of 18.3 ± 9.8 cm.

Soil carbon content is mainly determined by the initial humus concentration of displaced soil masses, the development intensity of grass root systems, the granulometric composition, and the intensity of pedestrian loading.

The level of $CO_2$ emissions from Rostov-on-Don urbic technosols, which constitute the components of humus horizons, is in close ranges, often below background values. This is due to the high stability of the humus complex of old arable soils, whose humus-accumulative horizons served as the parent material for the technosols. The majority of humus substances in the RAT horizons are associated with clay minerals and non-hydrolyzed residue, which results in their low mineralization propensity even when displaced and subjected to additional wetting.

In contrast, the recultivation-humus horizons of the urbic technosols in Sirius also formed from chernozem material atypical for the region, exhibit different behavior. Here, the soil organic matter, transferred into new thermodynamic conditions, has lost its stability and is now actively mineralizing, leading to increased $CO_2$ emissions. This process, coupled with the decrease in RAT horizon densities, indicates a lack of system stability and may be an indirect confirmation of concerning adverse trends in the context of carbon neutrality for landscape decisions on the Black Sea coast.

**Keywords:** urban soils, chernozems, urbic technosols, soil organic matter.

jaroslava.sobocka@nppc.sk

**ABSTRACT**

Environmentally sensitive areas within urban land (U-ESA) play an essential role in maintaining urban ecological balance and ecological safety. U-ESAs are ecological elements in and around a city that have a reduced ability to regenerate if they are somehow damaged by urbanization. Microclimatic regulation of heat capacity in built-up urban environments is strongly determined by the soil sealing i.e. by pavement, asphalt, concrete and the like. Obviously, compared to open green areas, this area contributes to extreme summer temperatures, and to the creation of urban heat islands (UHI). In terms of soil and vegetation conditions, these phenomena significantly reduce the ecological functions and ecosystem services of urban soil. For mapping of urban environmentally sensitive areas (U-ESA), soil sealed surfaces in the urbanized environment were identified, soil properties and quality, including green urban infrastructure were classified and mapped. The U-ESA assessment methodology is based on a multi-criteria approach, in which several attributes were profiled: 1. mapping of land cover/land use and soil sealing using the extended nomenclature of the Urban Atlas 2012 for the city of Bratislava, 2. modelling the occurrence of urban heat islands (UHI) and their spatial distribution using the MUKLIMO model; 3. mapping of urban soils using the concept of pedo-urban complexes (PUC) and assessing their quality; 4. identification and classification of urban vegetation types; 5. overlapping and synthesis of results using GIS tools (© ESRI ArcGIS). The main outputs: 1. geospatial information is the basis for a balanced spatial design and organization of plans and studies of cities in which environmentally sensitive areas are identified, 2. in densely built-up areas, deteriorating living conditions intensify, especially in the presence of urban heat islands (UHI) 3. soil sealing surfaces are one of the main causes of increased heat, but not entirely, polluted air and microclimatic conditions play a role. The most ecologically sensitive areas appear to be city centres which are characterized by dense historical buildings and impermeable or semi-permeable soil cover (more than 80%), where an increased effect of UHI and a reduced degree of availability of public green spaces can be observed.

**ABSTRACT**

Long-lasting research on soils of the city of Moscow permitted to identify main genetic groups of urban soils. These are *quasi-native* soils preserved in urban forests and parks, *urbo-native* soils with anthropogenic horizons below 40-50 cm thick; soils of the synlithogenic trend of pedogenesis – *urbostratozems* – growing upward due to additions of urban material along with the cultural layer; *weakly developed soils* on human-made sediments; sealed soils – *ekranozems*; purposefully constructed soils – *konstructozems (*reclaimed soil-like bodies). Soil properties in this assemblage reflect both pedogenetic trends depending on the geographical location and features of urban geochemistry. The matrix for building urban soils are Quaternary deposits transported from different geomorphological areas. Geochemical features of Moscow soils are related to calcareous construction and demolition materials, industrial and transport emissions and significant aerial dust load; they all contain diverse pollutants, either organic, or mineral.

The early stages of urban pedogenesis are represented by young soils on eroded, transported and/or human-made substrates with initial shallow humus horizons, as well as constructed soils, including those with artificial lawn. In full-profile soils, *urbic diagnostic horizon* is obligatory, and its thickness serves as a divide between urbo-soils and urbostratozems, its properties are described and substantiated by its origin. It is composed of periodically deposited layers – strata – of human-made materials, urban dust and waste, thus corresponding to the synlithogenic trend of soil formation, namely, soil formation synchronous to the deposition of parent material.

Soils in Moscow with a thick urbic horizon (> 40-50 cm) are qualified for *urbostratozems* – archetypal soils for settlements on the one hand, and final result of urban soil evolution on the other hand. The unity of the mineral matrix in the landscape-geomorphological areas, the geochemical background and bioclimatic conditions on the city territory allows us to speak about the genetic relationship between soils of the city and the unified pattern of urban soils evolution.

# Threshold sand content of sand-clay mixtures is affected by clay mineralogy and compaction effort

**Evan C. Mascitti**[1*]

[1] *Stockbridge School of Agriculture, University of Massachusetts – Amherst, Amherst, MA*

*emascitti@umass.edu

**ABSTRACT**

Imported soil mixtures are used in urban and trafficked areas for engineering, environmental, and agricultural applications. Sand-clay mixtures are particularly useful where dimensional stability, bearing capacity, and reduced permeability are desirable. In a coarse-grained soil, loads are borne by a skeleton of particle contacts between sand grains and soil behavior is relatively unaffected by changes in water content. Small quantities of fines have little impact on soil behavior because they fit comfortably within the intergranular voids. With further additions, the sand grains lose contact with one another and soil behavior becomes dominated by the fines and the extant water content. The sand content associated with this particle fabric has been termed the threshold sand content or TSC. TSC is often defined in the literature as the sand content yielding maximum bulk density (i.e. minimum porosity or void ratio). The TSC value will vary for any unique pair of sand and clay components because the particle arrangement is governed both by the sand-size distribution and the plasticity of the clay phase. Knowing TSC for a given clay soil can inform mix design for structural applications (where maximum density is desirable) and agricultural/environmental applications (where sand content must exceed TSC to preserve larger voids for plant growth and water infiltration).

The objective of this research was to discern how clay mineralogy, mixture ratio, and compaction effort influence the threshold fines content of sand-clay mixtures. A washed sand was mixed with either kaolinite, illite, or smectite clay at ratios ranging from 50-80% sand by dry mass. Mixtures were subjected to Proctor compaction testing using either the Standard or Modified effort. For each clay soil, the threshold sand content was defined as the sand content resulting in the lowest total porosity. TSC values ranged from 60-75% depending on clay type and compaction effort, while total porosity at TSC ranged from 21-30%. TSC was highest for smectite, intermediate for kaolinite, and lowest for illite. Additionally, TSC was higher for soils compacted using the Modified effort. This suggests that for the most accurate prediction of field behavior, TSC should not be quantified using a density-based definition, because the TSC value varies with loading conditions. It is suggested that TSC be instead defined by using mechanical soil test methods (shear strength, hydraulic conductivity, etc.) and loading parameters relevant to the application of interest.

# Hydrothermal Carbonization of Urban Organic Waste: Is it a sustainable pathway for soil restoration in highly urbanized regions?

**L. Le Brun-Suárez[1*], C. Siebe[1], L.N. Mora-Palomino[1], and T. Abbruzzini[1]**

[1] *Universidad Autónoma de México (UNAM), Instituto de Geología, Ciudad de México, México*

*lorenzalebrun@comunidad.unam.mx

**ABSTRACT**

Highly urbanized areas such as Mexico City generate large amounts of organic waste that, if not properly managed, contribute to greenhouse gas emissions and environmental degradation. **Hydrothermal carbonization (HTC)** is an emerging technology that converts humid organic residues into a carbon-rich material known as **hydrochar (HC)**, offering a sustainable strategy for both urban waste management and the recarbonization of soils. This study investigates the potential of HC produced from the organic fraction of municipal solid waste at the **Hydrothermal Carbonization Plant of Mexico City** as an organic amendment for degraded and urban soils. Controlled **incubation experiments** were conducted on six contrasting substrates (Silica sand, mining tailings, sodic soils, Acrisol, Phaeozem, Regosol) amended with **HC, pyrochar, and compost** to quantify $CO_2$ emissions and estimate carbon mineralization. In parallel, analyses of **enzyme activity** and **microbial biomass** were performed to evaluate the effects of HC on soil microbial functioning. Preliminary results indicate that HC shows relatively **low recalcitrance** but can **enhance microbial activity** depending on soil type. Degraded soils, such as saline soils and mining tailings showed an increase in organic carbon and microbial activity. Future work will focus on **conditioning treatments** to remove phytotoxic compounds and further improve hydrochar's agronomic potential. These findings highlight the promise of HTC-derived materials to integrate **urban organic waste valorization and soil rehabilitation**, advancing circular-economy strategies and climate-mitigation goals in rapidly urbanizing regions.

# Healthy Soils for Healthy Communities – A Community-based Urban Soil Initiative from Los Angeles

**Yujuan Chen**[1*]

[1] *Department of Environmental Sciences, Tennessee State University, Nashville, TN, United States*

*yujuan.chen@tnstate.edu

**ABSTRACT**

Soil is the brown infrastructure in cities. To better understand and utilize the potential of soils in cities, we launched the "Healthy Soils for Healthy Communities" Initiative in Los Angeles (LA), CA, United States. As the first phase of the initiative, this project aimed to determine the current status of LA County soils, identify the most pressing urban soil issues and community needs through community consultation and outreach, and provide a framework for future work regarding urban soil research, policy, public education, and community engagement in the region. We conducted four county-wide online surveys with residents, educators, policymakers, and soil-related professionals, seven focus groups with key stakeholder groups, various meetings and events, a review of the literature, and worked with universities, government agencies, non-profit organizations, and community groups to achieve these objectives. We found LA County had almost 50% impervious surfaces and 44% bare soils with 45% human altered soils. We also found resident knowledge about factors that affect soil health was low and the majority of residents (76%) are very or extremely concerned about soil contaminants and pollution in their communities. However, only 12% of them have ever tested their soils. But interest in soil-related issues is high, with 76% of participants being either extremely or very interested in the topics listed on the survey. Additionally, cross-cutting themes identified in focus groups include a need for: 1) Accessible and transparent soil data and testing; 2) Effective community engagement and streamlined communication; and 3) Building alliances among community, policy, and science professionals and leveraging organizations/ individuals/agencies already doing the work. To address the identified needs, we proposed to establish a Los Angeles Urban Soil Collaborative consisting a set of core activities, demonstration projects, community outreach programs, and the scaling up of these activities through collaborations.

# Do local non-statutory habitat designations reflect differences in below-ground biodiversity and functioning in urban green space?

**Peng Huang[1,2*], Richard D. Bardgett[2], and David Johnson[2]**

[1]Department of Earth and Environmental Sciences, Michael Smith Building, The University of Manchester, Manchester, M13 9PT. UK
[2]Lancaster Environment Centre, Lancaster University, Bailrigg, Lancaster LA1 4YQ. UK.
[*]E-mail Address of Presenting Author: peng.huang-2@manchester.ac.uk

**ABSTRACT**

Urban green spaces provide essential ecosystem services, and a range of statutory and non-statutory designations are used to protect them. However, these designations are often based on above-ground characteristics, and it remains unclear whether they also reflect belowground processes that underpin multiple ecosystem services. Here, we evaluated soil-based ecosystem processes and services in urban green spaces designated as Sites of Biological Importance (SBIs) and in adjacent, near-identical non-designated sites. We tested the hypothesis that aboveground characteristics used to designate SBIs would be mirrored by differences in soil processes supporting key ecosystem services. Seasonal dynamics of soil nutrient concentrations, soil $CO_2$ efflux (respiration), and litter decomposition were measured using a reciprocal litter transplant design to separate litter and environment driven effects. SBI designation interacted with seasonal variation, showing significantly higher soil nutrient concentrations, microbial biomass carbon, dissolved organic carbon, and improved soil water retention. Activities of oxidative enzymes (peroxidase and phenol oxidase) were also higher in SBIs, indicating an enhanced microbial capacity to process complex carbon compounds. In contrast, soil respiration did not differ between SBIs and controls and was mainly driven by soil moisture and canopy cover. The litter transplant experiment revealed a positive home-field advantage in non-designated areas but the opposite response in SBIs. Overall, these findings demonstrate that SBI designation captures important belowground differences, particularly in nitrogen-related nutrient storage and enzyme-mediated decomposition, emphasizing the broader ecological value of non-statutory designations for sustaining urban soil functions.

**Acknowledgments**

We thank the various landowners and local authorities for giving us access to the green spaces used in this study; Dr Ully Kritzler and Debbie Ashworth for technical support. We also thank the Greater Manchester Ecological Unit for access to data and information on SBI sites. This work was supported by a UKRI Natural Environment Research Council (NERC) award 'Maximising Ecosystem Services in Urban Environments' ref. NE/W003120/1.

# Assessment of trace elements mobility in Technosols developed on heaps of historical polymetallic ore mining in the Sudety Mts., SW Poland

**Damian Murach*, Łukasz Uzarowicz, Wojciech Kwasowski, Piotr Jankowski, Artur Pędziwiatr**

*Department of Soil Science, Institute of Agriculture, Warsaw University of Life Sciences – SGGW, Warsaw, Poland*

*damian_murach@sggw.edu.pl

**ABSTRACT**

Technosols developed on historic mining waste heaps, due to the low efficiency of mining in the past, may contain large amounts of trace elements that were extracted during the mining process. As a result of soil-forming processes, these elements may be mobilized in the environment. The aim of the study was to assess the degree of mobility of selected trace elements (As, Cr, Ni, Co, Cu, Zn, Pb, Cd, Sb, Fe and Mn), in Technosols developed on the spoil heaps of historical polymetallic mining centers (mainly copper and arsenic) in Miedzianka, Radzimowice, and Czarnów in the Sudety Mts., SW Poland. Twelve soil profiles were investigated. The Zeien and Brümmer (1989) sequential extraction procedure was applied to determine the operationally defined chemical forms of selected elements – fractions (F) with decreasing mobility: F1 – mobile fraction (water-soluble and exchangeable); F2 – specifically adsorbed; F3 – bound to Mn oxides; F4 – bound to organic matter; F5 – bound to amorphous or poorly crystalline Fe oxyhydroxides; F6 – bound to crystalline Fe oxides; F7 – residue. The extracts were analyzed using ICP-OES, and mobility was assessed as a percentage of the sum of F1 and F2. The total content of the studied elements, calculated as the sum of all seven fractions, was as follows (in $mg \cdot kg^{-1}$): As (108–57407), Cu (23.2–9167), Zn (104–3191), Pb (36.9–1975), Co (22.7–760), Cr (25.4–274), Cd (3.8–217), Ni (36.9–171), Sb (0.9–61.6), Fe (50140–159019), and Mn (401–5824). Arsenic was detected mainly in F5 and F6, as well as in F7 and F4. Copper, zinc, and nickel were present in all forms, mainly in F5, F6, and F7, but a significant proportion of forms in F1 and F2 was also observed. Lead was found primarily on F4, F5, and F6. Cobalt was mainly found in F3 and F7, and in some profiles also in F1 and F2. Chromium was mainly present in F7, and to a lower degree also in F5 and F6. Cadmium occurred in various forms, mainly in F5 and F7, and also in significant amounts in F1 and F2. Antimony and iron were primarily found in F7, as well as in F5 and F6. In some profiles, a significant proportion of F4 was found. Manganese occurred mainly in F3, but also in F7, F1, and F2. The most mobile elements were cadmium and zinc (up to over 40%). The proportion of mobile manganese reached over 30%. Cobalt, copper, nickel, and antimony were also mobile (up to about 20%). The mobility of lead reached over 10%. Arsenic, iron, and chromium occurred in hardly mobile forms. The significant proportion of mobile forms of certain trace elements may pose a potential threat to the local environment due to the bioaccumulation of elements by plants or their leaching into groundwater.

# Who Bears the Burden? Trace Element Contamination and Environmental Justice in Chicago's Urban Parks

**Anna A Paltseva[1*], Eriell M. Jenkins[2], Holly Heafner[2], Victoire Soumano[2], James Montgomery[3]**

*[1] Departments of Agronomy, Horticulture and Landscape Architecture, Purdue University, West Lafayette, Indiana USA*

*[2] Delta Urban Soils Laboratory, School of Geosciences, University of Louisiana at Lafayette, Lafayette, Louisiana USA*

*[3]Department of Environmental Science and Studies, DePaul University, Chicago, Illinois USA*

*apaltsev@purdue.edu

**ABSTRACT**

This research examines patterns and intensity of trace element contamination in soils from five urban parks in Chicago, with a focus on how soil conditions and metal concentrations relate to the socio-economic and demographic profiles of nearby communities. Portable X-ray fluorescence (pXRF) was employed to quantify concentrations of lead (Pb), arsenic (As), chromium (Cr), copper (Cu), nickel (Ni), zinc (Zn), and manganese (Mn) in collected soil samples. Results show that parks situated farther from the urban core and located in neighborhoods characterized by lower household incomes and higher proportions of minority residents, most notably Douglass and Humboldt Parks, contain markedly elevated trace element levels. Conversely, parks closer to downtown, including Grant, Webster, and Cottontail Parks, display comparatively lower contamination and are surrounded by areas with higher median incomes and property values. These patterns underscore clear socio-economic inequities in urban environmental quality. Overall, the findings emphasize environmental justice concerns, demonstrating that marginalized communities experience disproportionate exposure to contaminated urban soils. The study supports urban planning actions such as prioritizing site-specific soil remediation, encouraging safer urban food production practices, and advancing policy interventions aimed at reducing environmental health inequalities.

# Challenges for SUITMA posed by the 2025–2034 Decade of Soil Sciences for Sustainable Development

**Edoardo A.C. Costantini**[1*]

[1] *CNR-IBE, Sesto Fiorentino; Accademia dei Georgofili, Firenze; Accademia Nazionale di Agricoltura, Bologna; (Italy)*

*E-mail eac.costantini@gmail.com

**ABSTRACT**

Soils are increasingly threatened by degradation, sealing, contamination, and unsustainable land use, particularly in rapidly expanding urban and peri-urban areas. Recognizing the urgency of generating actionable scientific knowledge to support the UN Sustainable Development Goals (SDGs), the International Union of Soil Sciences has launched the 2025–2034 Decade of Soil Sciences for Sustainable Development (DSSSD). This global initiative aims to strengthen research, foster international collaboration, and enhance the visibility of soil functions across sectors, ensuring that soil health becomes an integral component of sustainable development policies. Within this framework, SUITMA faces specific challenges, as well as strategic opportunities, in advancing the goals of the Decade.

When properly studied, managed, and integrated into spatial planning through Nature-Based Solutions (NBS), SUITMA soils can make substantial contributions to climate-change mitigation, biodiversity enhancement, and human well-being in urban and peri-urban contexts. The effective implementation of NBS requires detailed, spatially explicit knowledge of soil properties, constraints, and ecosystem services. Such knowledge supports the definition of permeability thresholds for private and public surfaces (e.g. gardens, parking areas, sidewalks), the design and placement of water storage and drainage systems, the planning of blue–green infrastructure networks, the assessment of soil suitability for urban agriculture, the adaptation of soil management practices for parks and urban trees, the definition of rootable soil volumes needed for tree nutrition and mechanical stability, and the safe management of soils surrounding pipelines and other underground infrastructures.

Emerging technical innovations—including proximal and remote sensing, digital soil mapping, and decision-support systems originally developed for precision agriculture—offer promising tools for improving the assessment, monitoring, and management of SUITMA soils.

Strengthening soil literacy enables more transparent, inclusive, and evidence-based governance of SUITMA soils, supporting the integration of soil considerations into urban policies, land-use regulations, and planning standards. This is particularly important in UNESCO-designated areas, such as biosphere reserves and geoparks, where conservation objectives must be reconciled with development pressures.

By advancing scientific understanding and promoting targeted, context-specific management strategies, the SUITMA community can play a decisive role in achieving the objectives of the DSSSD, ensuring that urban soils contribute fully to resilient, sustainable, and inclusive cities.

# Bioremediation of Explosive-Contaminated Soil at Military Sites: New Perspectives on Bioavailability and Ecotoxicological Effects

**S. Zhao*, Y. Zhu, M. Han, B. Dong and S. Luo**

*State Key Laboratory of Chemistry for NBC Hazards Protection, Beijing CHINA*
*spzhao@mail.ustc.edu.cn

## ABSTRACT

Military production, warfare, exercises, ammunition disposal, and other activities have led to widespread soil contamination with explosive compounds. Bioremediation is the optimal method for remediating explosive-contaminated soil. The research team has systematically conducted studies on the bioremediation of explosive contamination, including phytoremediation, microbial remediation, and ecological restoration. However, simply using the disappearance of TNT as an indicator still presents issues such as "incomplete degradation/residual bound forms" and "increased toxicity of intermediate products." Strengthening research on the bioavailability and ecotoxicological effects of explosives in soil will provide a basis for sustainable risk management and remediation of explosive-contaminated sites through plant/microbial-based approaches. In terms of the mechanisms of microbial deep degradation of explosive contaminants and the development of artificial transformation systems, multi-omics approaches were used to assess the micro-ecotoxicological effects of TNT and its intermediate products. A total of 22 highly efficient TNT-degrading microorganisms were screened, and a multi-enzyme cascade reaction system for deep TNT transformation was designed and constructed. The mechanisms by which synthetic microbial communities reshape the microbial ecology of contaminated soil were also investigated[1-3]. To address the issue of changes in the bioavailability of TNT and its degradation products due to interactions with soil minerals, a dark-field imaging research method was established to visualize interactions between particulate matter and organic pollutants by leveraging the light-scattering properties of particles combined with chromogenic reactions. The study found that the surface interactions between TNT and minerals/metals can be categorized into three types: physical adsorption ($Fe_2O_3$, $Al_2O$, $Fe_3O_4$, $SiO_2$, CuO, Pb), adsorption-reduction (Cu, Al), and adsorption-hydrolysis (MgO). Dark-field microscopic observation and scattering spectroscopy not only provide high spatial resolution but also reveal significant differences in adsorption between soil particles. This method plays a valuable role in studying interactions between organic pollutants and soil matrices, as well as the mechanisms governing pollutant bioavailability[4]. To address the issue of combined contamination by heavy metals and explosives at military sites, simulated soil experiments were conducted, integrating 16S rRNA gene sequencing and non-targeted metabolomics to investigate the effects of heavy metal ions (e.g., $Cu^{2+}$, $Zn^{2+}$) and nanoparticles (e.g., Cu NPs, CuO NPs, ZnO NPs) on TNT bioremediation. High concentrations of $Cu^{2+}$, $Zn^{2+}$, and Cu NPs completely inhibited TNT degradation, while ZnO NPs and CuO NPs showed partial inhibition at tested levels. Co-exposure to TNT and heavy metals significantly reduced microbial diversity. Copper and zinc heavy metals inhibited TNT-degrading microorganisms through multiple pathways, including oxidative stress, enzyme inactivation, membrane damage, and disruption of gene regulation.

# Urbanization Alters Soil Nutrients and Heavy Metals in Tropical Coastal Parks: A Case Study from Haikou, China

**ABSTRACT**

Urban soil quality is critically shaped by anthropogenic activities. This study assessed the impact of urbanization intensity on key soil properties in Haikou, a tropical coastal city. Soil samples from seven parks along an urban-rural gradient were analyzed for total and available carbon (C), nitrogen (N), phosphorus (P), Fe, Al, and heavy metals (Cr, Pb, Cd, As).

Results revealed that intensive urbanization significantly altered soil biogeochemistry. Total C and N declined by up to 23%, while total P accumulated, indicating a decoupling of elemental cycles. Available nutrients shifted antagonistically, with N decreasing and P increasing, which may exacerbate N limitation and P runoff risk. The soil organic carbon pool became more labile, as evidenced by a higher proportion of particulate organic carbon, suggesting reduced long-term C stability. Concurrently, a decline in Fe and Al oxides was observed, which is critical for nutrient and contaminant sequestration. Heavy metals, particularly traffic-associated Cr and Pb, were markedly enriched in central urban parks. Multivariate analysis confirmed that anthropogenic drivers (loaded with P, Pb, Cr) increasingly overrode natural pedogenic factors (C, N, mineral-associated organic carbon, Fe) along the urbanization gradient.

We conclude that urbanization induces a synergistic pressure on urban park soils: it not only directly adds contaminants (e.g., heavy metals) but also simultaneously degrades the soil's inherent ability to mitigate these pressures (e.g., through loss of stabilizing minerals and organic matter). This combination amplifies ecological risks. Therefore, location-specific management is imperative: central urban parks require strategies focused on organic matter enhancement and heavy metal immobilization to restore buffering capacity, while peri-urban greenspaces need optimized nutrient management to prevent eutrophication. This study provides a mechanistic framework for understanding and managing soil multifunctionality in tropical coastal cities under rapid urbanization.

# The Impact of urbanization on the physicochemical properties and microbial nutrient limitations of inland wetland soils

**Ping Zhong[1,2], Jiamin Cao[2], Yiting He[2], Zhi Cao[1,2], Shuguang Liu[1*]**

*[1] School of Ecology, Hainan University, Haikou, PR China*

*[2] College of Life and Environmental Sciences, Central South University of Forestry and Technology, Changsha 410004, PR China*

*E-mail Address of Presenting Author: jt251707130001@hainanu.edu.cn

**ABSTRACT**

In the context of the Anthropocene, rapid urbanization has become a primary driver of land surface transformation, posing severe challenges to soil health and ecological functions of inland wetlands; however, how urbanization drives the evolution of soil properties and shifts in microbial metabolic limitations remains unclear. Here, we quantified urbanization intensity using impervious surface coverage and established 22 sampling sites across the Taihu Lake Basin, systematically analyzing soil physicochemical properties and extracellular enzyme activities to elucidate the impacts of urbanization pressure on inland wetland soil properties and microbial nutrient demands. We found that with increasing urbanization intensity, soil bulk density, pH, and concentrations of calcium, magnesium, and sodium significantly increased ($p < 0.05$), while organic carbon and ammonium nitrogen contents significantly decreased ($p < 0.05$). Enzyme activity vector analysis revealed that soil microbial carbon limitation intensified significantly with urbanization, and nutrient limitation shifted characteristically from nitrogen to phosphorus limitation ($p < 0.05$). Our findings reveal the cascading effects of urbanization-driven inland wetland soil degradation from structural deterioration to microbial metabolic reorganization, providing theoretical foundations and early warning indicators for maintaining wetland soil ecosystem functions and sustainable management in the Anthropocene.

# Urban soils mulching: temperature and moisture regulation in urban soils under different substrates

**Makar Silaev[1*], Riana Akhmetzyanova[1], Zakhar Ejelev[1]**

[1] *Faculty of Soil Science, Lomonosov Moscow State University, Moscow, Russia*

*silaevmv@my.msu.ru

**ABSTRACT**

Urbanized territories in humid regions face soil degradation and disrupted water and temperature regimes. Mulching is a nature-based solution for urban soils, yet comparative substrate studies under humid conditions remain insufficient. This research examines how organic and mineral mulches regulate temperature and moisture in urban soils, informing landscape design.

The study was conducted at the instrumental sites of the soil station of Lomonosov Moscow State University during 2021-2023. The experimental design included 12 plots covered with 11 different mulching substrates of 5 cm thickness: 7 organic substrates (coconut chips, painted and unpainted pine chips, larch bark of coarse and fine fractions, pine bark of coarse and fine fractions) and 4 mineral substrates (serpentine, marble, volcanic tuff, foam glass), plus a control (bare fallow).

Soil temperature was recorded at 0 cm (directly under mulch), 5 cm, and 10 cm depth (3-hour intervals). Moisture content of the upper layer (0-10 cm) was measured during the summer periods. Characterization of mulching substrates included determination of minimum water-holding capacity (WHC).

Organic substrates showed superior WHC (54.5-83.3%) versus mineral materials (0.7-3.8%). Coconut chips had maximum WHC (83.3%). Soil moisture under mulch increases by 6.6-14.6% compared to bare fallow, with the greatest increment observed beneath fine-fraction organic substrates: coconut chips (31.0%), fine larch bark (31.8%), and fine pine bark (29.5%).

During June 2023, mineral substrates exhibited high temperature amplitudes (15.9-19.6°C at surface) due to low WHC and high thermal conductivity. Volcanic tuff showed highest amplitude (17.3°C at 5 cm) due to low albedo and enhanced evaporation. Organic substrates demonstrated stable regimes with amplitudes of 9.4-12.8°C (30-45% lower than mineral materials). Coconut chips (10.3°C) and fine larch bark (9.4°C) provided optimal buffering. Foam glass exhibited organic-like properties (11.3°C amplitude), confirming pore structure importance. At 10 cm depth, organic substrates maintained the most stable regime.

Fine-fraction organic substrates substantially increase moisture and temperature stability. Foam glass offers a promising recycled alternative. Light-colored organic materials (larch/pine bark) deliver optimal performance: maximum moisture retention and minimal temperature extremes. The correlation between water-holding capacity and temperature stability demonstrates mulching's potential as a nature-based solution for mitigating urban heat islands and supporting vegetation resilience in cities.

**ABSTRACT**

Rare earth elements (REEs) are strategic resources whose intensive mining and use have led to widespread soil contamination, particularly in China. Soil colloids, the most reactive soil components, play a critical role in the occurrence, release, and transport of REEs, yet the mechanisms governing REE colloidal forms and fluxes across different mining settings remain poorly constrained. Here, we systematically investigated the occurrence, release behavior, and co-transport mechanisms of ionic and colloidal REEs across three representative Chinese REE mining types—igneous carbonate rock, igneous metamorphic rock, and ion-adsorption deposits—using ores, tailings, abandoned soils, and contaminated farmlands.

Size-resolved extractions and AF4-based analyses revealed two dominant REE colloidal fractions (5–70 nm and 250–500 nm) with distinct compositions and formation pathways. Small colloids were closely linked to mineral weathering intensity and metal (Fe–Mn) oxides, whereas larger colloids were primarily associated with clay minerals. REE fractionation differed markedly among deposit types: LREEs dominated colloids in carbonate-hosted systems, MREEs prevailed in metamorphic deposits, and mixed patterns occurred in ion-adsorption deposits. Simulated rainfall experiments showed that REE release from carbonate and metamorphic tailings was dominated by colloid-facilitated transport, while ion-adsorption systems released REEs mainly in ionic form via ion exchange and reductive dissolution, resulting in substantially higher release fluxes. Residual ammonium-based leaching agents further amplified REE mobilization from ion-adsorption tailings.

Overall, this study provides mechanistic insights into how mineralogy, weathering, and soil colloids jointly control REE occurrence, fractionation, and transport, highlighting colloid-mediated processes as critical drivers of REE pollution spread. These findings offer a scientific basis for improving risk assessment and management of REE-contaminated soils.

# Characterization, hazards assessment and remediation of heavy metals-explosives contaminated soil in military training ranges

**Yongbing Zhu[1*], Sanping Zhao[1], Mengwei Han[1], Songhao Luo[1],Bing Dong[1], Bing Xing[1]**

[1] *State Key Laboratory of Chemistry for NBC Hazards Protection, Beijing, China*

*zhuyb16@mail.ustc.edu.cn

**ABSTRACT**

Long-term live-training with munitions on military training ranges can lead to cumulative environmental impacts. The type and extent of contamination depends on the type of range, period of activity, soil chemistry and contaminant chemistry. Small arms firing ranges typically have high concentrations of metals and metalloids. Military ranges typically have high concentrations of energetic compounds, Such as perchlorates, white phosphorus, explosives and propellants etc. The characterization of military training ranges for energetics and metals is very important for understanding these contaminants' environmental fate and behavior, as defense agencies work to preserve ranges and prevent the migration of characteristic compounds into surface and ground waters. This paper will discuss the main techniques used for the analysis of heavy mteals and explosives in soils and water, remediation technologies for heavy metals-explosives contaminated soil. Analytic techniques focus on the areas of sample preparation and detection. For explosives, higher concentrations are found in sites that have undergone a low order detonation than in sites with a high order detonation. For heavy metals, higher concentrations are found in small arms firing ranges.

Remediation technologies for small arms firing ranges include leaching and immobilisation whereas for military ranges, methods such as alkaline hydrolysis, photolysis, bioremediation and phytoremediation have been tested. A lot of work has been done to immobilise metals/metalloids using soil amendments, which show a high effectiveness in stabilising them. Explosives can be transformed into simpler non-toxic forms by photolysis, bioremediation or phytodegradation. Explosives contaminated soils have been treated by incineration (32.1%), composting (46.5%), the redox process (1.2%), alkaline hydrolysis (12.6%) and solidification/stabilization(7.9%). Based on the results of recent pilot-scale treatability studies, in situ bioremediation has been proved to be effective in explosives contaminated soil remediation. The introduction of bacteria transgenes into plants has been used to enhance uptake and degradation of explosives in transgenic plants. Adoption of appropriate remediation technologies in impacted military ranges will reduce heavy metals bioavailability and explosives levels, inprove military soldiers health and ensure ecological environment safety.

# Phytoremediation Potential of Native Garden Plants in Urban Soil

**Chae Yeon Kim [1], Dokyun Lee [1], Sang Woo Han[1], Keum-Ah Lee [2], Saeng Geul Baek [3], Young-Nam Kim [1*]**

*[1] Kyungpook National University (Department of Crop Science, Sangju 37224, Republic of Korea)*

*[3] Sejong National Arboretum (Department of Garden Material, Sejong 30106, Republic of Korea)*

**ABSTRACT**

Urban soil has been contaminated with heavy metal(loid)s (HMs) due to the legacies of long-term anthropogenic activities. These contaminants in urban soil can pose serious health risks to humans, requiring remediation strategies to restore soil quality. This study evaluated the phytoremediation potential of native plant species in HMs-contaminated soil and identified the species with superior efficiency through a pot experiment. We selected 10 species of Korean native plants (*Melica scabrosa* Trin., *Carex matsumurae* Franch., *Dystaenia takesimana* (Nakai) Kitag., *Spiraea ouensanensis* H. Lév., *Vitex rotundifolia* L.f., *Gentiana scabra* Bunge, *Allium taquetii* H. Lév. & Vaniot, *Allium spirale* Wild., *Eupatorium lindleyanum* DC., and *Eupatorium fortunei* Turcz.) and 3 exotic species (*Allium tuberosum* Rottler ex Spreng, *Eupatorium lindleyanum* 'Pink Frost', and *Spiraea japonica* 'Nana') for comparison. These seedlings were transplanted to contaminated soil (330, 13, and 415 mg/kg for As, Cd, and Pb, respectively) and non-contaminated soil. Plant growth and physiological responses were monitored for 16 weeks. Total and available concentrations of HMs in soil were quantified, and various factors related to metal uptake by plants were calculated. Each species had five replicates in contaminated soil and three replicates in non-contaminated soil. As a result, native plants such as *M. scabrosa*, *V. rotundifolia*, *E. fortunei*, and *E. lindleyanum* showed significantly higher shoot height in HMs-contaminated soil than in non-contaminated soil at Week 16. Native *C. matsumurae* and *E. fortunei* showed 103% and 13% higher dry weight (DW) in HMs-contaminated soil compared to non-contaminated soil, respectively, whereas *D. takesimana* and *A. spirale* had 54% and 27% lower DW, respectively. For photosynthetic pigments, in Week 4, *M. scabrosa* and *A. taquetii* showed significantly higher chlorophyll and carotenoid contents in the contaminated soil than in non-contaminated soil, indicating that the tolerance mechanism to metal stress was activated at the seedling stage. Conversely, the lower content of the two pigments at harvest was attributed to long-term exposure to metal contamination. Total and available concentrations of HMs in soil did not alter during the cultivation. On the other hand, the concentration of HMs absorbed in plants varied with the plant species and the metal types. In general, *C. matsumurae*, *E. lindleyanum,* and *E. fortunei* showed a high capacity to absorb As, Cd, or Pb and accumulated them in the shoot parts, and the transfer factor, bioconcentration factor, and bioaccumulation factor related to this tended to be higher than those of other plant species. As a result of principal component analysis, native *E. lindleyanum* exhibited the highest efficiency in remediating Cd and As in HMs-contaminated soil, demonstrating strong plant performance and tolerance to metal stress.

# Multidimensional approach to anthropogenic markers - evidence from urban soils in Krakow (SE Poland)

**Kinga Jarosz[1*], Jolanta Dąbek-Głowacka[1], Krzysztof J. Jurek[2] Mateusz Stolarczyk[1], Mateusz Sobucki[1], Jan M. Michalik[3] Mariusz Lemke[1], Milena Adamowicz[1] and Marek Michalik[1]**

**ABSTRACT**

Reconstructing the evolution of geochemical processes in cities is critical for soil protection and urban ecosystem management, and provides an environmental context for the historical development of urban space. Urban soils act as stratified archives in which technogenic inputs and natural sedimentary layers jointly record shifts in land use, industrial activity, fuel use, and building practices. This study applies a multidimensional approach to evaluate anthropogenic markers preserved in urban soils of Krakow (SE Poland) and to test whether independent proxies converge toward a coherent reconstruction of changing anthropogenic pressure.

Four profiles were excavated in representative urban settings down to horizons corresponding to sediments of a former riverbed. Each profile was described in detail (soil structure, texture, artefact abundance, and type) and sampled at high vertical resolution. We assessed a broad suite of anthropogenic proxies: (i) magnetic particles and magnetic properties, as indicators of high-temperature combustion and industrial emissions; (ii) technogenic components such as fragments of construction materials, slags/cinders and soot; (iii) mineralogical composition; (iv) bulk geochemistry for major and trace elements; (v) persistent organic pollutants; and (vi) selected isotope ratios to support source attribution where applicable.

The integration of field descriptions with magnetic, mineralogical, chemical, and isotopic information, therefore, yields an internally consistent multi-proxy record of increasing and changing human impact, consistent with successive phases of urbanization and industrialization. Beyond site-specific reconstruction, the dataset provides a basis for a critical appraisal of the sensitivity, robustness, and interpretative limits of individual anthropogenic markers in complex urban soil settings, supporting their informed use in urban soil classification, monitoring, and historical environmental analysis.

The design targets soil-science challenges where single indicators may be ambiguous. Magnetic and artefact-based proxies track particulate inputs and construction-related transformations, while mineralogical and isotopic information help separate lithogenic background, river-derived material, and anthropogenic additions. Using stratigraphic ordering, the profiles allow chronologies to be inferred and distinguish intervals dominated by combustion residues from phases of construction and backfilling. Together, these proxies improve the identification of technogenic horizons in soil archives.

**ABSTRACT**

Nanjing is one of the old towns in China and dates back to more than 7000 years ago. Like other cities in China Nanjing grows very fast, from population of 2.6 million in the year 1949 to 9.6 million today. The urbanization rate is 87%. Nanjing has spread over the surrounding farmland and covers it by older and modern constructions. Different impacts of urbanization on soils can be observed. Soils of original horticultural and farmland has been changed to soils for urban use such as park areas, school yard, public lawn, roadside, between houses of residential areas constructed. Nanjing experienced the typical change of soil features by urbanization. In part the change differed between the older part and new construction areas of the city. The changes concerns the skeleton (stone) content, bulk density, pore volume and air and field capacity, pH value, carbonate, organic carbon, nitrogen, and phosphorus content, total stored organic carbon in soil profiles and C:N:P ratio. The changes of physical and chemical characteristics in urban soils will result in some environment problems. As a city with a long history, the formation of so-called cultural layers has special soil features, which can be used as a record of human activities. The urban soils in the old commercial, industrial and residential areas of Nanjing were generally with high organic and black carbon, as well as heavy metals, but their concentration levels varied significantly among the cultural layers formed in different dynasties. The studies of urban soil in Nanjing show new types of ecosystems which we have to learn to understand. The presentations will give some ideas what we can expect from soils.

*E-mail: wangmin@zhku.edu.cn

**ABSTRACT**

Accelerated urbanization underscores the importance of black carbon (BC) in urban soils, a key component of soil organic carbon with implications for ecosystem function and human health. This meta-analysis systematically integrated data from 54 studies comprising 4,548 sampling sites across 40 Chinese cities, supplemented by targeted field sampling, to examine the distribution, sources, and influencing factors of soil BC in urban environments. After rigorous screening, standardization, and outlier removal, correlation analysis and multivariate statistics were applied. Results showed an average urban topsoil BC content of 6.70 ± 5.34 g/kg, with marked spatial heterogeneity: higher concentrations were observed in eastern compared to western regions, and in northern relative to southern cities. Fossil fuel combustion—primarily vehicular emissions and industrial coal burning—was identified as the dominant source of BC, while biomass burning served as a secondary contributor, with additional local inputs from urban expansion and straw burning. Among natural factors, higher precipitation in southern regions enhanced BC migration, leading to reduced concentrations. Anthropogenic factors, however, exerted a stronger influence: cities with higher urbanization levels and greater energy consumption exhibited significantly elevated BC inputs. This study provides a comprehensive understanding of BC distribution patterns and source apportionment in China's urban soils, offering scientific support for urban environmental management and soil quality improvement amid ongoing urbanization, thereby contributing to sustainable urban development.

**ABSTRACT**

Soil organic carbon (SOC) in urban greenspaces can provide important ecosystem services for a large number of urban population around the world. However, the distribution, stocks, and drivers of SOC change in urban greenspaces are relatively unknown compared with those of natural ecosystems. To address this knowledge gap, we utilized 744 SOC measurements (0-30 cm depth) collected from urban greenspaces across 148 cities in China to investigate the key the distribution and drivers of surface SOC stocks (Fig.1).

Our analysis revealed weak correlations between in-field SOC measurements and estimates derived from widely used global SOC datasets (e.g., SoilGrids250m v2.0 and HWSD v2.0), underscoring the necessity for improved characterization of SOC distribution and its determinants in urban greenspaces (Fig.2). By employing Random Forest (RF) and SHapley Additive exPlanations (SHAP), we found that the enhanced vegetation index (EVI), mean annual precipitation (MAP), and social-economic status indicated by night-time light density (NLD) and population density (POP) were the most important predictors of surface SOC in Chinese urban greenspaces (Fig.3). RF model-predicted surface SOC in urban greenspaces was higher in moderately developed cities than in underdeveloped or highly developed cities. SOC increased with EVI, but displayed a hump-shaped trend with MAP, NLD, and POP. Spatial prediction of SOC stocks from the RF model showed that there were 0.21 (0.20-0.22, 95% confidence intervals) Pg C in the top 30 cm of soil in urban greenspaces of China (Fig.4), which was 17% and 50% greater than estimated by SoilGrids250m v2.0 (0.18 Pg C) and HWSD v2.0 (0.14 Pg C), respectively. Our study provides valuable data support and scientific guidance for carbon neutrality and urban greenspaces ecosystem management in China.

## ABSTRACT

Rare earth elements (REEs) are critical materials facing severe supply risks. Agromining, which uses hyperaccumulator plants to extract REEs from soils into harvested biomass, offers an eco-friendly alternative but is limited by the absence of efficient valorization pathways, since impurity cations complicate recovery. Here, we present an innovative strategy to directly upcycle biomass from the *Dicranopteris linearis*—rich in REEs, Al, and Si—into a high-performance biomass-derived REE catalyst (BioREOs) via a simple one-pot calcination (600 °C 2h ). The resulting BioREOs catalyst completely pyrolyzes polypropylene within 30 minutes at 400 °C, generating approximately 70% liquid oil with superior selectivity and efficiency compared to commercial REY catalysts. Mechanistic studies reveal that REEs within BioREOs stabilize an aluminosilicate framework, optimize Brønsted/Lewis acid site distribution, and promote selective β-scission while suppressing undesirable secondary cracking. We further identify potassium as a key interfering element that masks active acid sites, underscoring the importance of pre-removal. We demonstrate that directly upcycling REE-rich biomass into BioREOs catalysts exhibits a 2-fold increase in economic value and a 5-fold reduction in carbon footprint relative to conventional REY catalysts production, thereby establishing a commercially viable route for REE agromining through the valorization of both REEs and impurities.

**ABSTRACT**

This study investigates the interaction between soil physical properties and the metabolic profile of onions (*Allium cepa* L.) cultivated in two distinct urban desealed sites in Ancona, Italy: Torrette and Vallemiano. Both sites were characterized by degraded technosols with high compaction and low organic content, treated with identical compost amendments. However, chemical analysis revealed a significant divergence in bulb composition: stachyose and raffinose were exclusively detected in onions from Vallemiano treated with compost, while being entirely absent in those from Torrette. These results are closely linked to the degree of soil sealing. In Torrette, the impermeable asphalt cover induced severe anoxic conditions, leading to a metabolic shutdown and preventing the energy-intensive biosynthesis of Raffinose Family Oligosaccharides (RFOs). Conversely, the degraded and heterogeneous surface at Vallemiano allowed for gas exchange and water infiltration. In this site, the combination of mechanical stress from fine-textured soils and chemical stress from secondary carbonates acted as an elicitor. Supported by the aerobic respiration permitted by the site's porosity, the onions utilized compost-derived nutrients to synthesize RFOs as essential osmoprotectants. These findings suggest that soil oxygenation is a prerequisite for the beneficial effects of organic amendments on plant resilience and that RFO accumulation serves as a bio-indicator of active metabolic adaptation in challenging urban environments.

**ABSTRACT**

Soils are the foundation of our urban environments but are rarely recognised for their multiple critical roles in climate regulation, flood control, local food production, connection of people to nature, and human health and well-being. Soil underpinning urban green spaces – particularly those with trees, are instrumental to delivering many of these benefits and the importance of urban soils is gaining greater attention internationally, for example, 'Healthy Soils for Healthy Cities' was the theme for World Soils Day 2025.

However, recognition of the value of urban soils is often overshadowed by the perception (and also the reality) of contamination from multiple anthropogenic activities. This focus on contamination, and sometimes overly precautionary approaches to its' management, can be key drivers for the unnecessary disposal of large volumes of soil to landfills. In New Zealand, soil was estimated to represent 87% of the 27.4 million tonnes of material disposed to landfills, including 'clean fills', in 2023 – highlighting also the significant opportunities for soil reuse.

In this presentation we outline three contrasting case studies from New Zealand that illustrate barriers and opportunities to realising different benefits of urban soils:

- Sustainable management of surplus soils (soils that have been disturbed through land and infrastructure development or natural processes – e.g. landslips, silt/sediment – and are unable to be beneficially used on-site)
- The nexus of 'background' soil concentrations, soil contaminant guideline values, waste acceptance criteria and the management of contaminated land and surplus soils
- The role of soil in increasing the 'sponginess' of cities to help manage and mitigate flooding events

We also draw on these case studies to identify key requirements for effecting improvements in urban soil quality as part of the development of a guide to regenerating urban soils.

# Effect of solar panel installation on past agricultural soils

**Masayuki Kawahigashi[1*], Mari Tezuka[1], Takuto Kajiwara and Takuya Takahashi[1]**

*[1]Tokyo Metropolitan University (Department of Geography, Institute, Tokyo, JAPAN)*

*khigashi17@gmail.com

**ABSTRACT**

The installation of solar panels is being promoted to increase the proportion of renewable energy sources in Japan's energy consumption. The installation requires civil engineering works on the ground, resulting in change in soil properties. Again, since the installed solar panel prevents solar radiation and rainfall on the ground, soil physico-chemical properties will be changed after the installation. This study investigated change in soil properties under and outside of the solar panels installed on past agricultural land. The soil under the solar panel installed previous paddy field has still kept mottles in the subsurface horizon with high Feo/Fed. However, the soil at the outside has no mottles and lower ratio of the secondary irons. Although the former soil was classified as Anthraquic Allophanic Andosols, the latter was Lowland Reformed Soils due to disappearance of mottles. Plants grow well on soils outside the solar panels due to taking rainfall and solar radiation compared to soils beneath the solar panels, resulting that lower available phosphorus and pH were recorded in the soils outside of the solar panels. Differences in the soil properties observed beneath and outside solar panels installed on upland fields cultivated for vegetables did not affect soil classification. The basement of solar panels also influences soil physical properties. Installation of solar panels using concrete block foundations makes land hard and difficult to reform the land. However, pile foundations influence on the ground with less damages, resulting in soft surface ground like as an agricultural field. Pile foundations are often used for solar panel installations that involve agricultural land uses. The future of field power stations using solar panels will increase anywhere in the world. However, power generation efficiency gradually declines due to dirt and degradation on the panel surface, potentially rendering it no longer worthwhile as compensation for land use. When the land use should be changed, the soil information is required. It is desirable to install solar panels in a manner that maintains the land in a condition suitable for conversion back to green spaces with productive soils.

## ABSTRACT

Subsurface soil acidity is a major constraint to agricultural production and remains difficult to ameliorate using conventional surface liming. A promising approach is to enhance the mobility of liming materials into the subsoil by increasing their solubility and reducing particle size, thereby promoting colloidal transport. Humic substances, particularly fulvic and humic acids contain diverse functional groups (e.g., carboxyl, amino, and hydroxyl) that may complex with calcium ($Ca^{2+}$) and facilitate the movement of lime-derived $Ca^{2+}$ and bicarbonate ($HCO_3^-$) into deeper layers, neutralizing acidity and increasing base cations. This study evaluated the effect of humate products on lime dissolution in acidic aqueous and soil systems. Potassium humate (K-humate), potassium fulvate (K-fulvate), and a fulvic-acid soluble powder were assessed for their influence on agricultural lime and dolomite dissolution over 14 days. An acidic sandy subsoil (10–20 cm) was used in the study. Dissolution was quantified by measuring increases in $Ca^{2+}$ and $Mg^{2+}$ concentrations in solution with ICP-OES. K-fulvate significantly enhanced lime dissolution in both aqueous and soil systems ($p < 0.001$). Non-linear Elovich model was well fitted ($r^2$=0.99) to Ca and Mg time-series data describing the kinetics of agriculture lime and dolomite dissolution in soil system over the 14-day period. Overall, dolomite dissolution in the soil system was more than double that in the aqueous system. This indicated that the humate products used in the study were not appreciably retained by the soil under experimental conditions and therefore did not inhibit their effect on lime dissolution, and facilitation of $Ca^{2+}$/$HCO_3^-$ movement into the subsoil. Additionally, the soil acted as a sink for dissolved ions, sustaining dissolution over time. Future work will include comprehensive evaluation of humate-amended lime on soil chemical properties and crop productivity.

**ABSTRACT**

Excessive application of mineral fertilizers has accelerated soil acidification in China, affecting the production of crops when the pH drops below a critical value. However, the contributions of natural soil acidification, induced by leaching of bicarbonate, and anthropogenic causes of soil acidification, induced by nitrogen (N) transformations and removal of base cations over acid anions by crop harvest, under different fertilization management strategies, in particular considering the impact of land use, climate, and soil type are not well quantified. In this study, we quantified soil acidification rates, in equivalents (eq) of acidity, by assessing the inputs and outputs of all major cations and anions, including calcium, magnesium, potassium, sodium, ammonium, nitrate, bicarbonate, sulphate phosphate and chloride, for 13 long-term experimental sites in southern China. The acidification rates strongly varied among fertilizer treatments and with the addition of animal manure. In non-calcareous upland soils, the main driver of soil acidification was the overuse of nitrogen (N) and associated nitrate leaching. Reducing the N surplus decreased the acidification rate with 10 to 54 eq per kg N surplus with the lowest value occurring in paddy soils and the highest in upland soils. Natural bicarbonate leaching was the dominant acid production process in all calcareous soils (23 keq $ha^{-1}$ $yr^{-1}$) and in non-calcareous paddy soils (9.6 keq $ha^{-1}$ $yr^{-1}$), accounting for 80% and 68% of total acid production rate, respectively. The calcareous soils were strongly buffered, and acidification led to a decline in calcium carbonate levels but with no or a limited decline in pH. In contrast, N transformations were the most important driver for soil acidification in upland crops on non-calcareous soils, accounting for 72% of total acid production rate of 8.4 keq $ha^{-1}$ $yr^{-1}$. In these soils, the soil pH considerably decreased being accompanied by a substantial decline in exchangeable base cation. The use of manure, containing base cations, partly mitigated the acidifying impact of N fertilizer inputs and crop removal, but enhanced phosphorus (P) accumulation. Combining mineral fertilizer, manure and lime in integrative management strategies can mitigate soil acidification and minimize N and P losses.

*[2] Key Laboratory of Ecosystem Network Observation and Modeling, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences (CAS), Beijing, 100101, China*

Xiaoqiong@caas.cn

**ABSTRACT**

Understanding soil organic matter (SOM) mineralization is critical for predicting soil carbon (C) cycling, yet the effects of diurnal temperature fluctuations and their interactions with labile C inputs remain unclear. Acidic arable soils were incubated for 42 days under constant temperatures (15 or 25 °C) or diurnal temperature fluctuations, without or with $^{13}$C-glucose addition. Diurnal fluctuations enhanced cumulative SOM mineralization and priming effects, with a higher temperature sensitivity ($Q_{10}$) of priming (2.6) than constant temperatures (2.4). The higher $Q_{10}$ was associated with an increased response of C-degrading enzyme activities to warming. At the community level, fungal diversity declined with warming, particularly under diurnal fluctuations. Although microbial networks were restructured, their topology exerted little influence on SOM mineralization. Instead, fungal diversity and cellobiohydrolase activity were the primary drivers of variation in SOM mineralization and its $Q_{10}$. These findings provide mechanistic insights into acidic soil C cycling under climate change, emphasizing the importance of incorporating daily temperature fluctuations into predictive models.

## ABSTRACT

The release of solid aluminum (Al) in soil, induced by exogenous acid, is the primary factor limiting crop growth in acidic soils. Biochar has been demonstrated to reduce the concentration of active Al in soil under equivalent acid input. However, the dynamic mechanisms by which it mitigates Al release remain unclear. A stirred-flow dynamic acidification experiment was conducted to comparatively analyze the kinetic processes of solid-phase Al release in soils amended with biochar and lime. The results indicate that the release of Al from each treated soil exhibits distinct stage characteristics during the acidification process: an initial phase with acceleration, a subsequent phase of deceleration, and a final phase with uniform speed. These stages can be accurately fitted using piecewise functions representing first-order dynamics, pseudo-first-order dynamics, and linear equations ($R^2$ >0.999). The fitting results suggest that the three stages are governed by proton diffusion, potential active Al diffusion, and solid-phase Al dissolution, respectively. At the end of the reaction, the cumulative release of Al from soil amended with biochars was 8.98% ~17.23% lower than that in soil amended with lime. This reduction primarily occurred at the early and middle stages of acidification. In the initial stage, biochar competes for $H^+$ by protonation of surface organic functional groups, thereby inhibiting $H^+$ involvement in the Al release reaction. Concurrently, biochar reduces the diffusion rate constant of $H^+$ in soil through its porosity, collectively decreasing the solid Al release rate. In the middle stage, both peanut straw biochar and rice straw biochar significantly decreased the soil Al diffusion rate constant, with reductions ranging from 20.29% to 62.75%. Notably, rice straw biochar also resulted in a 17.84% reduction in the potentially active Al content in the soil. Consequently, the effect of rice straw biochar in slowing down the release rate of soil Al was superior to that of peanut straw biochar during the middle stage of acidification. In the later stage of acidification, the release rate of soil Al was not affected by biochar. Biochar enhances the kinetic stability of solid Al release in acidified soils by improving soil pH buffering capacity, reducing the potential active Al content, and optimizing soil pore structure. These findings offer a theoretical foundation and technical support for the long-term prevention and management of Al toxicity in acidic soils.

## ABSTRACT

Organic amendments, e.g., livestock manure, straw, green manure, have shown profound performance to enhance soil carbon (C) sequestration and crop productivity. However, despite extensive research on their individual benefits, the synergistic effects of combining plant-derived C and livestock manure inputs on soil pH buffering capacity (pHBC)-the key determinant that governs proton neutralization and reflects the soil long-term resistance to acidification. In the present study, based on a 42-year ongoing field experiment, we explored the response of pHBC and crop productivity to synergistic incorporation of plant-derived C input (green manure, green manure combined with straw) vs. diverse-derived C input (livestock manure combined with plant-derived C input) from various organic amendments. Mineral fertilization caused pH decline by 0.12-0.39 units, compared with diverse-derived C input. Plant-derived C input showed no significant effect on pHBC either after three or four decades versus control. However, the diverse-derived C input, e.g., synergistic incorporation of green and livestock manure, increased soil pHBC by 31-40% compared with control. This improvement was primarily attributed to increases in exchangeable $Ca^{2+}$ and the accumulation of soil organic matter (SOM), particularly humic substance compositions. Furthermore, the protonation of organic anions released during humic acid dissociation provided abundant proton-binding sites under diverse-derived C input, thereby enhancing the soil's intrinsic pH buffering capacity and strengthening its resistance to further acidification. In addition, the exchangeable $Al^{3+}$ was decreased by 67%-88% with diverse-derived C input, relative to control. This was due to the accumulation of humic acids promotes Al-organic complex formation, consequently reducing the exchangeable $Al^{3+}$ in soil solution. The increase in Alp content under diverse-derived C input also confirmed that. Critically, the mitigation of soil acidification establishes a critical foundation for improving crop yields, average outperforming control and plant-derived C input by 32% and 12%, respectively. These findings highlight that the diverse-derived C input based on soil amendments as agronomically optimal and environmentally sustainable strategy to mitigate soil acidification and sustain crop productivity in acid soil area.

# Co-application of lignosulfonate and calcium–magnesium phosphate fertilizer, an effective liming strategy for acidic purple soils in southwest China

***Debo He*** [1, 2], ***Joann K. Whalen*** [2], ***Bo Zhu*** [1 *]

[1] *Institute of Mountain Hazards and Environment, Chinese Academy of Sciences, Chengdu, 610041, China*
[2] *Department of Natural Resource Sciences, McGill University, Montreal, Quebec H9X 3V9, Canada*
*E-mail Address of Presenting Author: *Bo Zhu*, bzhu@imde.ac.cn

**ABSTRACT**

Purple soils in southwestern China are facing the dual challenges of soil acidification and declining fertility. Particularly, the accumulation of phytotoxic exchangeable aluminum ($Al^{3+}$) and the reduction of available phosphorus, which respectively promote the leaching of base cations and constrain crop growth, collectively constitute a substantial threat to soil health and food security. The disadvantages and high costs associated with amendment lime highlights the need for alternative soil amendments. Here, we demonstrate an efficient co-application strategy using a base ion-enriched organic amendment, calcium lignosulfonate, in combination with calcium–magnesium phosphate fertilizer to ameliorate acidic purple soils (Figure 1). During the maize growing season, this co-application of 1 wt% calcium lignosulfonate and 1 wt% calcium–magnesium phosphate fertilizer increased soil pH by 0.32–1.16 units, reduced exchangeable $Al^{3+}$ by up to 88%, and enhanced soil organic matter and available phosphorus contents by 24–35% and 142%, respectively. These improvements translated into substantial agronomic benefits, with maize yields increasing by 62–176% compared with unlimed soil conditions. Molecular modeling revealed that the functional groups of calcium lignosulfonate exhibit strong competitive adsorption of $Al^{3+}$ ions over base cations and facilitating the formation of stable $Al^{3+}$–sulfonate precipitates (Figure 2). Moreover, the co-application restructured beneficial microbial communities and enhanced functional genes involved in soil carbon and phosphorus cycling (Figure 3). These amendments not only promoted soil organic acids and ABC transporters to enhance the immobilization and detoxification of exchangeable $Al^{3+}$, but also increased available phosphorus and enzyme activities to alleviate phosphorus limitation. Collectively, these physicochemical and microbial improvements indicate that the co-application of calcium lignosulfonate and fused calcium–magnesium phosphate fertilizer represents an economically viable and sustainable strategy for detoxifying phytotoxic exchangeable $Al^{3+}$, enhancing the fertility of acidified purple soils, and safeguarding soil health and food security.

## ABSTRACT

Rapid acidification of purple soils in southwestern China severely threatens crop productivity by intensifying exchangeable acidity, accelerating base-cation depletion, and inducing phytotoxic $Al^{3+}$ stress. High costs and limited persistence of conventional lime underscore the need for practical and scalable alternatives. Here, we demonstrate that the co-application of calcareous parent rock powder (M) and a self-selected acid-suppressing bacteria (H) provides a highly effective strategy for restoring acidified purple soils during maize cultivation. The combined M+H treatment markedly improved soil chemical properties, elevating soil pH to 5.14–5.17, reducing exchangeable acidity by more than 80%, and doubling exchangeable base cations compared with the untreated control. Soil available P and rapidly-available K increased to 80–85 mg $kg^{-1}$ and 12 mg $kg^{-1}$, respectively, accompanied by enhanced carbonate buffering and cation exchange capacity. These benefits translated into substantial agronomic gains, with maize root biomass, total biomass, and hundred-grain weight increasing by 60–120%, 90–110%, and 150–200%, respectively. Importantly, the M+H synergy also restructured beneficial microbial communities and strongly stimulated the expression of ABC transporters and functional genes associated with organic acid metabolism, P mobilization, and $Al^{3+}$ detoxification. These microbial enhancements accelerated the immobilization and detoxification of phytotoxic exchangeable $Al^{3+}$, forming a stable soil–mineral–microbial buffering system that sustains long-term soil fertility improvement. Collectively, these findings highlight that the co-application of calcareous parent rock powder and acid-suppressing microbes represents an innovative, low-cost, and scalable solution for mitigating $Al^{3+}$ toxicity, rebuilding fertility, and enhancing crop productivity in acidified purple soils—offering substantial potential for improving regional soil health and agricultural resilience.

**ABSTRACT**

Dissolved organic matter (DOM), as a sensitive indicator reflecting changes in the soil organic carbon pool, its characteristic variations and driving factors has long been a research focus worldwide. The incorporation of organic amendments such as crop straw into agricultural soils influences both the quantity and composition of soil DOM, thereby regulating organic carbon turnover and playing a pivotal role in terrestrial ecosystem carbon cycling. The decomposition and transformation of returned straw into soil DOM constitute is a highly complex process involving chemical, physical, and biological interactions. These processes are governed by multiple factors including environmental conditions, intrinsic properties of the straw, and microbial activity. Soil aggregates serve as crucial protective microenvironments for soil organic matter; at the same time, their formation is closely linked to the effects of organic matter and microbial transformations. Consequently, elucidating how soil microorganisms drive organic matter transformation at the aggregate scale is of great significance for understanding the mechanisms underlying soil carbon sequestration. Our study investigated how combined organic-inorganic fertilization influences the molecular characteristics of dissolved organic matter (DOM) within different soil aggregates and its interaction with bacterial communities. This long-term experiment evaluated the effects of five treatments: a no-fertilizer control (CK), chemical fertilizer alone (NPK), and NPK in combination with straw (NPKS), straw and manure (NPKSM), or straw-derived biochar (NPKSB). Soil was fractionated into large (LMA), small (SMA), and micro-aggregates (WMA) for analysis. Results showed that the NPKSM treatment increased the aromaticity and nominal oxidation state of DOM in LMA and SMA, but decreased them in WMA. It promoted the accumulation of recalcitrant compounds like lignin and tannins in macro-aggregates, driven primarily by thermodynamically favorable processes. The transformation of DOM components increased by 3.77%-34.94% in these aggregates. Bacterial community analysis revealed that microbes in SMA tended to synthesize DOM and exhibited stronger collaboration, particularly through interactions between lignin and Acidobacteriota, which enhanced carbon sequestration. This research clarifies the microbial-mediated mechanisms of soil carbon cycling in red soil aggregates under different fertilization.

## ABSTRACT

Mycorrhizae play an important role in mediating soil aggregate formation. Intercropping can influence rhizosphere mycorrhizae , but the mycorrhiza-mediated effects and mechanism on soil aggregates in intercropping system remains unclear. This study aims to investigate the effects of maize//soybean intercropping on soil aggregate stability and the mycorrhiza-mediated mechanism in acid soil under intercropping.

**Methods:** Based on a 7-year continuous field positioning experiment, two planting patterns: maize monoculture (MM) and maize//soybean intercropping (MI) were compared under four phosphate application rates (P0, P60, P90, P120, corresponding to 0, 60, 90, 120 kg $P_2O_5$ $ha^{-1}$, respectively), the effects of maize//soybean intercropping on mycorrhizal colonization, glomalin content, soil aggregate composition, and stability were analyzed.

**Results:** The results showed that, maize//soybean intercropping significantly improved soil aggregate atability and mycorrhizal colonization. Under different phosphate application levels, compared to the corresponding monoculture, maize // soybean intercropping increased the soil macroaggregate content by 11.48%,the mean weight diameter(MWD) average increased by 5.35% ,and the geometric mean diameter (GMD） average ncreased by 6.72%. The mycorrhizal colonization rate, hyphal density and spore density of intercropped maize average increased by 33.2%,30.7% and 29.15%, respectively. The easily extractable glomalin(EEG) and total glomalin (TG)average increased by 23.49% and 20.22%, respectively. Random Forest model analysis indicated that, soil macroaggregate content contributed the most to soil aggregate stability, while the important contributing factors affecting soil macroaggregate content were, in order: total glomalin, easily extractable glomalin, hyphal density, mycorrhizal colonization rate, and spore density. Structural equation modeling further revealed that maize//soybean intercropping enhanced the content and proportion of macroaggregates in red soil by increasing mycorrhizal colonization and glomalin content, thereby promoting the stability of red soil aggregates.

In conclusion, maize//soybean intercropping mediated the formation and stabilization of soil aggregates by significantly stimulating the mycorrhizal colonization and their secretion of glomalin, thereby improving soil structure and ultimately promoting increased crop yield.

## ABSTRACT

Biochar and compost derived from straw present synergistic effects on acidity mitiga-tion and carbon sequestration in acidic soil, however, the differential synergistic effects and mechanisms remain poorly understood. This study investigates the comparative effectiveness of rice straw biochar (BC) and compost (DC) on acidic soil amelioration through an incubation experiment. BC demonstrated superior performance in soil pH elevation (0.39 vs. 0.28 pH units) and exchangeable acidity reduction (69% vs. 62%) due to higher alkalinity (148.51 vs. 115.73 cmol $kg^{-1}$) than DC. Additionally, BC decreased soil potential active Al pool more than DC (35.1% and 25.2%) through promoting hy-drolytic precipitation. Carbone fractions analysis showed that BC enhanced soil or-ganic carbon more effectively (83.7% vs. 64.0%), it reduced ROC (27.6%) and DOC (24.0%), contrasting with DC's increases (31.6% and 93.8%, respectively). The contrary effect was attributed to BC's lower active carbon content, higher alkalinity, and C/N ratio. Both amendments improved soil fertility, with BC and DC increasing ex-changeable $K^+$ (14.0 vs. 12.3 times), $Ca^{2+}$ (5.4 vs. 4.9 times), $Mg^{2+}$ (3.7 vs. 5.2 times), and ECEC (11.8% vs. 15.2%). These findings demonstrate BC's superior acidity mitigation and carbon sequestration, while DC shows greater active carbon enhancement and fertility improvement.

## ABSTRACT

Soil acidification leads to the activation of solid-phase aluminum (Al), and the toxicity of Al and manganese (Mn) in acidic soils is the primary cause of poor plant growth and reduced yields of crops in such soils. When plants are subjected to Al stress in acidic soils, their root systems actively secrete low-molecular-weight organic acids into the rhizosphere soil solution. These organic acids form low-toxic or non-toxic Al-organic acid complexes with the active Al in the soils, thereby mitigating Al toxicity. This is the primary mechanism by which plants adapt to Al stress in acidic soils. Recently, we discovered a novel mechanism by which a plant adapts to Al and Mn toxicity in acidic soils. When plants are subjected to the stresses of Al and Mn, their roots produce fewer surface functional groups and surface negative charges, thereby reducing the adsorption of $Al^{3+}$ and $Mn^{2+}$ by the roots and alleviating the toxicity of these two cations to the roots. In hydroponic experiments, when rice grows in a nutrient solution containing Al and $NH_4^+$, the rice absorbs $NH_4^+$ and releases $H^+$ into the nutrient solution through its roots, which leads to a decrease in the pH of the nutrient solution, and should enhance the toxicity of Al to rice roots. However, Al causes less damage to rice roots growing in nutrient solutions containing $NH_4^+$ than those growing in nutrient solutions containing Al and $NO_3^-$. The measurements of zeta potential and infrared spectroscopy of rice roots showed that the number of functional groups and negative charges on rice roots grown in $NH_4^+$ nutrient solution was lower than that of rice roots grown in $NO_3^-$ nutrient solution, and the adsorption capacity of rice roots for $Al^{3+}$ and $Mn^{2+}$ was also lower in the former than in the latter, providing experimental evidence for the above mechanism. Similar hydroponic experiments were conducted on corn, soybeans, and wheat, and similar experimental phenomena were observed, indicating that these plants have the same mechanism of adaptation to Al and Mn toxicity. Adjusting the pH of a red soil to 4.5 and 6.5 respectively, and then conducting pot experiments on these plants, it was found that the number of functional groups and negative charges on the roots of plants grown in pH 4.5 red soil was lower than those grown in pH 6.5 red soil, indicating that plants use the above mechanism to alleviate the toxicity of Al and Mn in acidic soils. Further research indicated that D-galactose, malate and trehalose were critical regulators of hemicellulose biosynthesis and cell wall remodeling of plant roots. Al stress downregulated D-glucosamine metabolism while upregulating cutin/suberin/wax components docosanoic acid and 22-hydroxydocosanoate. This shift reduced synthesis of hemicellulose, inhibited cell wall assembly enzymes, and thus decreased cell wall negative charge and anionic oxygen-containing functional groups.

# Incorporating lime into acidic subsoil improved root growth and rhizosphere microbial activity in wheat

## ABSTRACT

Soil acidification is a widespread problem threatening sustainable crop production in many agricultural regions worldwide. In Western Australian agricultural regions, 70% of surface soils and approximately 50% of subsurface soils are below the target pH ($CaCl_2$) for optimal crop growth. Lime application is one of the common practices to improve soil acidification, as it neutralizes soil acidity, raises pH, and enhances nutrient availability. However, the movement of lime from topsoil to subsoil is slow, leaving the deeper soil layers in unfavorable conditions for crop growth. Recent research demonstrates the potential role of rhizosphere microbes in the mitigation of environmental stress. However, how soil re-engineering with lime affects soil microbial communities is poorly understood. We used acidic subsoil (pH4.6 in $CaCl_2$, 10–40 cm) and neutral topsoil (0–10 cm) collected from a farm in Grass Valley (31.40°S, 116.41°E) in the wheatbelt region of Western Australia Grass Valley, Western Australia, to re-construct soil profiles into 40-cm deep PVC columns after air-died and sieved. The subsoils were amended with lime (1 g $kg^{-1}$ soil). Half of the soils were steam sterilized to compare microbial activity. Wheat plants were assessed at the tillering and milking development stages for analyses of root morphology, photosynthetic performance, soil pH, and microbial biomass carbon (MBC). Results revealed that lime application significantly enhanced microbial biomass in the subsoil during the milking stage. Moreover, there was lime × sterilization interaction in the pH in both topsoil and subsoil at both growth stages. Sterilization significantly increased intercellular $CO_2$ concentration (Ci) and stomatal conductance (Gs). Principal component analysis demonstrated that soil re-engineering promoted subsoil root proliferation in the presence of active microbial communities at the tillering stage. During the milk development stage, soil re-engineering and active microbial presence greatly enhanced canopy greenness, photosynthetic activity, and color saturation. In conclusion, soil re-engineering with lime significantly improved soil pH in subsoil, promoted wheat growth, and microbial activities in the subsoil. In return, improved soil microbial activities promoted root growth in the subsoil through altering root morphology, regulating stomatal behavior, and enhancing canopy photosynthetic performance and color vitality.

# Spatio-temporal Variation Characteristics and Driving Mechanisms of Soil pH in Farmland of the Changbai Mountain–Liaodong Region

**Runxue Bi[1]*, Hongtao Zou[1]**

*College of Land and Environment, Shenyang Agricultural University, Shenyang, China*

Brx0604@163.com

**ABSTRACT**

Soil acidification impacts regional food security and the sustainable development of agricultural systems. To formulate and implement targeted measures for preventing and mitigating acidification in farmland soils, it is essential to clarify regional soil pH heterogeneity and its influencing factors. This study, based on a comparison of 6,428 pairs of surface soil pH data collected at identical locations in the Changbai Mountain–Liaodong region in 1984 and 2024, elucidates the spatial variability characteristics of agricultural soil acidification in this area and its influencing factors. Results indicate that over the past four decades, the mean surface soil pH in the Changbai Mountain–Liaodong region has decreased by 0.5 to 1 pH units. Over 90% of farmland exhibits varying degrees of acidification, with the phenomenon showing a trend of expanding from localised areas to broader zones and progressing from mountainous to hilly terrain. Notably, the rate of acidification intensified significantly more between 2010 and 2024 than during the preceding decade from 1980 to 2010. Changes in the surface pH of agricultural soils are closely linked to factors such as climate, atmospheric deposition, topography, and inherent soil properties, reflecting multi-level coupling mechanisms under complex environmental conditions.

**ABSTRACT**

Soils are classified as Permanent charge soil (PCS) and Variable charge soil (VCS). However, the distinct acidification responses in the two soil types are still unclear. This study aimed to clarify the mechanism of ion exchange reactions governing soil acidification and their differences in PCS and VCS, and provide specific and tailored practices for acidification amendment of croplands with different surface charge properties. The release of ions and basic properties of two PCS (PCS-QX, PCS-XC) classified as cambisols and two VCS (VCS-QY, VCS-ML) classified as Typic Hapludults after soaking in acid were determined. The results indicated that the release of calcium ions ($Ca^{2+}$) and magnesium ions ($Mg^{2+}$) in PCS was higher than in VCS; conversely, the release of aluminum ions ($Al^{3+}$) in PCS was lower than in VCS. Both PCS and VCS showed the same patterns in the release of potassium ions ($K^{+}$) and manganese ions ($Mn^{2+}$), following the sequence of VCS-QY > PCS > VCS-ML. Moreover, the release of iron ions ($Fe^{2+}$) in the two soil types was extremely low. The release of $Al^{3+}$ in PCS was best described by the Elovich equation, indicating that the surface reactions governed it; conversely, VCS was best described by the parabolic diffusion equation, indicating that the intragranular diffusion governed it. Across all soil types, the release of $Ca^{2+}$ and $Mg^{2+}$ was best described by the two-constant rate equation, indicating complex release mechanisms. The release of $K^{+}$ and $Mn^{2+}$ was best described by the Elovich equation and the parabolic diffusion equation, respectively, which was attributed to the specific adsorption of $K^{+}$ and the reduction dissolution process of manganese oxide, respectively. In summary, the acidification of PCS is primarily governed by non-pH-dependent cation exchange processes, whereas pH-dependent surface charge alterations and mineral dissolution dominate that of VCS. As a result, improving PCS acidification should focus on replenishing base cations, whereas improving VCS requires fundamentally increasing its negative charge and reducing aluminium toxicity through the application of organic fertilisers to raise pH levels. Future research should focus on the distinct acidification mechanisms and behaviors in surface properties between PCS and VCS.

Keywords: Acid sulphate soil, Climate change mitigation, Rice paddy, Nutrient cycling

## ABSTRACT

Since the adoption of the Paris Agreement in 2015, climate change mitigation has become an urgent global issue, and agriculture is a major source of methane ($CH_4$) and nitrous oxide ($N_2O$) emissions (FAO, 2021b; Gütschow et al., 2021; Saunois et al., 2020). Rice, the staple food for nearly half of the world's population, is mainly produced in Asia (FAOSTAT, 2024). However, flooded paddy fields emit $CH_4$ due to methanogenic activity under anaerobic conditions. Intermittent irrigation is an effective strategy for reducing $CH_4$ emissions, but temporary soil drying may alter the dynamics of other soil constituents. In Asian coastal regions, acid sulfate soils (ASS) are widely distributed and may inhibit rice growth under alternating flooding and drainage due to soil acidification. With increasing food demand, the utilization of marginal soils such as ASS is expected to expand, highlighting the need for rice cultivation practices that ensure stable yields with reduced environmental impacts.This study aimed to identify the optimal drainage intensity of intermittent irrigation that reduces greenhouse gas emissions (GHG) from ASS paddy while maximizing rice yield.

A pot experiment was conducted using soils collected from Ogata Village, Akita Prefecture (OG), Inashiki City, Ibaraki Prefecture (IN), and a research field at Hachimandai (HM) as a control. Three water management treatments were applied: continuous flooding (CF), moderate intermittent irrigation (MD), and intensive intermittent irrigation (PL). The rice cultivar IR64 was used. GHG fluxes were measured using the closed chamber method, and $CH_4$ and $N_2O$ concentrations were analyzed by gas chromatography. After harvest, rhizosphere growth, yield components, and basic soil physicochemical properties were evaluated.

Soil pH ($H_2O/H_2O_2$) values were 7.35/5.08 for OG soil and 4.23/3.52 for IN soil, which did not meet the criteria for sulfuric acidity. However, the low pH($H_2O_2$) of IN soil suggested the presence of pyrite ($FeS_2$). Available phosphorus contents were similar between OG and IN soils, whereas calcium content was much higher in OG soil (32.85 cmolc $kg^{-1}$) than in IN soil (3.49 cmolc $kg^{-1}$), possibly due to shell-derived calcium before land reclamation. Under CF conditions, post-harvest rhizosphere growth was highest in HM soil, followed by OG and IN soils. In contrast, rhizosphere growth in IN soil improved under MD and PL conditions compared with CF, suggesting suppression of hydrogen sulfide ($H_2S$) production by intermittent irrigation. Grain dry weight and aboveground biomass were consistently lower in IN soil across all treatments. Aboveground biomass was highest under CF in HM and OG soils, whereas it was highest under PL in IN soil.

Moderate intermittent irrigation in ASS paddy can suppress $H_2S$ production and improve rice growth and yield, while also tending to reduce $CH_4$ emissions. Further analysis is ongoing to clarify soil–water management interactions.

# Liming regulates MAOC-POC trade-offs in paddy soils through a coupled mineral-microbial mechanism

## ABSTRACT

Excessive application of chemical fertilizers has accelerated soil acidification in paddy soils of southern China, reducing rice productivity once pH falls below a critical threshold. Liming is widely used to raise soil pH, yet how different lime materials regulate soil organic carbon (SOC) fractions via microbe–mineral interactions remains poorly understood. Here, we conducted a controlled incubation experiment to quantify how contrasting lime materials influence SOC fractionation and stabilization in paddy soils. Increasing pH systematically redistributed SOC among fractions: higher pH enhanced cation bridging and favored the accumulation of mineral-associated organic carbon (MAOC), a relatively stable pool important for long-term carbon storage. In contrast, elevated pH weakened Ca-mediated bonding within particulate organic matter, leading to pronounced losses of particulate organic carbon (POC), a more labile pool that supports short-term nutrient supply. Microbial communities responded differentially across treatments. Fungi increased strongly with rising pH, whereas bacterial responses were constrained by threshold effects, together increasing the fungal-to-bacterial ratio. This shift in microbial dominance redirected carbon turnover from rapid, broad-substrate decomposition toward a strategy prioritizing the degradation of more recalcitrant carbon, producing a "quality increase, quantity decrease" pattern in the SOC pool. Integrating mineral and microbial evidence, we showed that SOC stabilization was constrained to a narrow pH window (5.5-6.5) governed by two coupled mechanisms: a "mineral adsorption threshold" that limits additional MAOC formation and a "microbial metabolic switch" that alters decomposition pathways, with $Ca^{2+}$ acting as a key fine-tuning agent. Maintaining paddy soils within this optimal pH range may therefore help balance the trade-off between long-term carbon sequestration (MAOC) and the active carbon pool (POC) that sustains soil biological activity, fertility, and crop production.

# Straw return exacerbates soil acidification in major Chinese croplands

**ABSTRACT**

Soil acidification in croplands is a worldwide problem threating grain production and agricultural sustainability. Straw return has been widely recommended as a practice of climate-smart agriculture. It is generally believed that straw return also helps to alleviate soil acidification, while this assumption has not been tested over large geographical areas. Here, we assess its contributions to soil acidification based on three datasets across China. Unexpectedly, we found straw return predominately aggravated soil acidification in 145 investigated field experiments. The magnitude of straw-induced soil pH change was negatively correlated with the initial soil pH. Based on data from a national soil survey, we estimated that straw return would exacerbate soil acidification in 77% and 80% of dry and paddy lands, respectively. Our analysis disclosed the first evidence of accelerated soil acidification by straw return at national scale, providing new insights into both sustainable straw utilization and soil acidification remediation.

## ABSTRACT

In pursuit of carbon neutrality, microbially induced carbonate precipitation has emerged as a promising technology for inorganic carbon sequestration. However, existing research has predominantly focused on single bacterial strains, with little attention paid to natural microbial aggregates such as periphyton. As a primary microbial community at the sediment–water interface, periphyton consists largely of photoautotrophic organisms. Our results demonstrate that periphyton is highly effective in inducing carbonate precipitation, primarily by raising the suspension pH above 9 through photosynthesis under light conditions, and secondarily via urease hydrolysis. For instance, in suspensions with an initial pH of 7.0, 2.5 mM $Ca^{2+}$, and 7.5 mM or 15 mM $NaHCO_3$ under light exposure, periphyton achieved $Ca^{2+}$ precipitation ratios of 72% and 97%, respectively. In contrast, no precipitation occurred under dark conditions. These effects were enhanced by stronger light intensity and higher $Ca^{2+}$ or $HCO_3^-$ concentrations. Additionally, the active pumping of $Ca^{2+}$ through ion channels and its extracellular concentration of $Ca^{2+}$ further promoted calcium carbonate precipitation. Thus, periphyton drives calcium carbonate precipitation through synergistic mechanisms, with approximate contributions of 38% from photosynthesis, 24% from urease hydrolysis, and 31% from microbial-mediated extracellular $Ca^{2+}$ pumping. In contrast, extracellular polymeric substances of periphyton reduced precipitation by adsorbing $Ca^{2+}$, thereby diluting its availability. Periphyton is also widespread on paddy soil surfaces. When established on such soils, it can raise the pH of acidic soils and their suspensions, and inducing calcium carbonate precipitation in alkaline soils. Therefore, periphyton holds significant potential for inorganic carbon sequestration and mitigation of soil acidification. These findings provide a theoretical foundation for developing periphyton-based strategies to address global climate change and soil acidification.

**ABSTRACT**

Soil acidification is a major constraint to global agricultural sustainability, and the progressive decline in soil buffering capacity further weakens soil resilience to acid inputs, creating a self-reinforcing cycle of accelerated degradation. Conventional soil conditioners can temporarily neutralize acidity but fail to enhance intrinsic buffering capacity or maintain long-term pH stability. In this study, a composite soil conditioner, GL/ND/BC/MMT, was prepared by chemically cross-linking gelatin (GL), dolomite (ND), biochar (BC), and montmorillonite (MMT). The incorporation of glutaraldehyde produced a three-dimensional gelatin network designed to enable controlled release of pH-buffering components. Porous structure was clearly observed by SEM, whereas FT-IR characterized the chemical composition and cross-linking within the composite. A series of acidification, moisture retention, soil incubation, and crop growth experiments demonstrated that GL/ND/BC/MMT exhibits superior buffering performance within pH 4.0–5.5, effectively resisting rapid pH decline under external acid stress. The conditioner also improved soil moisture retention, showed good biocompatibility, and promoted crop growth. Mechanistic investigations revealed strong synergistic effects among the components: biochar's porosity and montmorillonite's cation-exchange capacity formed a dual adsorption barrier for excess $H^+$, dolomite provided continuous $CO_3^{2-}$/$HCO_3^-$ release for sustained neutralization, and the cross-linked network enabled slow release of buffering agents, thereby suppressing re-acidification[1][2]. Overall, this study presents a high-performance composite conditioner with synergistic amelioration mechanisms, offering an effective and sustainable approach for mitigating soil acidification and enhancing long-term soil health.

**ABSTRACT**

The rotation of oilseed rape and rice in southern China typically incorporates alternating periods of flooding and drying during the rice cultivation season. However, this pattern has led to cadmium release during drainage periods, resulting in excessive cadmium levels in rice grains. This is closely linked to the transformation of iron, sulfur and cadmium in the soil, as well as the formation and structural characteristics of the root-surface iron plaque formed by rice. Nevertheless, limited research has examined how rape straw incorporation influences the formation of iron plaque on root surfaces and the availability of cadmium in the rhizosphere, hindering the development of agronomic strategies to regulate cadmium uptake in rice through straw return management. Consequently, this study employed waterlogged soil incubation and rice rhizotron experiments to investigate: the formation of soil $SO_4^{2-}$ and the mechanisms of sulphide reduction and $S^{2-}$ formation driven by sulphate-reducing bacteria during rape straw decomposition; the reduction of $Fe^{3+}$ and formation of $Fe^{2+}$ driven by iron-reducing bacteria in response to soil Eh changes. This clarified how rape straw incorporation affects the concentration and composition of iron plaque on rice roots, as well as how it affects cadmium availability in the rhizosphere. According to our research, the iron plaque's formation changed dynamically during each stage of the growth period. Root iron plaque dissolved as a result of field drying and drainage during the filling stage. Cadmium uptake by roots and its transfer to different above-ground tissues were prevented by the formation of root iron plaque. Rape straw incorporation promoted sulphate migration and accumulation on rice root surfaces, where it was reduced to $S^{2-}$, thereby influencing iron redox processes and consequently affecting iron plaque formation. These processes regulated $Cd^{2+}$ precipitation, dissolution, and migration in soil. Rape straw application decreased soil Eh, which mostly decreased cadmium availability. But as soil DOC decreased throughout the mid-to-late phases of flooded incubation (after 45 days), soil solution Eh increased, thereby raising cadmium availability. Subsequent investigations will further explore the relationship between the release of $Cd^{2+}$ induced by the oxidation of CdS and FeS-Cd coprecipitates in soil and the cadmium sequestration capacity of the iron plaque on rice roots.

## ABSTRACT

Straw return is an important agricultural practice for increasing soil organic carbon (SOC) and improving both fertility and acid buffering capacity (pHBC) in Ultisols. Common straw-return strategies include direct straw incorporation, application of straw-derived manure, and use of straw biochar. Nevertheless, the mechanisms through which long-term application of these different straw-derived amendments influences SOC accumulation and pHBC within particulate organic matter (POM) and mineral-associated organic matter (MAOM) remain poorly understood. This study combined microbial biomarkers with $^{13}C$ nuclear magnetic resonance spectroscopy to examine the dynamics of microbial- and plant-derived carbon in POM and MAOM under different straw-derived amendments, along with their impacts on SOC molecular composition. Compared with inorganic fertilizer alone (NPK), equal-carbon inputs of straw (NS), straw plus manure (NSM), and straw biochar (NC) increased SOC by 34.2%, 91.3%, and 158.3%, respectively, and enhanced bulk soil pHBC by 0.8%, 11.4%, and 7.7%. The NSM treatment synergistically increased the accumulation of both microbial- and plant-derived carbon in POM and MAOM, significantly raising protein and lignin contents. The NS treatment mainly enhanced plant-derived carbon and lignin content in POM, whereas the NC treatment largely retained original biochar carbon within POM, increasing its char content. Functionally, the NSM treatment significantly raised the abundance of active functional groups in POM and showed the highest concentrations of –COOH, –OH, and $–NH_2$ groups in MAOM, thereby substantially improving the pHBC of POM, MAOM and bulk soil. The NC treatment increased active functional groups in POM, enhanced its pHBC, and contributed to moderate pHBC improvement in bulk soil. In contrast, the NS treatment did not significantly improve pHBC in either POM or MAOM, limiting its overall effect on bulk soil pHBC. Collectively, these results demonstrate that combined straw and manure application enhances pHBC more effectively by promoting microbial-derived carbon accumulation, which in turn increases protein content and key functional groups involved in acid buffering.

## ABSTRACT

Excessive nitrogen fertilizer application is a primary driver of soil acidification. However, long-term observational data on the rates of soil acidification induced by different types of nitrogen fertilizers are scarce. Soil acidification profoundly impacts soil quality, biodiversity, and crop productivity, yet the intricate mechanisms by which it mediates aluminum toxicity, nutrient availability, and microbial community dynamics to affect crop yield remain unclear. This study utilized a 9-year field experiment to investigate the soil acidification rates and their subsequent impact on crop yield under five different nitrogen fertilizer treatments: ammonium sulfate (AS), calcium nitrate (CN), urea (U), controlled-release urea (UR), and urea with straw incorporation (US), all applied in conjunction with superphosphate. Our findings revealed that, with the exception of the CN treatment, all other nitrogen fertilizer treatments exacerbated soil acidification. Ammonium sulfate exhibited the strongest acidification effect, accelerating the process in the 0-40 cm soil layer. Urea-based treatments showed a secondary acidification effect, primarily occurring within the 0-20 cm depth. Severe acidification led to substantial dissolution of active aluminum, significant reductions in calcium, magnesium, and potassium nutrients, and a decline in bacterial and fungal diversity, ultimately resulting in substantial maize yield losses. Mechanistic analysis indicated that severe soil acidification in red soil primarily reduces crop yield by increasing $Al^{3+}$ concentrations, which in turn impairs nitrogen use efficiency. This is attributed to the accumulation of dissolved $Al^{3+}$ on root surfaces in both exchangeable and complexed forms. This not only alters root morphology, significantly reducing total root length, surface area, root diameter, and root tip number, but also its uptake by aboveground plant parts suppresses chlorophyll synthesis and limits maize plant height. In contrast, the contributions of decreased mineral nutrient availability and altered microbial community structure to the inhibition of maize yield were relatively minor. These results provide a foundational basis for optimizing agricultural nitrogen fertilizer application practices and developing sustainable management strategies for acidic soils.

**ABSTRACT**

Intensive nitrogen fertilization in agricultural ecosystems has profound impacts on soil nitrogen cycling, yet the mechanistic understanding of how long-term nitrogen inputs alter microbial-mediated nitrogen transformations remains limited. While previous research has focused primarily on application rates, the temporal dimension of nitrogen management has been largely overlooked. Here, we present a global meta-analysis of 2,824 observations from 88 field studies specifically examining how nitrogen application duration, rather than just amount, shapes soil nitrogen cycling processes. Machine learning analysis revealed application duration as the dominant driver of nitrogen cycling changes, explaining greater variance than that explained by application rates across all functional genes examined. Long-term nitrogen application (>20 years) dramatically increased ammonia-oxidizing bacteria (AOB) abundance by 904% while modestly affecting ammonia-oxidizing archaea (AOA) by 142%, fundamentally altering the balance of ammonia oxidation processes. In acidic soils with long-term nitrogen application, AOB responses (1,107%) substantially exceeded AOA responses (179%), demonstrating that substrate availability becomes the primary driver of microbial community structure structure under long-term nitrogen enrichment. Our findings demonstrate that nitrogen application duration, more than amount, determines soil nitrogen cycling responses, creating progressive changes with substantial shifts occurring after 20 years of continuous fertilization. These results reveal duration-dependent mechanisms that provide a new framework for nitrogen management, enabling simultaneous maintenance of agricultural productivity and reduction of environmental impacts through duration-optimized application strategies.

# The amelioration effects of different biomass and their derived biochars on acidified yellow cinnamon soil under equal raw material mass conditions

**Yonggang Xu, Tianci Shao, Jingling Jiang, Tianyi Zhang, Tianxia Bai, Dan Dong, Tingwu Liu***

*Collaborative Innovation Center of Regional Modern Agriculture & Environmental Protection, Huaiyin Normal University, Huai'an 223300, China*

**ABSTRACT**

Due to its alkaline properties, biochar has been widely applied in the amelioration of acidic soils. However, most existing studies have evaluated its effectiveness based on equal application rates of biochar mass, with limited comparative research conducted relative to the feedstock. In this study, biochars were produced from corn stover and pig manure at pyrolysis temperatures of 300°C, 500°C, and 700°C. The alkalinity characteristics and contribution ratios of four major components were analyzed. A laboratory incubation experiment was conducted to assess soil improvement under equivalent raw material input. Results indicated that pig manure-derived biochar exhibited higher alkalinity, pH, and contents of nitrogen (N), calcium (Ca), and magnesium (Mg) compared to corn stover-derived biochar, whereas carbon (C), hydrogen (H), and potassium (K) contents were relatively lower. Total alkalinity in both biochars increased with rising pyrolysis temperature. The contribution ratio of organic alkalinities increased, while carbonate and other inorganic alkalinities contents declined when the pyrolysis temperature exceed 500°C. During the incubation period, both pig manure and its corresponding biochar steadily elevated soil pH, with the raw pig manure treatment showing the most pronounced effect. In contrast, the corn stover treatment initially reduced soil pH, and its derived biochar showed no significant impact on pH adjustment. Compared to the control, the pig manure treatment significantly enhanced soil available nitrogen content, with the greatest accumulation observed for nitrate nitrogen, whereas corn stover application decreased soil nitrate nitrogen levels. Real-time quantitative PCR analysis revealed that both pig manure and its biochar substantially increased the abundance of ammonia-oxidizing bacteria and archaea, with the pig manure treatment exhibiting a significantly greater effect than other treatments. In conclusion, under equal raw material mass input, pig manure and its biochar demonstrate superior efficacy in rapidly ameliorating acidic soil compared to corn stover-derived materials. Furthermore, raw pig manure not only exhibits the strongest improvement potential but also contributes significantly to nitrogen enrichment.

# Differences in life history strategies of bacteria between paddy and upland soils and implications for carbon sequestration

**Chaolei Yuan**[1*], **Jiao Yang**[1,2]

[1] *School of Agriculture and Biotechnology, Sun Yat-sen University, Shenzhen, 518107, China*

**ABSTRACT**

Previous studies on the life strategies of soil bacteria in response to organic matter (OM) inputs have largely focused on unsaturated upland soils, rather than flooded soils. Through meta-analysis and soil incubation experiments, we found that, unlike in upland soils, Actinobacteria and Proteobacteria in paddy soils appeared oligotrophic. This divergence was because the same bacterial phylum in paddy and upland soils comprised different members with distinct physiological and ecological characteristics. The life history strategies of some bacterial phyla could shift with soil moisture and the C:N ratio of added OM. Importantly, the content of bacterial necromass carbon in soil mineral-associated organic carbon was related to copiotrophs. Therefore, bacteria that contribute to organic carbon sequestration in upland soils may not play the same role in paddy soils (Fig. 1). These findings can help improve our application of the copiotroph-oligotroph framework and advance our understanding of bacteria-mediated carbon sequestration processes in flooded soils.

Prior to this study, we conducted a preliminary methodological investigation to determine whether added OM and storage influence the characterization of soil microbial communities. The results indicated that both freshly-added and aged plant residue did not affect bacterial communities in air-dried soils. However, for alkaline and oligotrophic air-dried soils, storage might have an effect even at - 80 °C (Yang et al., 2025). This methodological work can help us optimize the storage of soils for microbial analysis and understand microorganism survival in dry soils.

**ABSTRACT**

The assessment and proper use of land for various purposes requires digital soil mapping. Nowadays, the use of machine learning techniques in digital soil mapping has been a major breakthrough. The resulting maps are accurate, objective and easily reproducible. Furthermore, the process is less expensive than traditional methods. A supervised machine learning technique needs soil samples and environmental covariates for the creation of a map. In general, the lack of soil samples in some regions is a major issue in digital soil mapping, as this prevents the creation of the maps. In the case of acid sulfate (AS) soils, the absence of maps can be a high risk for the environment. This is due to the fact that AS soils can lead to environmental damage when they are oxidized during the drainage of the land. Therefore, in the unavailability of maps, AS soils may be accidentally drained by external activities related to agriculture, forestry or urban activities. A possible solution for mapping areas with few soil samples is to use soil samples from other regions. In a previous work, we showed that a machine learning model is able to correctly classify soil samples from a region where it had not been trained if the composition of the soils of the region where it has been trained is the same [1]. In this study, we have analyzed whether a machine learning technique is capable of predicting the AS soils of a region when the model has been trained in a region with a very different soil composition. For this, four different regions located in the coastal areas of Finland have been considered. As in the previous work, the machine learning method used is Random Forest, which has shown very high predicted abilities for the classification and prediction of AS soils [1-5]. The results show that in the most of the cases analyzed, the model is able to correctly predict the AS soils when the model is trained with soil samples from other regions. This is a significant advancement in the field because it permits the first recognition of regions with a limited number of soil samples.

# The Acid Sulfate Soil Distribution Mapping in The Buffer Area of Nusantara Capital City, Kalimantan, Indonesia

**Wirastuti Widyatmanti [1*], Kurniawan Nugroho[1]**

[1] *Faculty of Geography, Universitas Gadjah Mada, Yogyakarta, Indonesia*

* wwidyatmanti@ugm.ac.id

**ABSTRACT**

The new capital city of Nusantara (IKN), Indonesia consist of various landscapes, including the 168 square kilometres mangrove forest along the Balikpapan Bay. The development planning of hub ports on this IKN buffer areas become a concern when proper environmental impact analysis, especially pertaining of the occurrence distribution of acid sulfate soil (ASSoils), has not been well conducted. The exploitation of mangrove pyrite content's soil will expose the pyrite to the air and its oxidation will severely degrade the soil and water quality of surrounding areas. To avoid these failures, the development on the coastal areas urgently needs the information of distribution of ASSoils, vertical and horizontally using robust and comprehensive approaches. This research aims to use remote sensing and hydro-geomorphological approaches to estimate the distribution of ASSoils in the mangrove ecosystem area of the IKN Buffer Zone.

Multi-spectral satellite imageries are processed to derive the information of catchment area, mangrove landcover, river and estuary classification, through multi-spectral classification and transformation (NDVI, NDWI, and Tasselled Cap). The model of multi-level landform mapping is used to combine all parameters to generate the hydro-geomorphic units (HGU) representing the mangrove soil formation process and characteristics. Various secondary data of hydrology and geomorphological parameters were integrated into the model to detail the HGU attributes. The soil sampling was conducted to collect mangrove soil of which to be analysed in laboratory. The result show that most of soils contain pyrite with range 1 to 2% associated with HGU 1, 2 and 4 that own combinations of soil and material of claystone, whereas area with pyrite less than 0,5 % related to HGU 3 and 5, with composition of limestone, silty claystone and marl. The more detail soil properties and mangrove types present the correlation between variables however it is less that is expected (<0,6) due to various environmental factors and soil sample handling issues in term of accessibilities. For conclusion and challenges future research collaboration are mangrove soils are critical to blue carbon strategies in Indonesia, serving as major carbon sinks that must be accurately assessed and protected. Comprehensive soil analysis is essential, especially in mangrove ecosystems where pyrite exposure and acid sulfate formation pose hidden environmental risks. Current soil sampling technologies face limitations in accessibility, especially in remote coastal zones, requiring innovation and logistical support. Standardization of soil handling and laboratory analysis must be aligned with international protocols to ensure data reliability and global comparability.

# Coupling of microbial iron and sulfate reduction with organic carbon stabilization in mangrove soil

**Heyimo Xia [1], Chaolei Yuan[1*]**

[1]*School of Agriculture and Biotechnology, Sun Yat-sen University, Shenzhen (518107), China*

[*]Corresponding author. E-mail: yuanchlei@mail.sysu.edu.cn.

**ABSTRACT**

Mangrove soil is a globally important carbon sink. Microbial-mediated iron and sulfate reduction is the major pathway for organic carbon (OC) decomposition in mangrove soil. However, there are also mechanisms that promote the stabilization of OC during the process of microbial iron and sulfate reduction: i) Microorganisms synthesize biomass when decomposing OC; ii) The secondary ferrous minerals generated can protect OC; iii) The $Fe^{2+}$ generated can catalyze the Maillard reaction to transform low-molecular-weight OC to macromolecular OC that is less decomposable. However, the interactions among these mechanisms and their impact on OC stabilization remains unclear. We collected soils from Futian Mangrove Reservation, Shenzhen and did an incubation experiment. There were four treatments: (i) unautoclaved soil + OC; (ii) autoclaved soil + OC; (iii) autoclaved soil + iron-reducing bacteria + OC; (iv) autoclaved soil + sulfate-reducing bacteria + OC. The contributions of microbial anabolism, mineral protection, and $Fe^{2+}$-catalyzed Maillard reaction on OC stabilization were investigated with advanced chemical, spectral, and molecular biology methods. This study can contribute to a better understanding of the coupling between carbon, iron, and sulfur cycles in mangrove soil.

# Coastal Acid Sulfate Soils and Their Mapping in Finland

**Jaakko Auri[1*], Anton Boman[2], and Stefan Mattbäck[2]**

[1] *Geological Survey of Finland (GTK), P.O. Box 96, FI-02151 Espoo, Finland*

[2] *Geological Survey of Finland (GTK), P.O. Box 97, FI-67101 Kokkola, Finland*

*jaakko.auri@gtk.fi

**ABSTRACT**

In Finland, acid sulfate soils (ASS) are sulfur-rich, acid-producing soils typically found below the highest shoreline of the ancient Littorina Sea. This saline phase of the Baltic Sea (9,800–4,000 BP) deposited sediments now found up to 100 meters above sea level due to post-glacial land uplift. At lower elevations, the Littorina Sea sediments are often overlain by deposits formed in a less saline environment during the gradual transition from the Littorina Sea stage to the present Baltic Sea.

Since 2009, the Geological Survey of Finland (GTK) has mapped the occurrence and properties of coastal ASS (cf. Edén et al., 2023), resulting in a public map service and a substantial database on the varying characteristics of ASS. Roughly 10,000 km² of the mapped area is underlain by ASS. The ASS proportion increases from south to north, reaching up to 29% in Lapland, and its highest on agricultural land at 35%. The mapping continues within the MASSIW project, which is partly funded by the Interreg Aurora and the Regional Council of Lapland.

The properties of ASS in Finland are strongly influenced by sedimentological conditions. ASS materials are often fine-grained and organic-rich clays and silts deposited in deep water, now common in low-lying agricultural areas of Southern Finland and Ostrobothnia. Coarser ASS materials occur in river delta and littoral deposits, especially along the coast of Northern Ostrobothnia. The largest coarse-grained ASS deposits are often associated with eskers that were reworked by wave action during the Littorina Sea phase. The acid-producing potential of ASS, determined by Titratable incubation acidity (TIA), correlates with lithology: gyttjas and organic-rich clays and silts have the highest potential, while coarse materials produce less acid but may still pose environmental risks.

In Finland, two main ASS types are recognized: sulfuric soils, which actively produce acidity and release harmful metals, and hypersulfidic soils, which can become active if redox conditions change following hydrological disturbance. Sulfuric soils are most commonly found in agricultural lands where the soil has been drained to 1–2 meters depth. Although forest soils have also been extensively drained in Finland, sulfide-rich layers in forest areas are often covered by peat, and drainage has not typically reached the sulfide-bearing subsoil (hypersulfidic soil).

In the current ASS map, all ASS types of have been combined into a single layer representing the occurrence of ASS. One goal of the MASSIW project is to refine the current ASS map using machine learning and modelling and produce maps that differentiate between various ASS types, lithology, and acid-producing potential.

**ABSTRACT**

Coastal wetlands have the potential to store large amounts of soil organic carbon (SOC) as a result of their saturated soils limiting aerobic decomposition. However, these environments also have the potential to form acid sulfate soils (ASS), which are characterised by the formation of Fe sulfides. Despite studies exploring the link between Fe and SOC in terrestrial settings and the potential reservoir of SOC in coastal wetlands, the influence of Fe in ASS on carbon storage in coastal wetlands has yet to be explored. This study aims to investigate the influence of pyrite and subsequent Fe species on the decomposition of SOC in a coastal ASS (CASS). Top soil samples (0-10 cm depth) where taken from the supratidal zone of a coastal wetland at Corner Inlet in Wilsons Promontory, Victoria, Australia dominated by Swamp Paperbark (*Melaleuca ericifolia*). Soils were incubated with additions of organic matter (OM), pyrite and a combination of both under saturated (anoxic) and non-saturated (oxic) conditions, along with replicates using acid-washed sand as the medium. Overall, under anoxic conditions, the addition of pyrite increased $CO_2$ fluxes for sand and soil mediums. However, under oxic conditions, this effect was less pronounced when additional OM was added compared to anoxic conditions. Therefore, the presence of pyrite has the potential to increase $CO_2$ emissions and reduce SOC storage in CASS wetlands.

# Peat in Australia - Diversity, Values, Risks and the Universal Occurrence of Acid Sulfate Soils in South Australia

**Christopher M. Auricht[1,2]*, Robert W. Fitzpatrick[2], Brett P. Thomas[2], Emily R. Leydon[2], Luke M. Mosley[2]**

[1] Auricht Projects, Brighton, South Australia, Australia

[2] Acid Sulfate Soils Centre, The University of Adelaide, Waite Campus, Urrbrae, South Australia, Australia

chris@auricht.com

**ABSTRACT**

Australian peatlands span tropical, arid, temperate, alpine and polar settings, yet remain poorly mapped outside Tasmania and the Australian Alps. National reviews highlight gaps not only in peat extent, condition, carbon stocks and hydrological sensitivity, but in paleo-environmental history, fire regimes and peat accrual rates, which have been quantified in very few studies. Within this broader context, South Australia (Sth. Aust.) hosts two major peatland provinces - the Fleurieu Peninsula and Lower South East, the latter comprising spring-fed, groundwater - and surface-water-driven wetlands that, under natural conditions, supported persistent peat accumulation. Additional peatlands also occur in other regions, although these have not yet been assessed for acid sulfate soil (ASS) characteristics.

New evidence from an 82-year paired-site resampling program (Stephens 1942; resampled 2024), combined with recent investigations of Fleurieu swamps, demonstrates that most Sth. Aust. peatland investigated to date contains organic-rich ASS materials, including hypersulfidic, hyposulfidic and sulfuric materials over fine-grained limestone or substrates. Re-examination of archived 1942 cores with contemporary profiles reveals major pedological and biogeochemical shifts where drainage, groundwater decline, drying–rewetting cycles and vegetation change have altered wetland hydrology and peat characteristics.

Undisturbed pre- 1942 sites under native vegetation displayed reversible wetting–drying dynamics, maintaining saturated hypersulfidic organic soils. In contrast, drainage and land- use change drive irreversible formation of sulfuric material, peat oxidation, structural collapse, reduced peat thickness and salt efflorescence. These processes, captured in a predictive ASS soil–landscape model (Fitzpatrick et al. 2025), illustrate how hydrological alteration accelerates pyrite oxidation, mobilises acidity and metals, degrades water quality and threatens peat carbon stability.

Investigations on the Fleurieu Peninsula confirm ASS occurrence in all assessed peatlands sampled, expanding the recognised distribution of inland ASS in cool- temperate regions of Australia. These findings place Sth. Aust. peatlands within the global context of wetland ASS processes and demonstrate their high sensitivity to climatic drying, drainage and vegetation change.

This work provides the first integrated demonstration of the universal occurrence and high vulnerability of ASS across all studied Sth. Aust. peatlands, supporting improved management frameworks and nature- based solutions. The results align strongly with IUSS Working Group objectives and contribute to SDGs related to water quality, agricultural resilience, biodiversity conservation and infrastructure protection.

# Neutralisation of Acid Sulfate Soils with Industrial Side Streams

**T. Kronberg[1*], J-E. Eriksson[1], M. Visuri[2], R. Nilivaara[2], J.Räsänen[3], H. Hirvasniemi[3], J. Auri[3]**

**ABSTRACT**

Sulfide-bearing soils are found along the Finnish coastline. When exposed to oxygen, sulfide minerals oxidise to sulfuric acid, leading to soil acidification and the mobilisation of harmful metals and metalloids into surrounding environments via runoff waters. Such soils are classified as hypersulfidic soils. Once the oxidation process has been initiated, these soils are classified as sulphuric soils, and together with hypersulfidic soils, they form subgroups of acid sulfate soils. Preventing oxidation-induced acidification through neutralisation of hypersulfidic soils is therefore essential to minimise environmental contamination.

This study investigated the neutralisation of acid sulfate soils using industrial side streams as alternative alkaline materials. Three acid sulfate soil materials from the Oulu region in Finland were examined. Two materials were fine-grained silty clays with high sulfur contents (0.8% and 0.7%), while the third was fine sand containing 0.04% sulfur. Chemical analyses were performed to determine the pre-incubation characteristics of both fresh and oxidised samples after 19 weeks of incubation. Total element concentrations were determined by ICP-MS following aqua regia digestion, and leachable element concentrations were analysed using a two-stage shaking test (SFS-EN 12457-3).

Laboratory oxidation experiments were conducted over 19 weeks to evaluate the effectiveness of industrial side streams, including alkaline ashes, slags, and crushed concrete, applied at varying dosages as neutralising agents. Calcite was included as References material. Soil pH was monitored throughout the incubation, and the leaching behaviour of metals and metalloids before and after oxidation was assessed using a modified SFS-EN 12457-2 leaching test.

Based on the laboratory results, the most promising neutralising materials were selected for pilot-scale outdoor testing. Four industrial side streams were applied at two different dosages in box experiments (40 L) and incubated under field-relevant conditions for six months. Soil pH development and element leaching were monitored throughout the test period using the same analytical methods as in the laboratory experiments.

All untreated soils and soils amended with insufficient amounts of neutralising agents acidified to pH < 4 during oxidation, resulting in increased leaching of harmful elements. In contrast, application of 100% of the theoretically calculated neutralisation requirement effectively prevented acidification and significantly reduced the leaching of metals and metalloids in both laboratory and pilot-scale experiments. The results demonstrate that industrial side streams can serve as effective neutralising agents for acid sulfate soils and offer a promising approach for sustainable soil management. However, the practical application of such materials must comply with current fertiliser and environmental legislation.

# Geophysical Methods for Mapping Acid Sulfate Soil Properties

**Anton Boman[1*], Lauri Rinne[2], Jouni Lerssi[3], Jaakko Auri[2], Staffan Nylund[1], and Stefan Mattbäck[1]**

[1] *Geological Survey of Finland (GTK), P.O. Box 97, FI-67101 Kokkola, Finland*

[3] *Retired from the Geological Survey of Finland (GTK)*

*anton.boman@gtk.fi

**ABSTRACT**

Airborne geophysics is effective for identifying large acid sulfate soil (ASS) areas at the catchment scale, but there is a growing need for high-resolution mapping of ASS properties at local scales. The MASSIW-project (funded by the Interreg Aurora and the Regional Council of Lapland) evaluates geophysical methods for characterizing soil properties such as grain size, depth to hypersulfidic material, oxidised horizon thickness, and groundwater depth. The focus is on electromagnetic (EM) methods, particularly GEM-2, and ground penetrating radar (GPR). Both methods have been widely used to map lithology, texture, and stratigraphy, but their application in ASS surveys remains limited.

Fine-grained (<63 µm) and coarse-grained (≥63 µm) Finnish ASS materials show similarly low pH during oxidation, but their impacts differ. Coarse-grained ASS materials have lower buffering capacity, allowing pH to fall below diagnostic thresholds even at low sulfide concentrations. Fine-grained ASS materials, especially with high organic content, has much higher acidifying potential due to higher sulfur concentrations (Mattbäck et al., 2022). These differences influence management: fine-grained soils need stricter monitoring, liming, and drainage control, while coarse-grained soils may allow more flexible approaches.

The study sites represent varying soil characteristics and are all located in Ostrobothnia, western Finland: Söderfjärden (62°59'52.2"N 21°36'19.5"E), a classic ASS site in an ancient meteorite crater with homogeneous, fine-grained, gyttja-containing sediments on farmlands; a sulfuric wetland Sokaluoto (63°35'12.2"N 22°33'28.1"E), with fine-grained, gyttja-containing ASS materials and a distinct boundary between black hypermonosulfidic and grey hypersulfidic layers; a sand mining area Sokaluoto (63°34'57.1"N 22°34'21.0"E), where coarse-grained materials overlie hypersulfidic fine-grained materials; and Viitavesi (63°39'52.2"N 23°24'54.1"E), with large spatial variations in topography and Quaternary sediment distribution.

Soil electrical conductivity (EC) and magnetic properties were measured using GEM-2, while GPR was applied to identify changes in soil composition. Together, these methods provide information on lithology and texture, stratigraphic layering, and the depth to the groundwater table. Preliminary results indicate that GEM-2 effectively detects thick, fine-grained hypersulfidic sediments and differentiates between fine- and coarse-grained soil materials. GPR provides valuable insights into vertical variations in lithology and texture and groundwater depth but is limited to areas with coarser materials.

**ABSTRACT**

The study investigates the geochemical and mineralogical processes controlling the formation, transformation, and stability of metastable iron sulfides, pyrite, and secondary Fe/SO4 minerals in a sulfuric wetland (pH ~3.0). The work aims to improve understanding of acid-generating mechanisms and redox dynamics under highly acidic conditions, with implications for wetland management and risk assessment in acid sulfate soil (ASS) systems. The long-term goal is to identify management strategies that could enable sustainable forestry. This research is part of the MASSIW-project, funded by Interreg Aurora and the Regional Council of Lapland.

In the 1950s, Plottret (63°35'12.2" N 22°33'28.1"E) was a freshwater glo lake located near Karviken. When Karviken was drained in the 1960s, Plottret was presumably partly drained as well, exposing hypersulfidic sediments and leading to the development of a sulfuric wetland. Peat formation, which would have prevented oxidation, was likely inhibited by the sudden drop in the water table. Additional acidification has been promoted by pugging from cattle and wildlife.

A 300 cm deep soil profile was obtained using a D-section peat sampler. The uppermost 10 cm qualifies (>20% organic matter), while the rest of the profile consists mainly of clay with 2–20% organic matter, except for a sandy layer at 120–127 cm (1.1% organic matter) indicating an erosional event. Materials were classified based on field and incubation pH (Boman et al., 2023): sulfuric materials at 0–70 cm; parasulfuric and hypermonosulfidic materials at 70–80 cm (transition zone); hypermonosulfidic materials at 80–120 cm; and hypersulfidic materials from 120–300 cm. The brown-yellow oxidised horizon (to 70 cm) is strongly acidic and contains jarosite and possibly schwertmannite. Sediments between 70–120 cm are black due to metastable iron sulfides, while those between 120–300 cm are grey with black streaks.

Titratable actual acidity (TAA) was measured on oxidised samples (0–70 cm) and titratable incubation acidity (TIA) on reduced samples (70–300 cm), while acid volatile sulfide (AVS) and chromium reducible sulfur (CRS) were analysed on all samples. Both TAA (93–141 mmol H+/kg) and TIA (77–268 mmol H+/kg) were generally high, except in the sandy layer where TIA was much lower. AVS was absent in the oxidised horizon but detected in small amounts (0.02%) just above the transition zone. CRS occurred at low concentrations throughout the oxidised horizon (~0.03%) and increased markedly near the transition zone (0.24%), matching AVS levels. Overall, AVS dominated in black sediment, whereas CRS was dominant in grey sediment.

# Improved sampling and laboratory methods using chip-trays for assessment and classification of acid sulfate soils

**R.W. Fitzpatrick [1]*, B.P. Thomas[1], C.M. Auricht [1,2], L.M. Mosley[1] and G. Lancaster[3]**

[1] *Acid Sulfate Soils Centre, Adelaide University, Urrbrae, South Australia, Australia*

[2] *Auricht Projects, Brighton, South Australia, Australia*

[3] *Environmental Analysis Laboratory, Southern Cross University, Lismore, NSW*

* Robert.fitzpatrick@adelaide.edu.au

**ABSTRACT**

The chip-tray method has been extensively used and refined in a wide range of acid sulfate soil (ASS) investigations globally (Fitzpatrick et al. 2010, 2025; Nystrand et al. 2025). The advantages of using chip-trays include rapid field collection and storage of moist soil samples, which offer standardised pH incubation conditions that represents a "realistic tool" to characterise and classify ASS (Isbell & NCST 2021) based on allowing the soil to "speak for itself" (Dent 1986). Field protocol involves using one chip-tray to display the morphology of intact soil samples for visual References and photographed for inclusion in profile descriptions. A second chip-tray is used for incubation pH testing by filling compartments to a thickness of 10mm with samples that are kept moistened with deionized water to prevent excessive desiccation (Fitzpatrick et al. 2010). However, incubation of organic-rich soils on Norfolk Island to identify hypersulfidic material using 10mm thick layers did not create optimal sulfide oxidation conditions unless samples were stirred 4 times per week (Fitzpatrick et al. 2025). Accordingly, Nystrand et al. (2025) recommended using 2 mm thick samples in chip trays for organic-rich and clayey soils in Finland. The laboratory Slab Incubation method also uses 2 mm thick slabs to speed-up incubation processes (Sullivan et al. 2018; Isbell & NCST 2021). This method involves smearing 2 mm slabs of soil with a roller onto a fine gauze mesh (2.0×1.5 mm) strip between 2 mm high spacers. A coarse plastic mesh (10 x10mm) is used to suspend the gauze mesh with smeared sample to allow maximum air penetration to both sides of the slab. Based on the Slab Incubation method, we have made 3 sequential inserts for each chip-tray compartment: (i) two 5mm thick plastic cross tile spaces (20 x 20mm), (ii) strip (4.7 mm X 2.4mm) of stiff plastic mesh (3 mm thick) placed on the 2 tile spaces and (iii) fine gauze mesh (2.0×1.5 mm) strip (4.7 mm X 2.4mm) placed on the stiff plastic mesh. Two compartments are each filled with layers of 2 mm thickness to duplicate samples. Incubation times are substantially reduced (up to 60% compared to 10mm thick layers) in all soils tested because of increased air penetration.

**ABSTRACT**

Acid sulfate soils (ASS) with sulfide minerals (i.e., contain hypersulfidic materials) are widely distributed in both coastal and inland regions globally, and if exposed to air, the oxidation of sulfide minerals results in the production of sulfuric acid with the formation of sulfuric materials (pH<4) along with a wide range of profound mineralogical changes. We report on the occurrence, genesis and properties of the wide range of Fe-oxyhydroxides (lepidocrocite), Fe- and Al-oxyhydroxysulfate minerals (schwertmannite, jarosite, natrojarosite, ammoniojarosite, hydronium jarosite) and efflorescent sulfate salts (tamarugite, sideronatrite, gypsum, epsomite, hexahydrite and others) on the surfaces of peats, clay peds and sands from a variety of disturbed wetlands with sulfuric soils from Australia and Finland. X-ray diffraction has been used to determine their mineralogy, inductively coupled plasma mass spectrometry for geochemical characterisation, and acid-base accounting to assess ASS potential. The composition of these minerals is influenced by the biogeochemical conditions of formation in receiving environments.

Salt efflorescence samples from Sulfuric soils with pH values as low as 2.2 in the Coonjimba Billabong, Northern Territory in Australia were found to contain a recently identified mineral giacovazzoite ($K_5Fe^{3+}{}_3O(SO_4)_6 \cdot 10H_2O$), in association with Na-jarosite, tamarugite, and hexahydrite.

As a result of the prolonged drying of freshwater wetlands across Norfolk Island sulfuric organic soils formed with the following prominent precipitates: (i) schwertmannite in ponded water and coating vegetation, (ii) iridescent floating films of schwertmannite on water that produce silver and gold Newton colours, due to “thin-film interference, (iii) lepidocrocite and schwertmannite on soil surfaces and (iv) ammoniojarosite coating vegetation on sulfuric organic soils through sorption or coprecipitation of ammonia concentration from cattle dung deposition.

In drying wetlands at Plottret near Socklot, in western Finland Sulfuric organic soils formed with prominent yellow precipitates of hydronium jarosite with traces of ammoniojarosite on micro-mounds and thin yellowish-brown precipitates of schwertmannite in adjacent hollows through likely sorption or coprecipitation of ammonia concentration from Moose dung deposition.

In drying wetlands and Lake Alexandrina during Australia's Millennium drought Sulfuric sandy soils with pH <2 formed with dominant sideronatrite [$Na_2Fe(SO_4)_2.OH.3H_2O$] and minor tamarugite. During subsequent rain events yellowish-red precipitates of schwertmannite formed in patches adjacent to where the sideronatrite formed due to the rapid transformation of sideronatrite to schwertmannite in rainwater.

These Fe-oxyhydroxides, oxyhydroxysulfates and efflorescent sulfate salts can be used as powerful indicators of the prevailing environmental conditions and highlight the potential for severe water quality degradation and risks to aquatic biota.

# Why the Effects of Vegetation Restoration on Soil Properties May Be Overestimated: Evidence from 30 Years of Long-Term Monitoring on the Loess Plateau, China

**Tonggang Zha[1], Xiaoxia Zhang[2], Hengshuo Zhang[3], Yile Pei[1], Shihao Gong[1]**

*E-mail: zhtg73@bjfu.edu.cn

**ABSTRACT**

Vegetation restoration is widely regarded as an important strategy for erosion control, soil recovery, and ecosystem improvement. However, the effects of vegetation restoration on changes in soil properties may be overestimated when the combined influences of topography, parent material, and other soil-forming factors are overlooked. Based on 30 years of continuous in situ monitoring at the Jixian National Forest Ecosystem Observation and Research Station in the loess region of western Shanxi, China, this study evaluated the effects of vegetation restoration on soil physicochemical properties, ecological stoichiometry, microbial processes, and soil organic carbon stability, and interpreted these effects within a soil-forming-factor framework.

(1) Soil physical properties were more strongly influenced by topography than by vegetation restoration alone. Slope and slope aspect explained variations in bulk density, total porosity, and capillary porosity more effectively. (2) The effects of long-term vegetation restoration on soil nutrients appeared limited and asynchronous. Although soil organic carbon (SOC) and total nitrogen (TN) increased slightly, total phosphorus (TP) declined, suggesting that nutrient changes cannot be interpreted as a consistent improvement driven by vegetation restoration. (3) Microbial communities were sensitive to vegetation restoration, but their responses more likely reflected functional reorganization driven by changes in substrate inputs, water availability, and nutrient limitation. (4) In the subsoil, variations in SOC stability were controlled by hillslope transport and transformation processes. Attributing SOC patterns solely to vegetation type may overestimate the vegetation restoration effect.

Overall, vegetation, however, represents only one component of the biological factor in soil formation. Soil properties are shaped jointly by climate, topography, parent material, time, and human activities. In the loess residual tableland and gully region, complex terrain, water redistribution, erosion and deposition processes, and thick loess parent material can mediate soil variation. Therefore, attributing post restoration soil differences entirely to vegetation restoration may overstate the true role of vegetation itself.

# The regulation of microbial life-history strategies on soil carbon cycling

**Zhenghu Zhou[1*], Xuesen Pang[1]**

[1]*Northeast Forestry University (School of Ecology, Harbin, China)*

*zzhou@nefu.edu.cn

**ABSTRACT**

Life history strategies of soil microbiomes determine their environmental adaptability and improve mechanistic understanding of soil carbon-climate feedback. Here, we investigated trade-offs among microbial high yield (Y), resource acquisition (A), and stress tolerance (S) strategies and their consequences for soil carbon mineralization potential along an aridity gradient spanning 9.6 million square kilometers. Results indicate increases in microbial carbon allocation toward resource acquisition and stress tolerance come at the expense of growth efficiency. The responses of Y-A-S strategies to increases in aridity follow a series of sequential thresholds. Aridification-induced abrupt increases in A- and S-strategies cause a sudden decrease in Y-strategy. Importantly, our findings link microbial Y-A-S life history strategies to SOC mineralization potential. We suggest that once aridity exceeds all thresholds of the Y-A-S strategies, the SOC mineralization potential shows a sharp increase, highlighting the cascading effects of aridity-induced shifts in microbial life history strategies on soil carbon cycling at a biogeographical scale. Overall, our findings suggest that variations in microbial Y-A-S strategies significantly influence soil carbon cycling and can be incorporated into microbial models.

# Heatwaves Increase Greenhouse Gas Emissions from Different Ecosystems

**Scott X Chang[1]*, Zhengfeng An[1], and Chong Li[1]**

[1] *Department of Renewable Resources, University of Alberta, Edmonton, Alberta, T6G 2E3, Canada*

*sxchang@ualberta.ca

**ABSTRACT**

Climate change has increased the frequency, intensity, and duration of extreme climate events worldwide. Those extreme climate events are either made more likely or more severe by human-driven greenhouse gas emissions. Extreme events disrupt the soil–plant–atmosphere continuum, destabilizing water and energy balances and altering the carbon cycle in terrestrial ecosystems. One of those extreme climate events is heatwaves. Our laboratory-based experiment indicates that heatwaves increase both $CO_2$ and $N_2O$ emissions without affecting $CH_4$ emissions in both agricultural and forest soils. Those responses increase with increasing frequency of heatwave events. Our field-based experiment, incorporating simulated grazing intensity and heatwave frequency treatments, indicates that heatwave events increase soil $CO_2$ but not $N_2O$ emissions in a rangeland ecosystem, regardless of simulated grazing intensity. Grazing intensity and heatwave treatments interacted to affect $CH_4$ emissions, with heatwave increasing $CH_4$ oxidation under heavy grazing. Our studies suggest a positive feedback mechanism of heatwaves to climate change. Heatwaves may also reduce plant photosynthesis rates and shift the allocation of photosynthates among plant components. Such shifts in biomass carbon allocation may further amplify the adverse effect of extreme climate events on ecosystem productivity. Long-term field experiments that incorporate multiple climate change factors need to be conducted at large scales to examine their effects and feedback mechanisms within the soil-plant-atmosphere continuum, thereby allowing us to better understand the impact of extreme climate events on terrestrial ecosystems.

## ABSTRACT

Soil nutrient stocks are crucial to ecosystem stability. Previous studies have examined variations in soil carbon (C), nitrogen (N), and phosphorus (P) stocks in response to climate warming; however, there is a lack of knowledge regarding how climate warming affects soil potassium (K) stock, although K is the second most abundant nutrient in plants. Furthermore, how climate warming affects the balance of C, N, P, and K stocks in the soil remains to be elucidated. Here, we investigated the changes in soil C, N, P, and K stocks under climate warming by sampling soil along a 6000 km northeast-southwest temperature gradient in China. We found that soil C and N stocks significantly decreased with increasing temperature. Soil C and N stocks exhibited a stronger response to temperature than to soil properties (i.e., soil pH, soil clay, silt, and sand contents), vegetation and soil types. However, soil P and K stocks remained stable with increasing temperature. Variations in soil P and K stocks were primarily regulated by soil properties, vegetation type, soil type, and soil parent material type. Frigid temperate coniferous forest, temperate coniferous and broad-leaved mixed forests and alpine meadow possessed the highest soil C and N stocks, followed by subalpine grassland, alpine grassland, temperate typical steppe and temperate meadow steppe. In contrast, semi-desert grassland held the lowest soil C and N stocks. Soil P and K stocks in subalpine grassland were higher than those in the other vegetation types. However, semi-desert grassland retained the lowest soil P and K stocks. Umbrisols and Luvisols held the largest soil C and N stocks, followed by Cambisols, Leptosols and Chernozems. Calcisols had the lowest soil C and N stocks. For soil P and K stocks, their contents in Leptosols were higher than those in the other soil types. Furthermore, soil C stock was closely correlated with soil N stock across this temperature transect, suggesting that coupled links between soil C and N stocks persisted across this temperature transect. The ratio of soil C or N stocks to soil P or K stocks decreased with increasing temperature, indicating that soil C and N stocks declined more rapidly than soil P and K stocks under climate warming, thus resulting in the decoupling of C-N and P-K stocks in soil. Our findings revealed that soil might become more limited in C and N than in P and K because of climate warming.

# Forest methane sink under climate change

**Xiaoqi Zhou***

*School of Ecological and Environmental Sciences, East China Normal University, Shanghai, China*

*E-mail: xqzhou@des.ecnu.edu.cn

**ABSTRACT**

In 2020, anthropogenic methane ($CH_4$) emissions decreased due to COVID-19 containment policies, but there was a substantial increase in the concentration of atmospheric $CH_4$. Previous research suggested that this abnormal increase was linked to higher wetland $CH_4$ emissions and a decrease in the atmospheric $CH_4$ sink. However, the impact of changes in the soil $CH_4$ sink remained unknown. To address this, we utilized a process-based model to quantify alterations in the soil $CH_4$ sink of terrestrial ecosystems between 2019 and 2020. By implementing the model with various datasets, we consistently observed an increase in the global soil $CH_4$ sink, reaching up to 0.35 ± 0.06 Tg in 2020 compared to 2019. This increase was primarily attributed to warmer soil temperatures in northern high latitudes. Our results emphasize the importance of considering the $CH_4$ sink in terrestrial ecosystems, as neglecting this component can lead to an underestimation of both emission increases and reductions in atmospheric $CH_4$ sink capacity. Furthermore, these findings highlight the potential role of increased soil warmth in terrestrial ecosystems in slowing the growth of $CH_4$ concentrations in the atmosphere.

## ABSTRACT

The escalating consumption patterns associated with industrialization and economic development have led to deforestation, biodiversity loss, increased greenhouse gas emissions, and widespread pollution. Modern agriculture and forestry face a range of significant challenges, with the depletion of soil phosphorus resources representing a critical and increasingly pressing concern. In this study, we conducted a 15-year transformation experiment in subtropical China and found that interplanting *Schima superba* with Chinese fir significantly increased rhizosphere P availability. Sequential P fractionation revealed a notable shift from stable P forms to moderately labile and labile P pools in mixed plantations, with $NaHCO_3$-Po increasing by 108% and NaOH-Po by 58.3% compared to pure plantations. Metabolomic analysis identified four organic acids, oxoproline, alanine-2, aconitic acid, and *N*-carbamylgluta mate-4 (*NCG* 4), secreted exclusively by Chinese fir roots in the mixed-species system. These root exudates were strongly correlated with $NaHCO_3$-Po levels and activated a microbial P-solubilization gene network. This included upregulation of inorganic P-solubilizing genes (*ppk*, *ppx*, and *pqqD*), high-affinity phosphate transporters (*pstA*, *pstB*, and *pstC*), and P-starvation response regulators (*phoB*, *phoP*, and *phoU*). Partial least squares path explaining 99%, 91%, and 81% of the variations in labile, moderately labile, and stable phosphorus fractions and modeling further indicated that changes in rhizosphere P fractions were driven by the interactions among root exudates, microbial functional genes, and environmental factors (Fig. 1). Together, these findings support a synergistic "root exudate-microbial gene" mechanism that transforms stable P forms into plant-available P, offering a blueprint for designing rhizosphere-engineered mixed-species plantations to overcome P limitation and promote sustainable forestry (Fig. 2).

**ABSTRACT**

Phosphorus (P) is a major nutrients for all organisms. Phosphorus in terrestrial organisms is mainly derived from soils, therefore soil P affects the growth and development of plants, soil microbes and other organisms, and thus key ecosystem functions and processes such as plant production, soil respiration and ecosystem carbon storage. Despite the knowledge gained and numerous site-level explorations or examinations, our understanding of soil P dynamics remain incomplete, in particular at the global scale. This has hindered our understanding of the role of P under global change, and its incorporation into land surface models. In the last decade, we have studied the concentrations, stock, dynamics, and drivers of P in (semi-)natural soils, at local, regional, and global scales. We have generated global datasets and maps of P in total and available forms, and P fractions separated by the Hedley fractionation procedure, and identified climate and parent materials as the key drivers of global variations in soil P concentrations. The improved understanding and datasets have been contributing to the representation and benchmark of soil P dynamics in land surface models.

# Effects of nitrogen deposition on plant community structure and niche characteristics in typical steppe

**Siyuan BAO[1], Zhendan WU[1], Renheng WU[1], Meijun SHENG[1], Shilong HE[1], He YE[1,2,3], Dianlin YANG[5], and Mei HONG[1,2,3,4*]**

## ABSTRACT

Atmospheric nitrogen deposition, as an environmental problem facing the world, has a variety of effects on grassland ecosystems. In order to analyze the corresponding mechanism of typical steppe plant communities on global change-nitrogen deposition, a simulated nitrogen deposition experiment was designed in the typical steppe of Ewenki Banner, Inner Mongolia in 2017.Nine nitrogen treatments were set up, and the pure nitrogen amounts were 0,25,50,75,100,125,150,175,200 kg · $hm^{-2}$ · $a^{-1}$, respectively, expressed as CK, N25, N50, N75, N100, N125, N150, N175, N200. The effects of nitrogen addition on plant community structure and niche in typical steppe in different years ( 2021-2023 ) were studied. The results showed that the number of species showed high nitrogen application level ( N200 ) < low nitrogen application level ( N15-N50 ). From 2021 to 2023, with the increase of nitrogen application level, the aboveground biomass ( AGB ) showed a significant increasing trend ( $P < 0.05$ ). From 2021 to 2023, the addition of low nitrogen level significantly increased the Shannon-Wiener index and Margalef index of plant communities ( $P < 0.05$ ), and the addition of high nitrogen level significantly increased the Simpson index ( $P < 0.05$ ). The soil pH value decreased with the increase of nitrogen application level in different years, and the soil pH value was significantly negatively correlated with the total AGB ( $P < 0.05$ ). Niche breadth is a comprehensive index reflecting the ability of species to utilize various resources. From 2021 to 2023, the niche breadth of L.chinensis was at a high level under nitrogen addition. The niche overlap values of species were mainly concentrated in the range of 0.3-0.8, and the average niche overlap increased first and then decreased with the increase of nitrogen application level, and the value was the largest under N50 treatment. In general, long-term nitrogen addition increased the productivity of typical steppe plant communities. Among them, the addition of low nitrogen level was positively correlated with the number of community species, Shannon-Wiener index, Margalef index and niche overlap value. The addition of medium and high nitrogen application levels was positively correlated with Simpson index. The key factors affecting the AGB of plant communities under different annual nitrogen additions were soil pH and precipitation. The addition of low nitrogen application level aggravated the competition for resources among plant community species. Under the addition of medium and high nitrogen application levels, the niche overlap value of L.chinensis was low, and low overlap may enable it to differentiate in resource utilization and reduce competitive pressure.

## ABSTRACT

Soil seed banks (SSB) are a vital reservoir of biodiversity and a key component of soil ecosystem services, underpinning plant community regeneration and soil health. While the individual effects of grazing and *Caragana korshinskii* invasion on SSB are known, their interactive effects remain unexplored. This study investigates how grazing management interacts with the allelopathic potential of this invasive woody plant to influence SSB properties, a critical aspect of soil ecological function in the context of global woody plant encroachment. We conducted a controlled experiment in a typical steppe ecosystem. The effects of simulated grazing and aqueous litter extracts from different parts (aboveground, belowground, whole plant) of *C. korshinskii* at varying concentrations on the SSB were assessed via a seedling emergence assay. The aqueous litter extracts of *C. korshinskii* significantly suppressed key SSB indicators of soil ecological function, including seedling emergence density, species richness, and seedling biomass ($P < 0.05$). The inhibitory effects followed the order: belowground parts (BP) > whole parts (WP) > aboveground parts (AP). BP extracts caused reductions of 28.9%, 36.6%, 29.0%, and 31.1% in emergence density, species richness, aboveground, and belowground seedling biomass, respectively. These allelopathic effects were concentration-dependent. Crucially, the experimental grazing treatment significantly alleviated this suppression. Under grazing conditions, the presence of extracts resulted in increases of 52.6%, 23.7%, and 46.3% in seedling emergence density, species richness, and belowground biomass, respectively, compared to non-grazed conditions. Our findings demonstrate that invasive woody plants can exert strong allelopathic pressure on the soil's regenerative capacity, potentially compromising soil biodiversity and ecosystem function. However, appropriate grazing management can modulate this negative impact, helping to maintain the ecological integrity of the soil seed bank. This study highlights that soil ecological processes, such as seed bank dynamics, are critical for ecosystem resilience. The results provide a scientific basis for managing soil ecosystem services and promoting grassland soil health under scenarios of plant invasion and land use change.

# Study on the Influencing Mechanisms of Mercury Accumulation Characteristics in Grassland Soils of Guizhou Province Under the Context of Ecological Restoration

**Yanmei Zhou[1*], Yixuan Shu[1], Jicheng Xia[1,2]**

[1]*Education, College of Resources and Environmental Engineering, Guizhou University, Guiyang 550025, China*

[2] *Urban karst critical zone & climate-environmental change observation and research station of Guizhou Province, Guiyang 550081, China*

*1830168137@qq.com

**ABSTRACT**

Grassland ecosystems cover approximately 40% of the global terrestrial area. As core mercury sinks and carbon pools in terrestrial ecosystems, their mercury and carbon cycling processes exert a pivotal regulatory role in global biogeochemical cycles and environmental health. In the core karst region of Guizhou Province, ecological restoration initiatives have effectively facilitated grassland rehabilitation. However, the response of mercury migration and accumulation in grassland soils to grassland restoration under varying geomorphological conditions remains poorly understood, which constrains the assessment of soil environmental health in the fragile areas of Southwest China.

In this study, 127 grassland soil profiles were collected across diverse geomorphological systems throughout Guizhou Province, and a total of 1312 soil samples were obtained by sectioning the profiles at different depths. Five indicators were analyzed for each sample, including total mercury concentration (THg), dissolved mercury concentration (DHg), pH value, soil organic carbon (SOC), and dissolved organic carbon (DOC). Additionally, data on the Normalized Difference Vegetation Index (NDVI), climatic factors, soil slope, and land use type changes since 1990 were integrated to decipher the mercury-carbon coupling mechanism and identify the underlying environmental driving factors. Preliminary statistical results indicate that the average THg concentration in grassland soils of karst areas is 150.5±77.7 ug/kg, with a corresponding average SOC concentration of 0.74±0.59 %. In contrast, non-karst areas exhibit a higher average THg concentration of 247.2±108.5 ug/kg and a significantly higher average SOC concentration of 2.79±2.10 %. This study aims to clarify the accumulation characteristics and stability changes of mercury in Guizhou's grassland soils under the context of ecological restoration, and to reveal the regulatory role of karst landforms in mercury migration and transformation. The findings of this research will provide a robust scientific basis for understanding the mercury-carbon coupling cycle mechanism in grassland ecosystems of the Southwest China karst region, offer valuable data support for soil mercury pollution prevention and control as well as the environmental effect assessment of ecological restoration projects under global change, and hold significant practical implications for enhancing the soil environmental health in fragile ecological zones.

# Characteristics of Serpentinite Soils in Northern Hokkaido

**Mei TSUCHIHASHI[1*], Makoto KOBAYASHI[2], and Maki ASANO[3]**

[1] *Master's Programs in Agro-Bioresources Science and Technology, University of Tsukuba, Tsukuba, Japan*

**ABSTRACT**

Serpentinite-derived soils are characterized by high concentrations of heavy metals and base cations, which can restrict plant growth [1]. In contrast, wet iron podzolic soils with high organic carbon content in the surface layers have been reported in northern Hokkaido, the northernmost prefecture of Japan, despite the presence of serpentinite geology [2]. This suggests that serpentine soils in northern Hokkaido differ from typical serpentinite-derived soils found in Honshu, the main island of Japan. However, their physicochemical characteristics remain unclear. Therefore, this study aims to clarify the characteristics of serpentinite soils in northern Hokkaido by comparison them with soils derived from sedimentary rock. Soil profile surveys were conducted at two adjacent sites within the Nakagawa Research Forest of Hokkaido University in northern Hokkaido, where serpentinite and sedimentary rock served as parent materials. Soil samples were collected from each horizon. General physicochemical properties of the collected soils were measured, and soil classification was carried out according to the Soil Classification System of Japan [3]. The soil profile surveys revealed that both the sedimentary rock soils and serpentinite soils had A horizons exceeding 10 cm in thickness, indicating that a thick A horizon was developed even in the serpentinite soils. In addition, the organic carbon content of the A horizons was higher in the serpentinite soils than in those on Honshu. Regarding podzolization processes, which are characteristic of podzolic soils, acid oxalate-extractable iron showed its maximum value in the Bs horizon, indicating iron accumulation. However, the chemical analytical values did not meet the criteria for podzolic accumulation horizons defined by the Soil Classification System of Japan, and iron mottling caused by stagnant water conditions was observed. Consequently, the serpentinite soils were classified into the hydromorphic soil group. These results indicate that, in serpentinite soils of northern Hokkaido, soil formation processes are influenced not only by leaching driven by organic acids but also by the aluminum and iron behavior under stagnant water conditions. In addition, this study examines inorganic materials involved in soil organic matter accumulation using density and particle-size fractionation methods to elucidate mechanisms of organic matter stabilization.

**ABSTRACT**

Large-scale afforestation is widely applied to control soil erosion and improve ecosystems in semi-arid regions, but it can also increase pressure on limited soil water resources. This study investigated how forest stand age influences soil moisture dynamics, soil water storage (SWS), actual evapotranspiration (ETa), and root water uptake (RWU) in black locust plantations on the Loess Plateau of China. Field observations from 2014 to 2021 were combined with HYDRUS-1D model simulations to compare young (14-year-old) and old (28-year-old) black locust forest stands under wet, normal, and dry climatic conditions. The HYDRUS-1D model showed strong performance in simulating soil moisture, with coefficients of determination ($R^2$) ranging from 0.81 to 0.88 during calibration and from 0.83 to 0.85 during validation, while RMSE values ranged from 0.018 to 0.024. The results showed that total SWS in the 0–300 cm soil profile was consistently lower in the old stand than in the young stand, with reductions of approximately 25–40% across years. In deep soil layers (100–300 cm), SWS in the old stand was 35–60% lower, indicating persistent deep soil water depletion. Actual evapotranspiration was 5–12% higher in the old stand, particularly during dry and normal years. Soil desiccation intensified with increasing soil depth and stand age, with strong desiccation frequently occurring below 100 cm in old stands during dry years. Root water uptake patterns differed between stands, with young stands extracting 25–60% more water from deep soil layers during drought, while old stands relied more on shallow and middle layers. Overall, the results demonstrate that older plantations impose greater stress on deep soil water resources, while younger stands show higher resistance to drought-induced soil desiccation. These findings highlight the importance of considering forest age and climate variability for sustainable afforestation and water management in semi-arid regions.

**ABSTRACT**

In southeastern (SE) China, rapid urban expansion has increased the extent of secondary and plantation forests converted from abandoned orchards, which could be potential hotspots of nitrous oxide ($N_2O$) emissions due to experiencing historical nitrogen (N) fertilizer applications and high N deposition. However, mechanisms underlying the dynamics of soil $N_2O$ emission from these lands remain poorly investigated, particularly under the significant influences of the SE Asian monsoon climate. In this work, we conducted a year-long observation and a short-term manipulation experiment to explore the factors driving soil $N_2O$ emissions from an urban forest converted from abandoned orchards in a mega city of SE China. Our results highlight its critical role as a significant yet underappreciated source of $N_2O$. Elevated concentrations of soil nitrate in the study area were driven by the combined effects of historical fertilization legacies and ongoing N deposition, providing abundant substrates for $N_2O$ emissions. Seasonal rainfall and rewetting events following droughts substantially influenced N dynamics, triggering $N_2O$ flux peaks during periods of rapid soil moisture changes. The annual $N_2O$ emissions in the study area reached 1.02 kg N $ha^{-1}$ $yr^{-1}$, significantly exceeding the emission strengths typically observed in other subtropical forests. The short-term drivers, such as rainfall-induced changes in soil moisture, were found to be critical for pulse releases of $N_2O$, whereas temperature and pH of soil water regulated the seasonal variations of $N_2O$ fluxes. These findings underscore the importance of integrated monitoring to capture both the immediate impacts of extreme climatic events and the long-term trends in emissions. Under sustained N deposition, urban forest soils play a vital role in regional N cycling, emphasizing their significance in global greenhouse gas assessments and strategies for mitigating climate change.

# Tree functional diversity enhances forest carbon and nitrogen storage across gradients

**ABSTRACT**

Increasing soil carbon and nitrogen storage can help mitigate climate change and sustain soil fertility. Although many biodiversity experiments indicate that higher plant diversity increases soil carbon and nitrogen stocks, whether these effects generalize to natural forests remains debated and how they vary with environmental context is unclear. Using Canada's National Forest Inventory and structural equation modelling, we quantify how tree diversity relates to decadal accrual of carbon and nitrogen in tree biomass and in organic and mineral soil horizons across broad gradients in light, water, and nutrient availability. Greater tree diversity increased soil carbon and nitrogen storage, consistent with experimental expectations. In the organic horizon, raising species evenness from its minimum to maximum increased soil carbon by 30% and soil nitrogen by 42%. In the mineral horizon, higher functional diversity increased soil carbon by 32% and soil nitrogen by 50%. Functional diversity also increased carbon gains in tree biomass, with stronger effects where light and soil nutrients were more available. Across soils, diversity effects intensified at sites with greater water and nutrient availability. Conserving and promoting functionally diverse, even forests, particularly in resource-rich environments, could substantially enhance carbon and nitrogen sequestration in natural forests.

## ABSTRACT

Subtropical forests play a vital role in global carbon cycling, acting as significant sinks for atmospheric $CO_2$ and $CH_4$. However, intensifying atmospheric nitrogen (N) deposition threatens to disrupt this balance by stimulating soil heterotrophic respiration ($R_H$) and nitrous oxide ($N_2O$) emissions while suppressing $CH_4$ uptake. Biochar amendment is a promising strategy to sequester C and improve soil health, yet its efficacy in counteracting the specific biogeochemical feedbacks triggered by N deposition remains unclear. This study synthesizes findings from a three-year field experiment to elucidate the microbial mechanisms by which biochar modulates soil greenhouse gas (GHG) fluxes under N deposition conditions.

Results showed that the N deposition significantly disrupted soil GHG balances. It stimulated $R_H$ by 8.1–9.8% annually by alleviating nutrient limitations, which upregulated the abundance of the fungal cellulolytic gene *cbh*I and enhanced cellobiohydrolase activity. Similarly, N deposition triggered a surge in $N_2O$ emissions (14.6–25.1%) by fueling nitrification and denitrification, evidenced by increased abundances of AOA*amoA*, *nirK* and *nirS* genes. Furthermore, it suppressed soil $CH_4$ uptake by 17–23%, primarily by inhibiting methanotrophs (*pmoA*) and stimulating methanogens (*mcrA*) via elevated inorganic N. Crucially, biochar amendment effectively counteracted these N deposition-induced negative feedbacks. (1) For $CO_2$: In the biochar application and N deposition treatment, biochar reduced $R_H$ by 8.1–8.9% compared to N deposition treatment alone. SEM analysis revealed this was driven by the suppression of *cbh*I-mediated organic matter decomposition and the promotion of *cbbL*-mediated autotrophic C fixation. (2) For $N_2O$: Biochar reduced emissions by 14.2–22.0% under N deposition. Mechanistically, biochar reduced labile substrates ($NH_4$, WSON) and downregulated the abundance of AOA*amoA*, *nirK* and *nirS*, thereby inhibiting the enzymatic pathways of nitrification and denitrification. (3) For $CH_4$: Biochar reversed the N-induced suppression, enhancing $CH_4$ uptake by 26–42% relative to N alone. This was attributed to increased soil aeration and labile C, which upregulated methanotrophic *pmoA* abundance and oxidation rates, while reduced inorganic N suppressed methanogenic *mcrA* abundance.

Biochar acts as a systemic regulator of soil microbial function, mitigating the global warming potential of N-saturated forests. We estimate that applying biochar to Moso bamboo forests across China could approximately reduce $R_H$-derived $CO_2$ by $7.6\times10^6$ t $yr^{-1}$, decrease $N_2O$ emissions by 1,949 t $yr^{-1}$, and increase $CH_4$ uptake by 6,478 t $yr^{-1}$. These findings underscore biochar's potential as a climate-smart forestry strategy.

# Soil-plant silicon cycle and climate change

**ABSTRACT**

Silicon is the second most abundant element in soil and widely participates in geochemical cycles. Research on silicon (Si) biogeochemistry and its beneficial effects for plants has received significant attention over several decades, but the reasons for the emergence of high-Si plants remain unclear (Pang et al., 2024). Hypotheses for the emergence of silicification include co-evolution with mammalian grazers and the role of environmental factors, such as high temperatures, drought, and low atmospheric $CO_2$ levels (de Tombeur et al., 2023). Here, we combine laboratory experiments, field studies and analysis of existing databases to test the role of temperature on the expression and emergence of silicification in terrestrial plants (Pang et al., 2025a). Firstly, the results of laboratory experiments show that Si is beneficial for plant under high temperature stress (40°C), but harmful under low temperature (0°C), whilst a 2°C increase results in a 37% increase in leaf Si concentrations. We then find that, globally, the average distribution temperature of high-Si plant clades is 1.2°C higher than that of low-Si clades. Across China, leaf Si concentrations increase with temperature in high-Si plants (wheat and rice), but not in low-Si plants (weeping willow and winter jasmine). From an evolutionary perspective, 77% of high-Si families (>10 mg Si $g^{-1}$ DW) originate during Earth warming episodes, while 86% of low-Si families (<1 mg Si $g^{-1}$ DW) originate during cooling episodes. On average, Earth's temperatures during the emergence of high-Si families are 3°C higher than low-Si families. Taken together, our evidence suggests that plant Si variation is closely related to global and long-term climate change. These findings on the link between plant silicification and changes in the Earth's temperature provide new clues regarding the interactions between Si and C cycling over geological timescales. In the future, we aim to further refine the interaction model among plant silicification, carbon cycling, and global temperature (Pang et al., 2025b). This model can be decomposed into the following cascading processes: First, the elevated atmospheric $CO_2$ concentration leads to global warming, and such a climatic context is likely to facilitate the emergence and expansion of high-silicon plants. These plants possess a strong capacity to absorb large amounts of monosilicic acid from the soil, which will promote silicate weathering. The cations released through silicate weathering will sequester $CO_2$ in the form of carbonates, which in turn exerts a negative feedback effect to reduce global temperature.

## ABSTRACT

Land-use change (LUC) is a core driver of dynamics in soil ecological function. Despite this, significant knowledge gaps remain regarding the variation of soil multifunctionality (SMF) across different LUC types, the relative contributions of soil environmental factors and microbial traits to SMF, and the identification of key drivers. This study focused on the Chaohu Lake basin in the middle-lower reaches of the Yangtze River. The impacts of LUC on soil microbial traits (diversity, network complexity and stability), physicochemical properties, mineral elements, and enzyme activities were investigated based on three land use types (grassland, cropland, and forestland). SMF was quantified using 26 indicators to identify its key drivers. The results demonstrated that after the conversion of cropland to forestland, soil properties and microbial community composition showed recovery toward a state similar to that of grassland, although microbial diversity decreased. Phosphorus could drive microbial community shifts. Trends toward recovery were also observed in microbial network complexity and stability, whereas only bacterial network stability increased significantly. Bacterial community assembly in grassland involved deterministic and stochastic processes. However, other land-use types primarily depended on stochastic processes, and total potassium served as a core driver of assembly. Cropland displayed the highest SMF, while the SMF of forestland recovered toward grassland levels. The drivers of SMF varied between soil layers. To be specific, physicochemical factors were predominant in the 0-20 cm layer, while chemical and mineral factors jointly drove SMF in the 20-60 cm layer. Notably, microbial network complexity emerged as a crucial microbial regulator of SMF. In general, reduced anthropogenic disturbance facilitated the recovery of SMF in forestland. In this study, knowledge gaps regarding SMF and LUC in the Chaohu Lake basin are addressed. Furthermore, this study underscores the critical role of microbial network complexity, elucidates the layer-specific differentiation of key drivers, and provides empirical insights for formulating ecological policies targeting regional land-use pattern optimization.

# Soil organic carbon fraction mediated microbial community assembly along stand age and seasonal gradients in temperate poplar plantations

## ABSTRACT

Despite harboring the largest forest carbon stocks, soil carbon persistence is mainly controlled by microbial regulators. However, there are large uncertainties about the mechanisms of microbial community ecology interaction with soil carbon speciation. In this study, we sampled soils from temperate Populus (*Populus euramevicana* cv.'I-214') Plantations of four different stand ages (3, 6, 10, and 13 years) for three seasons (spring, summer, and autumn). Through integrated analyses, including high-throughput sequencing, co-occurrence network construction, null and neutral modeling, and assessments of soil physicochemical properties, we found that stand age, season, and the interaction between them significantly affected soil organic carbon (SOC), easily oxidizable organic carbon (EOC), particulate organic carbon, mineral-associated organic carbon, and recalcitrant organic carbon (ROC) ($P < 0.001$), while dissolved organic carbon was not affected. During summer, all fractions of carbon except EOC increased in trend with stand age. Afforestation improved bacterial diversity and richness, and age-related changes in bacterial community composition ($P < 0.001$) were dominated by stochastic assembly processes, most likely in spring, mediated by soil pH, SOC, ROC, cellulase activity, and C/P ratio. In contrast, fungal community composition was strongly affected by seasonal variation ($P < 0.001$) through deterministic assembly processes, which were weakest in spring, and showed greater dispersal limitation than bacterial communities. Specific microbial modules were a significant predictor for different carbon fractions ($P < 0.05$). Stand age favored the accumulation of stable organic carbon, while seasonal variations enhanced the consumption of labile organic carbon. Overall, this study emphasizes divergent microbial assembly - carbon linkages along stand age and seasonal gradients and highlights the critical role of microbial community assembly in soil carbon sequestration and stabilization.

**ABSTRACT**

A global stoichiometric crisis is raising with increasingly higher availability of carbon (C) and nitrogen (N) relative to phosphorus (P) from various human-induced inputs and depletion of P-containing minerals; this promotes microbial P strategies shifts from acquiring to recycling. However, the component-specific P incorporation under varied nutrient availability remain unclear, which is an intriguing issue with broad consequences for microbial P (re-)cycling. We quantified P incorporation into microbial DNA and phospholipids by 33P labeling under four contrasting conditions (low/high P soil × low/high CNP addition). We found preferential P allocation to microbial DNA and phospholipids for P-rich and P-poor soils, respectively. P incorporation rate and turnover of the two P pools can be intensified by C availability via shifting microbial composition towards a stronger representation of their functional traits. Our results suggest that phospholipid can serve as a variable P storage to be potentially depleted via intracellular recycling under strong P limitation, which can "conserve" the microbial P cycling, aggregate soil P depletion and increase plant-microbial competition under global changes.

## ABSTRACT

Prairie restoration, defined as the re-establishment of native prairie vegetation and disturbance regimes on lands previously converted to agriculture or other intensive uses, is widely adopted as a strategy to enhance soil carbon sequestration and improve soil health. However, empirical evidence linking restoration age to soil physical and biogeochemical properties remains limited, particularly across landscapes with complex land-use histories. In this study, we examined soil carbon stocks and soil health indicators across a prairie restoration chronosequence in southern Wisconsin, USA.

We sampled soils from prairie sites restored at six time points spanning 1987 to 2024, along with two remnant prairies and one agricultural References site. Sites were located in close geographic proximity to minimize variation in climate and parent material. At each site, soil water infiltration was measured *in situ*, replicated soil cores were collected to 30 cm depth (partitioned into 0-10 cm and 10-30 cm increments), and soils were analyzed for soil carbon and nitrogen concentration and stocks, microbial biomass carbon (via chloroform fumigation-extraction), and selected soil physical and chemical indicators including bulk density, pH, and cation exchange capacity.

This study aims to evaluate how soil carbon stocks, microbial biomass, and soil physical properties vary with time since prairie restoration. We further examine the extent to which restored prairies converge toward remnant prairie soil conditions, and whether legacy effects of previous agricultural use persist across soil depths.

By integrating soil biogeochemical and physical measurements across sites with contrasting restoration chronosequence, this work seeks to improve understanding of soil recovery trajectories following prairie restoration. The findings will provide insights relevant to prairie restoration strategies and contribute to assessments of restored grassland as long-term carbon sinks.

**ABSTRACT**

Atmospheric deposition from industrial activity in the Athabasca Oil Sands Region (AOSR) of Alberta, Canada, poses a significant threat to boreal forest health. While the Wood Buffalo Environmental Association's (WBEA) Forest Health Monitoring (FHM) program has tracked these impacts since 1998, the long-term response of soil chemistry remains poorly understood. This study analyzes a 13-year (2011 – 2024) dataset from 12 unburnt FHM sites located at different distances from major emission sources. Soil samples from the forest floor (LFH) and three mineral soil layers (0 – 5, 5 – 15, and 15 – 30 cm) were collected across three sampling events (2011, 2018, and 2024) and analyzed for chemical properties. Mixed-effects models were employed to assess temporal trends, spatial gradients, and the distribution of total C, S, and N; bioavailable N, S, and P; pH; and exchangeable basic cations and Al. Results indicate that spatiotemporal trends were more pronounced in the LFH than in mineral horizons. In the LFH, extractable S, $SO_4$-S, $NH_4$-N, and exchangeable Ca were 37%, 46%, 79%, and 18% lower in 2024 than in 2011, respectively. Spatially, total S, pH, Ca, Mg, and BC:Al ratios in the LFH were significantly higher at sites closer to emission sources. Conversely, across all mineral layers, total C increased by 40% over the study period. Critically, no evidence of soil acidification was observed, even at high-deposition sites, due to the significant buffering capacity provided by basic cations. This long-term perspective is essential for predicting ecosystem resilience and formulating science-based policies to protect the boreal forest amidst ongoing industrial activity.

**ABSTRACT**

Clarifying the distribution patterns and drivers of soil organic carbon (SOC) and its labile fractions is essential for evaluating forest carbon sinks. Larch, which is widely distributed across northern China and has strong environmental stress tolerance, exhibits unclear SOC spatial variation pattern in its plantations. We hypothesized that soil properties act as direct drivers, whereas geographic and climatic factors exert indirect effects via hydrothermal conditions. Based on 0–30 cm soil samples from 41 sites, we examined the spatial variations and multiple drivers of SOC, particulate organic carbon (POC), easily oxidizable organic carbon (EOC), and dissolved organic carbon (DOC). Combined with random forest and structural equation modeling, we disentangled the multi-scale driving factors and regulatory pathways of these carbon fractions. Results showed that SOC and labile fractions decreased with soil depth and exhibited clear latitudinal and longitudinal gradients, SOC and EOC increasing along both latitude and longitude. EOC (7.55 ± 0.45 $g \cdot kg^{-1}$) and POC (5.24 ± 0.52 $g \cdot kg^{-1}$) were the dominant fractions, whereas DOC (0.132 ± 0.008 $g \cdot kg^{-1}$) accounted for the smallest proportion. SOC had a synergistic relationship with EOC and POC, but exhibited an inverted U-shaped relationship with DOC. Soil nitrogen and phosphorus were key direct drivers of SOC, POC, and EOC variations. Geographic factors, particularly latitude, strongly influenced POC and DOC through effects on hydrothermal conditions such as the mean annual temperature and precipitation. Overall, soil properties served as direct intrinsic drivers, whereas geographic and climatic factors and stand characteristics operated mainly through indirect pathways by regulating carbon input and decomposition. This study reveals the synergistic regulation of SOC stability in larch plantations by multiple environmental factors, clarifying the differential regulatory mechanisms of SOC and its labile fractions along a geographic gradient. These findings provide a scientific basis for enhancing soil carbon sequestration in larch plantations.

# Spatial Characteristics of Soil Organic Carbon in Forests of China

**Wenfa Xiao[1*], Zhilin Huang[1], Jizhen Chen[1] and Lei Lei[1]**

[1] *Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, 100091, China*

* xiaowenf@caf.ac.cn

**ABSTRACT**

In the context of global efforts to address climate change, China has made an active commitment to achieving carbon neutrality before 2060. As a vast country with significant regional variations in topography, climate, soils, and forest types, China has also undergone one of the world's largest forest restoration initiatives in recent decades. These combined factors have profoundly altered and improved the quality of forest soils across the nation. However, the remarkable spatial heterogeneity of China's forests introduces substantial uncertainty in estimating forest carbon sequestration potential and emission reduction capacity. Therefore, it is urgently necessary to obtain comprehensive baseline information on forest soils at the national scale, particularly regarding soil organic carbon (SOC).

Over more than a decade of effort, China has completed its first relatively systematic national forest soil survey, revealing key soil properties including bulk density, pH, organic carbon, total nitrogen, total phosphorus, total potassium, available potassium, and available phosphorus. Based on the 1:250,000 forest vegetation distribution database—covering 2.35 million forest polygons—together with 40 covariates in five categories (at 200 m spatial resolution) and 8,304 forest soil SOC samples collected from 31 provinces, municipalities, and autonomous regions between 2015 and 2023, a spatial model and digital soil mapping techniques were applied to simulate and map the spatial distribution of forest SOC. By integrating gravel content and bulk density data from soil profiles, SOC density was estimated across soil layers. Combined with China's 2021 national forest inventory data, the national forest soil organic carbon storage and its spatial characteristics were quantified.

The results showed that the mean SOC density within the top 100 cm of forest soils in China was 139.00 t/ha, with the highest values observed in the Southwest (167.38 t/ha) and Northeast (156.57 t/ha) regions. The total forest SOC storage was estimated at 27.78 Pg C, with the Southwest and Northeast contributing 34.75% and 18.86% of the total, respectively. This investigation provided the first comprehensive national baseline dataset of China's forest soil information, offering valuable support for the development of forest management strategies and for improving the scientific estimation of forest soil carbon stocks under the global climate change context.

# Mechanisms of soil organic carbon accumulation under green manure cover in citrus orchard

**Jiajia Zhang[1]*, Wenfa Xiao[1], Lixiong Zeng[1] and Lei Lei[1]**

[1] *Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, 100091, China*

*zhangjiajia@caf.ac.cn

**ABSTRACT**

Living green manures are widely recognized as an effective practice for enhancing soil organic carbon (SOC) in orchard ecosystems, yet the underlying accumulation pathways remain poorly understood across soil textures. To elucidate these mechanisms, we conducted field experiments in citrus orchards with living smooth vetch (*Vicia villosa* var. *glabresens*) cover and clean tillage under two contrasting soils: sandy loam and silty clay loam. We also used a microcosm experiment with isotope labeling to quantify SOC fractions and the C source and fate in root, mycelium, and coexistence pathways under citrus–vetch intercropping versus citrus and vetch monocropping.

In sandy loam, vetch cover markedly increased particulate organic carbon (POC, 106~239%) and mineral-associated organic carbon (MAOC, 43~243%), leading to a 232% rise in surface SOC. In silty clay loam, SOC increased by 19% in the topsoil through modest POC (13%) and MAOC (4%) gains, while MAOC within deeper layers showed a declining trend. In sandy loam, vetch cover enhanced microbial carbon pump (MCP) efficiency via greater nutrient availability, clay and mineral factors, driving microbial necromass C contributions to both POC and MAOC. By contrast, in silty clay loam, POC accumulation was mainly plant-derived C but diluted microbial contributions with in topsoil (ΔMCP efficiency < 0); MAOC in deeper layers tended to destabilize due to MCP efficiency being constrained by elevated mineral protection and phosphorus availability.

Vetch cover increased both vetch- and citrus- derived C in POC by 10.83%, but decreased citrus and native SOC in MAOC by 46.72% via the root pathway. Through the mycelium pathway, vetch C was retained in POC (3.25%) and MAOC (0.23%), while 92.04% of citrus C was stabilized in MAOC, resulting in a 1.4 fold increase compared to citrus (64.9%) and vetch (66.6%) monocultures. Under vetch cover, root–mycelium pathways increased rhizosphere MAOC by 45.5%, which was 1.9 times higher than citrus monoculture (15.6%) and exceeded the combined effect of citrus and vetch monocultures (24.6%), resulting in a 56.6% net SOC gain. Distinct C and N allocation from vetch via root and mycelium activated r-strategists (gram-negative bacteria) and k-strategists (saprotrophic fungi) microbial groups to preferentially assimilate recent photosynthate, respectively, enhancing microbial carbon use efficiency and amino sugar accumulation efficiency. This reduced the priming effect and promoted C stabilization across SOC pools in distinct forms.

Overall, vetch cover markedly enhanced SOC accumulation, but the dominant mechanisms differed by soil texture and pathway. Citrus–vetch interactions strengthened mycelium-mediated MAOC formation, achieving a synergistic "1 + 1 > 2" effect on SOC stabilization. These findings underscore the need to tailor green manure management to soil texture to optimize carbon sequestration and ecosystem sustainability in perennial orchard systems.

## ABSTRACT

Fire-deposited charcoal is a widespread and long-lasting component of fire-affected ecosystems, yet its ecological roles in subtropical forest soils remain insufficiently explored. Through a series of long-term field-based charcoal manipulation experiments in *Pinus massoniana* plantation timber harvest sites in southern China, we examined how varying amounts of fire-derived charcoal influence soil microbial communities, nutrient dynamics, and carbon (C) stability following broadcast burning. Results consistently demonstrated that charcoal significantly alters key aspects of soil ecological functioning across multiple temporal scales. One year after charcoal application, a taxon-specific shift in the relative abundance of soil bacterial and fungal genera was observed, although overall microbial diversity remained unaffected. Soil pH emerged as the dominant factor regulating bacterial abundance and diversity, while available phosphorus also contributed to structuring microbial community composition. Five years after burning, 11 out of 32 measured soil indicators—including soil organic matter (SOM), microbial biomass carbon, and enzyme activities—differed significantly among treatments. Plots with higher charcoal inputs effectively alleviated fire-induced soil degradation, restoring soil organic matter and microbial properties to levels comparable to the unburnt control, whereas plots with reduced charcoal inputs showed limited recovery and remained degraded. Seven years after treatment, charcoal continued to exert beneficial effects on soil C stabilization. Although it did not alter dissolved organic C, charcoal markedly enhanced microbial C assimilation, the C pool management index (CPMI), and the proportion of soil organic C associated with small, stable aggregate fractions (<0.05 mm) at the surface layer (0–10 cm). MBC was also elevated in deeper soils (10–20 cm) of charcoal-amended plots, indicating a depth-dependent response. Collectively, these studies reveal that fire-derived charcoal contributes to soil quality recovery, microbial reorganization, and long-term C stabilization in subtropical forest plantations. By improving soil chemical balance, promoting microbial functionality, and facilitating the incorporation of organic C into stable aggregates, charcoal serves as an essential ecological legacy of fire that enhances post-disturbance soil resilience. These findings underscore the importance of managing charcoal generation and retention in broadcast burning practices to sustain soil health and support ecosystem restoration in subtropical plantation forests.

# Aggregate-mediated mechanisms of soil carbon and greenhouse gas emission under green manure cover in citrus orchard

**Lei Lei[1*], Meng Zhang[1], Hongbing Yang[1], Lixiong Zeng[1] and Wenfa Xiao[1]**

[1] *Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, 100091, China*

**ABSTRACT**

Living green manures are recognized as an effective strategy to enhance soil organic carbon (SOC) storage and improve soil quality in orchard ecosystems. However, the underlying mechanisms linking soil aggregate stability, carbon stabilization, and greenhouse gas (GHG) emissions under long-term cover cropping remain unclear. To address this knowledge gap, this study investigated citrus orchards in the Three Gorges Reservoir area to explore how long-term legume cover cropping reshapes soil aggregate structure and carbon stabilization processes, and how these structural and biochemical changes jointly regulate $N_2O$ emissions.

Clean tillage (CK) and smooth vetch (*Vicia villosa* Roth var. *glabresens* Koch) cover cropping maintained for 4, 6, 7, 10, and 11 years were compared. Soil aggregates were fractionated into large macroaggregates (LMA, 2–8 mm), small macroaggregates (SMA, 0.25–2 mm), and microaggregates (MIA, <0.25 mm), and their carbon fractions were analyzed through field sampling and laboratory incubation experiments. The results showed that, long-term smooth vetch coverage significantly increased LMA (3.63%–34.35%) while reducing SMA and MIA fractions (4.35%–27.09% and 18.22%–59.86%), and enhanced both particulate (fPOC, oPOC) and mineral-associated organic carbon (MAOC). These changes indicated a transformation of labile carbon into more stable forms, with calcium ions and pH identified as key regulators of MAOC formation. PLS-PM analysis showed that aggregate stability and the fPOC/MAOC and oPOC/MAOC ratios contributed to SOC increases of 41.46%–117.32%.In parallel, smooth vetch cover significantly increased mean $N_2O$ and $CO_2$ emission fluxes, but emissions declined after 11 years as aggregate stability improved. Aggregate size significantly influenced GHG fluxes ($p < 0.001$), and PLS-PM results revealed that cover duration regulated $N_2O$ emissions via three main pathways: modulating soil moisture, enhancing water-stable aggregate stability (W_MWD), and optimizing the microbial C:P threshold elemental ratio (TER C:P).

Together, these findings demonstrated that long-term legume cover cropping enhances both structural and chemical stability of soil carbon, thereby achieving dual benefits of SOC sequestration and GHG mitigation. This integrated understanding provides a scientific basis for sustainable orchard management and climate-smart agricultural practices in subtropical regions.

# Phosphorus Limitation and Adaptation Strategies for Productivity Formation of Pinus massoniana Plantations in China

**Lixiong Zeng[1*], Zunji Jian[1], Lei Lei[1], and Wenfa Xiao[1,2]**

[1] *Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, China*

[2] *Chinese Academy of Forestry, Beijing, China*

*zenglx@caf.ac.cn

**ABSTRACT**

China has the largest area of plantations globally, contributing to 25% of the global increase in green area. However, improving the productivity of these plantations remains a core challenge. Phosphorus (P), an essential element for plant growth and metabolism, plays a critical role in energy storage, transfer, and transformation. In China, planted forests (e.g., *Cunninghamia lanceolata*, and *Pinus massoniana*) are predominantly distributed in subtropical regions where available P levels are low, significantly impacting forest productivity. This study addresses two primary issues: (1) Is the productivity of *P. massoniana* plantations limited by soil P availability? (2) How does this species respond to low P (that is P limitation) during its growth cycle? The data comes from two aspects: literature data (1990-2019) and survey data (2012-2019).

We found that over 85% of the surveyed sites exhibited deficient levels of total P and available P, indicating P deficiency as a major factor determining soil fertility in *P. massoniana* plantations. Spatially, total P levels were higher in eastern, northern, and southern regions of subtropical China, while available P was more abundant in eastern and northern regions. Vertically, available P decreased with soil depth. With the increasing latitude, leaf N:P ratio and soil acid phosphatase (ACP) activity increased, indicating P limitation even at high latitude. Increased soil ACP activity compensated for P deficiency, while high N:P ratios (>16, a threshold for P limitation) in needles reflected P stress. Multiple regression models demonstrated that soil total P significantly influenced the annual net primary productivity of *P. massoniana* plantations, explaining 8-35% of the variation. Structural equation models accounted for 11-13% of ANPP variation, highlighting indirect effects of soil total P on productivity through root P uptake. Soil available P consumption transitioned to accumulation at around 30 years of stand age. With increasing age, the N:P ratios of all organs (except the branches and the current year leaves) >16, and showed an increasing trend. Also, soluble sugar/ starch ratio increased first and then decreased in the coarse roots, and the maximum value was reached at 37 years. Soil available P and ACP activity significantly increased after 28 years of age, while soil enzyme-P decrease at the same age.

In conclusion, the planted forests of *P. massoniana* in subtropical China suffer from severe P deficiency, which is the key limiting factor for productivity. The degree of P limitation increases initially and then decreases over the growth cycle, peaking at 37 years. This tree species employs two main strategies to cope with P limitation: physiological absorption strategies involving internal P mobilization and reduced trunk growth in older stands, and soil P utilization strategies enhancing ACP production to improve P availability.

**ABSTRACT**

Recent studies have shown that biochar by artificially adding is a reliable method to reduce atmospheric carbon dioxide concentrations. Stable biochar alters soil structure, water absorption, and microbial activity, which in turn affects the short-term turnover of natural soil organic carbon through the priming effect. However, there is a knowledge gap regarding how biochar influences the direction, persistence and magnitude of the priming effect on soil native organic carbon, as well as the underlying microbial response mechanism. The objectives of the study are to investigate the priming effect of biochar on natural soil respiration, soil respiration temperature sensitivity, soil microbial diversity, microbial community structure, enzyme activity and carbon source utilization under different biochar dosages. These findings will help clarify the soil carbon self-circulation model and provide a scientific basis for subtropical management of subtropical bamboo forest. To understand the interaction effects of biochar-root in forest trees, we examined the root morphology and soil microbial community on moso bamboo plantations (*Phyllostachys edulis*) as well as one-year old its seedlings with four biochar addition treatments (control: CK 0 $t \cdot hm^{-2}$,low biochar: LB 5 $t \cdot hm^{-2}$, medium biochar: MB 10 $t \cdot hm^{-2}$ and high biochar: HB 20 $t \cdot hm^{-2}$). The results showed that biochar addition decreased the soil respiration rate, and this decrease became smaller as the biochar dosage increased. Compared with CK, the mean soil respiration rate in LB, MB and HB decreased 2.33%–54.72%, 1.28%–44.21% and 0.09%–39.22%, annual mean soil moisture increased 0.62%–75.58%, 0.87%–48.18% and 0.68%–74.73%, respectively. Compared with control, total microbial biomass in 0-10 cm increased 9.1% and 3.5% after the first and the second year' biochar addition for LB, increased 22.0% in the first year and decreased 9.0% in the second year for MB, both increased 7.1% and 7.8% for HB. Biochar addition significantly decreased Chao abundance, Shannon's indicator of bacteria in HB, and increased Simpson's indicator of bacteria in HB, microbial biomass at 10–20 cm soil, polyphenol oxidase activity, invertase and urease activity at 0–10 cm soil. Annual cumulative soil respiration was significantly and positively correlated with the biomass of total PLFAs, gram-negative bacteria, bacteria, and arbuscular mycorrhizal fungi ($P < 0.05$) at 0–10 cm soil. The contribution of the decomposition of biochar-self to soil carbon mineralization was 0.8%–1.1%, root contribution for that increased 3.1%–4.0%. In conclusion, low biochar addition significantly decreased soil carbon emission by increasing microbial biomass and soil enzyme activity at 10–20 cm depth. It also altered the microbiological community structure and biodiversity, which lays the foundation for long-term forest ecosystem C sequestration in forest ecosystems and provides a practical References for climate change mitigation.

**ABSTRACT**

The decomposition of organic matter is a major determinant of the biosphere – atmosphere carbon feedbacks and ecosystem nutrient recycling. Decomposition depends on the characteristics and diversity of plant-produced organic matter as the primary energy source, and is further regulated by an astounding diversity of soil organisms ranging from prokaryotes to macro-invertebrates that are organized in highly complex food webs. It can also be indirectly regulated by plant canopy driven modifications of micro environmental conditions. However, the complexity of interactions across trophic levels has made it difficult to quantify how biodiversity regulates ecosystem processes. Furthermore, simultaneous climate and biodiversity change are of particular concern, because biodiversity may contribute to ecosystem resistance and resilience and may mitigate climate change impacts. Yet, the extent and generality of how climate and biodiversity change interact, remain insufficiently understood. Here we show a regional study by manipulating diversity from litter to decomposer across stands of tree diversity gradients, to disentangle the complex interaction multi-trophic diversity. We show litter diversity consistently accelerating decomposition, which could be further facilitated by decomposer diversity. Tree diversity also indirectly facilitates the complementarity of decomposition with favoring microenvironment and decomposer activity. Furthermore, with an inter-biome experiment, we tested here how biodiversity in the multi-trophic decomposer system drives decomposition in forest ecosystems under drier conditions. Our results show at a relevant spatial scale covering distinct climate zones that forest floor biodiversity across trophic levels has a strong potential to mitigate drought effects on C and N dynamics during decomposition. Preserving biodiversity at multiple trophic levels contributes to ecosystem resistance and appears critical to maintain ecosystem processes under ongoing climate change.

**ABSTRACT**

A shared future for humanity requires enhancing human well-being within a healthy environment. This can be achieved by promoting sustainable development through efficient soil management that enables carbon storage across diverse ecosystems worldwide. This study summarizes three decades of research on soil organic matter (SOM) management in forest and related systems in the eastern Amazon (Brazil) and the Congo Basin. Effective soil management is essential for climate change mitigation, food security, land restoration, and biodiversity conservation, as demonstrated by long-term studies in forest and pasture ecosystems of the Brazilian Amazon, and in forest plantations, agroforestry, and fallow systems in the Congo Basin.

Pasture establishment and afforestation generally increase soil organic carbon, particularly in topsoil, as observed in 17-year-old pastures in the Brazilian Amazon and in mixed forest stands in the Congolese coastal plains, thereby contributing to climate mitigation. However, over time, SOM quality becomes more labile-both in Amazonian pastures and in Congo Basin plantations (five years into the second 7-year rotation)-potentially reducing long-term carbon storage benefits. These findings highlight limitations in achieving certain Sustainable Development Goals (Agenda 2030) and underscores the need for improved management strategies.

Ecosystem management tailored to local environmental resilience can enhance carbon storage and associated co-benefits, supporting healthy soils, ecosystems and humans. For example, legumes improve soil fertility, particularly nitrogen availability, and enhance bacterial and fungal communities compared with non-leguminous species. However, species selection is critical, as some legumes, such as *Calliandra*, may produce lower yields than natural fallows dominated by *Chromolaena*, which is better adapted to acidic soils. Biodiversity may also be threatened by invasive species: *Chromolaena* often performs well, whereas *Acacia mangium* increases carbon and nitrogen stocks and improves phosphorus availability in topsoil but carries a high risk of invasiveness. Its use therefore requires careful risk assessment prior to implementation.

Overall, managing carbon through appropriate tree-based ecosystem strategies can promote climate change mitigation and biodiversity conservation, ensuring long-term ecosystem sustainability and human well-being.

**ABSTRACT**

Vegetation composition is an important factor driving changes in soil function in forest ecosystems. In order to investigate the effects of community characteristics and soil cementitious substances on soil aggregate stability in different forest types in Zhangguangcailing mountains, we compared the changes in soil aggregate stability and the differences in the content of cementitious substances in three typical forest types in Zhangguangcailing mountains (dark coniferous forests, mixed spruce coniferous forests, and montane poplar birch forests); analyzed the effects of organic and inorganic cementitious substances on aggregate stability; and explored the mechanism of the role of community characteristics on aggregate stability using the partial least-squares throughput model. The effects of organic and inorganic cementitious substances on the stability of aggregates were analyzed, and the mechanism of community characteristics on the stability of aggregates was investigated using the partial least squares throughput model. The results showed that (1) the particle size of aggregates in the three forest types was mainly concentrated in the range of 2-0.25 mm, and the soil aggregate stability of the mixed conifer forest was significantly higher than that of the other two forest types. (2) Compared with the dark coniferous forests, the total organic carbon of the mixed conifer forests and the mountain poplar birch forests were 57.1% and 44.2% higher, the total particulate organic carbon was 56.9% and 48.4% higher, and the total mineral-bound organic carbon was 66.3% and 71.3% higher, respectively. The above three kinds of organic carbon contents in the dark conifer forest were significantly lower than those in the other two forest types ($P$<0.05); (3) the complexed state of iron oxides showed that the mountain poplar birch forest > cloudy fir mixed conifer forest > dark conifer forest, and the amorphous form of iron oxides and free iron oxides did not have any significant difference among the soil layers ($P$>0.05). (4) Partial least squares throughput modeling showed that community characteristics had a direct highly significant negative effect on iron oxide content (throughput coefficient of -0.459, $P$ ≤0.001), and a direct positive effect on organic carbon, but not significant ($P$>0.05). Soil iron oxide had a significant positive effect on soil organic carbon (throughput coefficient of 0.349, $P$≤0.1) and a positive but non-significant effect on aggregate stability. Soil organic carbon had a highly significant positive effect on soil aggregate stability (throughput coefficient of -0.693,$P$≤0.001). In summary, soil aggregate stability was highest under mixed spruce-fir forest; organic cementitious materials played a direct role in soil aggregate stability, and inorganic cementitious materials played a role as an indirect factor; the influence of different forest types on aggregate stability was mediated by cementitious materials, and changes in forest type directly affected the inorganic cementitious materials in the soil, and the inorganic cementitious materials directly affected the accumulation and transformation of organic cementitious materials, thus affecting aggregate stability. Inorganic cementitious substances directly affect the accumulation and transformation of organic cementitious substances, which in turn affects the stability of aggregates. Therefore, the upper layer of vegetation can mediate the state of iron oxides, affect its interaction with soil organic carbon, and ultimately have an impact on the aggregates. This study can provide a theoretical basis for revealing the coupling relationship between the stability of forest dark brown soil aggregates and cementing materials.

**ABSTRACT**

Forest degradation caused by human activities, invasive species and previous land use has led to a decline in soil physical quality and ecosystem functioning in Mistbelt forests. Active ecological restoration has been implemented to address this decline through the planting of indigenous tree species, yet there is limited data on how short-term restoration affects soil physical properties. The study evaluated the early impacts of restoration on soil physical and hydraulic properties across three Mistbelt forest sites. It was arranged in a 2 x 3 factorial design, with factors comprising two statuses (restoration and References) and three gradients partitioned into blocks, which were replicated 10 times. A two-way analysis of variance was used to analyse soil properties including soil bulk density (BD), total porosity (TP), soil moisture content (MC), mean weight diameter (MWD), glomalin-related soil protein (EE-GRSP), aggregate stability, etc. Results demonstrated that the most improved responses were observed in Izingcuka, as compared to the Swallowtail and Madonna and Child sites. At Swallowtail restoration, the results showed slightly elevated BD (1.24 g $cm^{-3}$), lower TP and lower MC (13%) than References site. This was likely due to previous land disturbances, including deforestation and soil compaction. The soils across the study were generally fine-textured soil, with high clay and silt content. This further explain the lower soil porosity and limited soil moisture availability observed. At the Zingcuka restoration site, MWD (3.44) and MC (63%), were notably higher, reflecting stronger aggregates stability and reduced water loss. In contrast, the Madonna and Child sites showed a more variable pattern, with increase in water content but had signs of restricted pore development and slower infiltration. No significant difference was observed ($p > 0.05$) in EE-GRSP, suggesting that the changes in soil structure are mainly driven by physical factors, such as such as clay content rather than restoration activities. Overall, the findings indicate that active forest restoration contributed to improvements in soil physical conditions, though the extent of recovery differs between sites and are still in their early stages.

**ABSTRACT**

Tropical dry forests (TDFs) are biodiversity hotspots and provide essential ecosystem services, yet they are among the most threatened biomes globally due to deforestation, overgrazing, and climate change. Soil processes in TDFs remain poorly understood, particularly regarding how chronic anthropogenic disturbances (CAD) alter microbial-mediated carbon and nutrient cycling. The TRILOBITE project addresses this knowledge gap by investigating the resistance and resilience of soil microbial communities to CAD-induced degradation and their role in soil organic carbon (SOC) sequestration during natural one year regeneration in the Tumbesian dry forests of southwestern Ecuador.

Our study combines a replicated degradation gradient with grazing exclusion plots to disentangle the effects of disturbance and recovery. We integrate the study of plant-soil feedbacks (PSFs), microbial community composition changes, and SOC fractionation using complementary approaches: ecophysiological indicators (fungi:bacteria ratio, metabolic quotient, microbial biomass C), litter decomposition assays, and high-throughput sequencing to assess phylogenetic diversity in bulk and rhizosphere soils. SOC pools were quantified through conventional fractionation and Vis-NIR spectroscopy to enable scalable monitoring.

Our results showed that SOC and mineral-associated organic matter (MAOM) decline significantly with CAD, accompanied by reductions in nitrogen and phosphorus and lower C:N ratios, indicating impaired nutrient retention. Aggregate stability showed no significant differences along the gradient, though a decreasing trend was observed with degradation. Microbial activity remained relatively stable across degradation stages, but fungal and bacterial alpha diversity decreased under disturbance. Notably, fungal community structure was strongly influenced by degradation and seasonality, whereas bacterial communities were less responsive. These patterns suggest that fungi may serve as sensitive indicators of ecosystem resilience thresholds.

Our findings emphasize the vulnerability of TDFs to CAD and highlight the importance of managing disturbance regimes to enhance soil carbon storage and biodiversity. By linking microbial traits to SOC dynamics, this research provides actionable insights for sustainable soil management, restoration planning and climate change mitigation through improved land stewardship in tropical dry forests.

## ABSTRACT

The fate of litter-derived carbon (C) inputs into forest soils determines soil nutrient cycling and C accrual, which in turn sustains ecosystem productivity and resilience. Forest soil C cycling is influenced by various factors, such as microbial substrate availability and nutrient demand. Further, wildfire can alter these C and nutrient cycles, affecting how litter-derived C is transformed and stabilized. To unravel the drivers of C stabilization in forest soils we performed a 72-day C-addition incubation, where we added different types of litter to soils with differing burn histories (50 years or 5 years since last burn), with and without additional inorganic nitrogen (N). $^{13}$C-labelled pine needle litter was added whole or after fractionation into structural and water-soluble components. The litter-derived C was traced to calculate soil priming and C-use efficiency (CUE). A CRDS analyzer was used to obtain high-temporal resolution $^{13}C$-$CO_2$ data throughout the course of the incubation. Priming was low in both soils, at times even negative. CUE was higher in the 50-year-since-burn soil compared to the CUE in the more recently burned soil. We found that CUE was highest with the labile litter fraction, which had the highest C:N ratio. Further, the addition of inorganic N had no effect on CUE or soil priming in either soil. These results suggest that C quality, but not necessarily N availability, was the primary driver of the fate of litter-derived C in these forest soils. Burn history also had a lasting impact on C cycling, with greater total C but less soil respiration and a lower CUE of added litter, demonstrating how wildfire can alter the fate of C inputs in forest soils.

# Developmental plasticity drives convergent shifts in phosphorus acquisition strategies toward root phosphatase activity in Moso bamboo under nitrogen addition

## ABSTRACT

Anthropogenic nitrogen (N) deposition is a major driver of global change. However, its effect on the developmental plasticity of plant nutrient strategies remains poorly understood. This is particularly critical in phosphorus (P)-limited subtropical forests, where N-induced shifts in biogeochemical cycles may intensify P constraints. Using Moso bamboo (*Phyllostachys edulis*) as a model system, we investigated the response of root P acquisition strategies and leaf P fractions to N addition at different developmental stages (young vs. mature). We identified a convergent shift in P-acquisition pathways in response to N addition: young bamboos transitioned from morphological (specific root length and area) to exudation-based strategies, whereas mature bamboos shifted from carboxylate-dominated to phosphatase-enhanced pathways. Ultimately, both stages converge during root phosphatase-mediated organic P mobilization. This strategic unification was also observed in the leaves: N addition significantly reduced inorganic P pools without altering structural P fractions (lipid-P, residual-P, and nucleic-P), indicating a prioritization of P for growth amid intensified limitation. The key drivers, including soil acidification, available P depletion, microbial biomass P accumulation, and root phosphatase activity, collectively influenced this root-leaf recalibration. By integrating specific root pathways and internal P fraction dynamics, our study advances the conventional "Get–Save–Return" framework, underscoring developmental plasticity as a central mechanism in tree responses to N deposition. These findings provide a new mechanistic understanding of nutrient cycling in subtropical forests under global climate change conditions.

## ABSTRACT

Vegetation restoration is a key ecological measure for reducing soil erosion. However, the direct and indirect regulatory mechanisms of different vegetation restoration measures on soil erosion resistance in the Three Gorges Reservoir Area (TGRA) remain unclear. Therefore, this study selected 7 types of vegetation restoration measures in Heigou watershed to quantifying soil physical and chemical properties, root traits, microbial community diversity, and separation capacity under different vegetation restoration types to clarifying the impact of vegetation restoration measures on soil erosion resistance. Meanwhile, combined with PLS-SEM, the direct and indirect regulatory mechanisms of biological and abiotic factors on soil erosion resistance were elucidated. The results showed that the soil contents of soil organic matter (SOM), total nitrogen (TN) and total phosphorus (TP) in tea plantation were significant higher than that in the other land uses. The root mass density (RMD) in bamboo forest was significant higher than that in the other land use types. The diversity of soil bacterial and fungal communities and soil aggregate stability were significantly higher in the mixed coniferous-broadleaf forest than in the other land use types. Different vegetation restoration measures significantly reduced soil separation capacity ($P<0.05$). Root traits and soil aggregate both had direct and significant negative effect on soil erodibility ($P<0.001$). Meanwhile, root traits had indirect and significant positive effect on soil aggregate by affecting the diversity of soil bacterial communities ($P<0.01$). Planting of plants with well-developed root system in the future can reduce soil erosion in the Three Gorges Reservoir area.

**ABSTRACT**

Nitrogen (N) deposition alters soil carbon (C) cycling through plant–microbial–mineral interactions; however, the evolution of soil organic carbon (SOC) pools in acid soil from N addition to N decline remains poorly understood. A decade-long field experiment in a subtropical acid soil—comprising seven years of N addition and three years of cessation—revealed that particulate and mineral-associated organic carbon (POC and MAOC) exhibit starkly contrasting dynamics. The POC pool and its proportion of SOC had a biphasic response to N addition and cessation: an initial decline (compared to control) with prolonged N addition exposure was followed by a recovery phase, a dynamic governed by plant-derived C inputs. This short-term (four-year) decline stemmed from N-induced microbial decomposition exceeding plant C inputs, reducing net plant-derived C. Recovery of the POC content to the control level during the long-term (seven-year) and post-cessation phases occurred through acidity-driven suppression of microbial decomposition, establishing a plant-derived C input-decomposition equilibrium. The MAOC pool and its SOC proportion continuously increased (2–17% vs control) during and after N addition, primarily driven by microbial necromass accumulation and increased mineral protection by iron and aluminum oxides. POC and MAOC shifted from coupling under short-term N addition to decoupling under long-term addition and after cessation, primarily due to asynchronous plant–microbial responses. Overall, our results confirmed that N addition leaves a positive legacy in MAOC that increases SOC stability, improving predictions for forest acid soils C dynamics under shifting N deposition regimes.

**ABSTRACT**

The impact of atmospheric nitrogen (N) deposition on the soil organic carbon (SOC) pool in Moso bamboo forests is directly related to the balance and stability of the forest's carbon (C) pool. This project employs a combination of in-situ $^{13}CO_2$ pulse labeling in the field and continuous $^{13}C$ labeling in the laboratory to explore the allocation of rhizodeposited C in the soil's active organic C pool and its response to N deposition. Additionally, high-throughput sequencing and quantitative PCR techniques are used to identify key microbial functional groups involved in the degradation of rhizodeposited C and their response to N deposition. Furthermore, metabolomic analysis is conducted to investigate the effects of N deposition on key primary metabolites in the rhizosphere soil of Moso bamboo, aiming to screen for differential metabolites. The findings indicate that N deposition increases the content of rhizodeposited C (CdfR) and its allocation in SOC of the rhizosphere soil. The increase in rhizodeposited C leads to a reduction in C-degrading microorganisms and functional genes but enhances the abundance of $CO_2$-fixing microorganisms and functional genes. Model analysis reveals that the increase in the soil's active C pool is caused by the increase in rhizodeposited C, which is mainly associated with the reduction in C-degrading microorganisms and the increase in $CO_2$-fixing microorganisms. Under N deposition, C-degrading fungi in the rhizosphere soil increase while C-degrading bacteria decrease, suggesting that C-degrading fungi may preferentially utilize rhizodeposited C, leading to a decrease in $SO^{13}C$ content and an increase in the proportion of $DO^{13}C$ and $MB^{13}C$ in $SO^{13}C$. Moreover, N deposition significantly increases the content of sugars (Melibiose, D-Lactose*) and amino acids and their derivatives (L-Lysine, L-Glutamine) in the rhizosphere soil in the short term. However, as the $^{13}C$ labeling duration increases, N deposition significantly enhances the content of sugars (Sucrose-6-phosphate, D-Melezitose) and nucleotides and their derivatives (Hypoxanthine, Allopurinol). The research outcomes will provide a scientific foundation for maintaining the balance of the forest SOC pool and identifying forest soil C sinks.

**ABSTRACT**

The low soil phosphate (P) bioavailability is a crucial factor determining plant productivity. It is an efficient strategy to greenly improve P bioavailability for phosphate-solubilizing microorganisms (PSM) to continuously activate soil P pool. However, the single-strain inoculants are not resilient enough to provide a highly efficient and stable function in the field. The construction of synthetic microbial communities (SynComs) is expected to solve this problem through the division and cooperation between microorganisms. Moso bamboo (*Phyllostachys edulis*) forests have high productivity despite the P-limited conditions, which be attributed to the recruitment of PSM by the 'rhizome-root integrated system'. The construction of SynComs for phosphate-solubilizing and elucidating their mechanism of enhancing P bioavailability will provide new ideas for greenly improvement of soil P bioavailability and productivity of Moso bamboo forests. Coupling field sampling, laboratory culture and field inoculation tests using high-throughput isolation and screening, this study parsed out and isolated the core taxa of PSM; the stable and highly efficient core microbiota for phosphate-solubilizing can be constructed; using the soil in situ zymography, the effect of this core phosphorus-dissolving microbiota on soil P cycle and bamboo growth was explored. These results are as follows:

(1) A total of 125 P-solubilizing bacteria were isolated from the bamboo rhizosphere, predominantly belonging to the phylum Proteobacteria (96.8%), followed by Actinobacteria (1.6%) and Firmicutes (1.6%). Three strains with the strongest P-solubilizing activity against insoluble phosphorus sources, including iron phosphate, aluminum phosphate, and lecithin, were selected to construct 27 P-solubilizing bacterial communities. Among these communities, 81.0% exhibited competitive relationships (–), while 19.0% displayed synergistic relationships (+). The SynCom, composed of SI-9, SIII-4, and SIII-20, exhibited the best P solubilizing activity, particularly under low phosphorus conditions, with an activity of 66.7 $mg \cdot L^{-1}$.

(2) In low phosphorus (LP) and high phosphorus (HP) conditions, compared with the control, the SynCom inoculation decreased the soil TC/TP and TN/TP ratios, indicating soil P limitation were alleviated by SynCom inoculation. SynCom inoculation increased soil available P (AP) content, particularly in LP conditions. Under LP conditions, compared with the control and single-strain treatments, the ACP activity in the SynCom treatment increased by 186.9% and 40.9%, respectively, with the hotspot area expansion by 1.4 and 1.3 times, and the *phoC* and *phoD* gene increased by 10.0%~24.8% and 2.3%~95.0%, respectively. The contents of Free iron oxide (Fed) and Free aluminum oxide (Ald) were lower than in the control, indicating that SynCom promoted organic P mineralization by increasing soil ACP activity, expanding the hotspot area and increasing the abundance of soil microorganisms containing P-related gene. It also promoted the dissolution of secondary mineral P by reducing Fed and Ald content. In LP and HP condition, compared with the control and single-strain treatments, SynCom inoculation increased the aboveground dry weight (14.8%~128.5%) and belowground dry weight (23.2%~331.9%) of Moso bamboo. These findings lay the foundation for enhancing soil P availability and productivity in Moso bamboo forests.

**ABSTRACT**

Stoichiometric homeostasis, the ability to maintain internal nutrient balance, is central to plant fitness under soil nutrient variability. While traditionally viewed as static, emerging theory posits it is a conditionally flexible trait, though empirical evidence is scarce. Through large-scale field investigations, nutrient additions, and data synthesis, this study shows that Moso bamboo (*Phyllostachys edulis*), a fast-growing plant species, employs a unique compartmentalized homeostasis strategy by decoupling nitrogen (N) and phosphorus (P) regulation across tissues. It achieves strict N:P homeostasis in leaves while allowing P flexibility in woody tissues to serve as reservoirs that buffer leaves from soil P limitation and microbial competition. This mechanism, consistently observed in bamboo across wide geographical and soil nutrient gradients, yields lower leaf N:P variability than 75 out of 91 co-occurring tree species, could be one of the critical factors for sustaining about 25% higher annual productivity than other forests (including evergreen-broadleaf, deciduous-broadleaf, and coniferous forest). These findings reconcile classical views of stoichiometric homeostasis and plasticity by demonstrating a flexible, compartmentalized mechanism that resolves growth-stability conflicts. Recognizing such flexible strategy advances the understanding of eco-evolutionary feedbacks in ecosystem stoichiometry and improves predictions of species adaptability, nutrient cycling, and carbon sequestration under global change.

# Plantation conversion of Eucalyptus promotes soil microbial necromass C accumulation

**First A. Min Wang[1*], Second B. Songyi Huang[1]**

[1] *Zhongkai University of Agriculture and Engineering (College of Horticulture and Landscape Architecture, Guangzhou, China)*
*E-mail: wangmin@zhku.edu.cn

## ABSTRACT

Context: Stand conversion in subtropical regions has altered soil physicochemical properties and microbial communities, leading to changes in microbially mediated processes, such as microbial necromass C (MNC) formation and accumulation. However, previous studies on the effects of stand conversion on MNC are lacking, leading to gaps in our understanding regarding the influence of long-term stand conversion on MNC accumulation in different soil layers and the relative importance of soil properties for regulating MNC.
Aims: In this study, we used field surveys and soil analysis to assess the effects of converting a Eucalyptus forest into other planted forest (broadleaf mixed forest [BM] and Acacia mangium Acacia auriculiformis forest [AM]) on soil properties, enzyme activity, microbial community composition, and MNC after conversion 20 years in Guangdong, South China.
Results: We found that the content of soil organic C (SOC) in the surface soil (0–10 cm after litter removal) increased by 64.9% when Eucalyptus was converted to AM, whereas there was no significant difference in the subsurface soil (10–20 cm). β-1,4-glucosidase (BG) and β-1,4-N-acetaminophen glucosidase (NAG) activity increased significantly, while leucine aminopeptidase (LA) activity decreased significantly in the surface soil. In the subsurface soil, BG activity did not change significantly; nonetheless, acid phosphomonoesterase (AP) activity decreased. The fungal, bacterial, and gram-negative bacterial biomass did not significantly differ among the different forests in the surface soil, but the fungal, bacterial, gram-positive, and gram-negative bacterial biomass decreased significantly in the subsurface soil. The ratio of fungi to bacteria was highest in the BM, whereas the ratio of gram-positive to gram-negative bacteria was highest in the AM. Soil fungal and microbial necromass C and the ratio of fungal to bacterial necromass C increased significantly in the surface soil when Eucalyptus was converted to AM. The contribution of MNC and fungal necromass C to SOC content significantly increased by 22.20% and 26.23%, respectively, when Eucalyptus was converted to AM. The main controlling factors of MNC accumulation in the surface soil were pH and total N, whereas soil enzyme activity (BG related to C-acquisition) was the dominant determinant of MNC accumulation in the subsurface soil.
Conclusion: Our study confirmed that converting Eucalyptus to AM promotes MNC accumulation in the surface soil by changing soil pH and TN content to affect soil enzyme activity and microbial community structure, and ultimately changed MNC accumulation. Therefore, effective forest management practices, such as reasonable stand conversion, must be developed to enhance forest SOC accumulation by increasing MNC accumulation.

# Afforestation improves soil multifunctionality through microbial activity and SOC molecular diversification

**Yue Li* and Zhanfeng Liu**

*South China Botanical Garden, Chinese Academy of Sciences, Guangzhou 510650, China*

*yue.li@scbg.ac.cn

**ABSTRACT**

Afforestation is widely advocated for its potential to enhance soil-based ecosystem services. However, the mechanistic understanding of how afforestation regulates soil multifunctionality (SMF)—encompassing nutrient provisioning, enzymatic activities, and microbial metabolic processes—remains incomplete. Existing research often relies on simple metrics of microbial diversity and largely overlooks the molecular diversity of soil organic carbon (SOC), an emerging dimension critical to decomposition dynamics and soil functioning.

To elucidate the effects of afforestation on SMF, we investigated a tropical restoration chronosequence comprising bare land, a *Eucalyptus exserta* monoculture, an afforested mixed-species forest, and an old-growth natural forest. We quantified SMF using averaging, multivariate, and multi-threshold approaches. Microbial community composition and functional diversity were assessed via phospholipid fatty acid analysis and GeoChip functional gene arrays, while SOC molecular diversity was characterized using analytical pyrolysis techniques.

Our results demonstrated that afforestation significantly increased SMF. This enhancement was more strongly associated with shifts in microbial community composition and increased complexity of microbial functional networks than with changes in Shannon diversity alone. Furthermore, SOC molecular diversity emerged as a key mediator linking microbial biodiversity to SMF.

By integrating microbial and SOC molecular perspectives, we believe that our findings underscore the value of promoting mixed-species plantations in tropical afforestation initiatives. They also highlight the importance of incorporating SOC molecular diversity into restoration planning to maximizing ecosystem multifunctionality.

# Soil Carbon Sequestration in forest soils: Limits and Potential versus Potential

**William R. Horwath**[1*]

[1] *Department of Land, Air and Water Resources, Universality of California, Davis, USA*
wrhorwath@ucdavis.edu

**ABSTRACT**

Climate change impacts, especially warming and changes water availability have led to a general decrease in net primary production (NPP) of primary forests (Silva and Horwath 2013). Along with the effects of atmospheric $CO_2$ increases this will impact the formation and persistence of forest soil, organic carbon (SOC). Forest SOC will be impacted by changes in the quality and amounts of NPP, N availability and soil temperature and moisture. The interaction of mean annual temperature (MAT) and mean annual precipitation (MAP) has a strong influence on SOC and is a strong selector of biome type and NPP potential, which directly affects SOC levels and persistence. For example, as forest biomes are forced up elevation due to changing climate, the effect of parent material will have a strong influence on the persistence of old SOC in surface and subsurface soils with basalt and andosols showing the most stability. The quality changes in NPP inputs will be reflected in changes in the C to N ratio or other chemical changes, such as accumulation of tannins which will influence decomposer metabolic efficiency, activity, and turnover. The priming effect (PE) on SOC and or NPP inputs will change. Changes in soil MAT and MAP will affect PE in both surface and deep SOC. As roots exploration increases in response to increased evapotranspiration, the role of root exudates in SOC formation, turnover and maintenance will affect its stability through increased priming effects. The increased production and transport of dissolved organic carbon (DOC) to subsoil will destabilize mineral associated organic carbon (MAOC). These potential outcomes could occur concurrently and result in increased DOC production throughout the soil profile under rising temperature and atmospheric $CO_2$ exacerbating SOC loss. These interacting outcomes become more complicated making the prediction of SOC persistence a challenge to incorporate into biogeochemical models. The results suggest negative feedback causing increased SOC loss with increasing mean annual temperature combined with the change in the amount and frequency of MAP. While carbon storage in tree biomass is predictable, the climate and soils factors affecting the sequestration of new SOC and persistence of old SOC has been difficult to predict. SOC is an intrinsic ecosystem characteristic, and it will remain a crucial research area to ensure forest biome protection and sustainable management.

# Forest Development Determines the Compositions and Structures of Soil Invertebrate Communities in Reclaimed Coastal Lands

**Lili Cao[1], Xiaoming Zou[2], Honghua Ruan[1*]**

*[1] Department of Ecology, Joint Center for Sustainable Forestry in Southern China, Nanjing Forestry University, Nanjing 210037, China; caolllychee@163.com (L.C.);*

**ABSTRACT**

Soil fauna is integral to facilitating material cycles, energy flows, and the conservation of biodiversity in terrestrial ecosystems. However, the impacts of forest development on the compositions and structures of soil invertebrates remain uncertain. Here, we assessed the dynamics in abundance and diversity of soil invertebrates across eight successional age stages of *Metasequoia glyptostroboides* tree plantations (7-, 16-, 21-, 26-, 31-, 36-, 41-, 46-year-old stands) in a reclaimed coastal land in China. We used pitfall traps to collect soil invertebrates and analyzed key soil and litter properties to understand their relationships with the faunal communities. The results revealed that the total abundance of soil invertebrates initially decreased during the young to near-mature stand period (7- to 31-year-old stands), whereas it increased along the age series, from the near-mature to overmature stand period (31- to 46-year-old stands). Specifically, the dynamics showed a U-shaped curve with stand development. Further, there was a significantly negative correlation between the Shannon–Wiener diversity index and the total abundance of soil invertebrates across this plantation chronosequence. The variations in abundance of detritivores were consistent with the total abundance of soil invertebrates during stand development. The abundance and diversity of the soil invertebrates were strongly correlated with the soil environment (e.g., soil organic carbon, litter biomass, and microbial biomass nitrogen). These findings highlight that the compositions and structures of soil invertebrates were significantly altered with *M. glyptostroboides* stand development. Thus, the management of plantations should consider the abundance and diversity of soil invertebrates and functional groups for improving soil structure and fertility. This provides important insights for studying the interconnection of above- and below-ground plantation ecosystems toward their optimal management.

# Microbial Community Assembly, Network Resilience, and Nitrogen Functional Stability Under Canopy Gap Disturbance in Karst Forest Soils

**Guangqi Zhang[1, 2, 3*], Yaxiong Xiang[1], and Mengting Hou[1]**

*[1]College of Forestry, Guizhou University, Guiyang 550025, China*

*[2] Research Center of Forest Ecology, Guizhou University, Guiyang 550025, China*

*[3]Guizhou Libo Observation and Research Station for Karst Forest Ecosystem, National Forestry and Grassland Administration, Guiyang 550025, China*

*E-mail gqzhang1@gzu.edu.cn

**ABSTRACT**

Canopy gaps are a common disturbance in subtropical karst forests, but their belowground consequences are not well understood. In particular, we know little about how gap size influences soil microbial assembly, nitrogen (N) cycling functions, and the role of rare taxa in maintaining functional resilience. We surveyed 16 natural canopy gaps (30–250 m²) in a mixed evergreen–deciduous karst forest in southwest China. Soils were sampled from the gap center, gap edge, extended edge, and adjacent closed-canopy forest. We characterized bacterial and fungal communities, built co-occurrence networks, and related community structure to soil N pools, potential N cycling processes, and indices of functional redundancy and functional stability.

Three main results emerged. (1) Canopy gaps increased both bacterial and fungal richness compared with closed-canopy soils. Bacterial richness rose steadily with increasing gap size, whereas fungal richness peaked at intermediate gap sizes. Community assembly in gaps was dominated by stochastic processes. For bacteria, the strength of stochastic assembly increased with gap size, suggesting that larger gaps promote dispersal- and drift-driven recruitment. For fungi, stochasticity followed a U-shaped pattern with gap size, consistent with stronger environmental filtering in some positions within the gap.

(2) Gap size and within-gap position reshaped microbial interaction networks. In large gaps, bacterial networks at the gap edge were more connected and more robust to simulated node loss than those at the gap center. Fungal networks showed the opposite trend, indicating contrasting stabilization strategies between bacteria and fungi. Keystone taxa in these networks were consistently drawn from rare bacterial groups rather than abundant groups. Rare taxa accounted for most network nodes, showed broader niche breadth than abundant taxa, and disproportionately maintained network robustness.

(3) Low-abundance but persistent rare taxa were the strongest biological predictors of microbial functional redundancy and functional stability, outperforming abundant taxa. Their relative abundance explained a large share of the variation in these stability metrics. Ammonium nitrogen ($NH_4^+$-N) was identified as a key environmental link between gap size and functional stability: higher $NH_4^+$-N was associated with greater microbial functional stability. Nitrogen cycling also shifted with gap size. Larger gaps tended to show higher nitrification potential, while ammonification, N fixation, and denitrification potentials tended to decline.

Overall, canopy gaps act as natural experiments that couple physical disturbance, soil nutrient status, and microbial community assembly. Our results indicate that rare bacterial taxa play a central role in holding together microbial networks, buffering N cycling, and sustaining functional redundancy in these fragile karst soils. These mechanisms suggest that managing canopy gap structure, and the associated inorganic N environment, could be used to support restoration and resilience in degraded subtropical karst forests.

## ABSTRACT

The "Home Field Advantage" (HFA) hypothesis posits that plant litter decomposition proceeds more rapidly in situ because local soil microbiomes are functionally adapted to decompose the biochemical and structural properties of native litter inputs. However, the mechanisms driving HFA responses, and their sensitivity to climate change, remain unclear. Here, we conducted a 24-month reciprocal litter–soil transplant experiment between temperate and subtropical forests to test how litter quality, nutrient content, and microbial community composition interactively shaped HFA effects. HFA effects were observed for both litter types, but underlying mechanisms differed. Specifically, temperate litter decomposed more slowly in subtropical soils likely due to the absence of key fungal taxa (*Mortierella, Russula, Trechispora)* with ecological traits needed to degrade lower-quality litter. In contrast, high-nitrogen, low-phosphorus subtropical litter suppressed the activity of fungal decomposers in temperate soils, likely by selecting for faster-growing bacterial taxa. Decouple and recouple trends were observed based on soil transplantation to novel climates. Dominant fungal taxa progressively resembled local fungal community composition following soil transplantation, and the relative abundance of climare-specific fungal Class (e.g., *Rhizophydiomycetes*, *Dothideomycetes* and *Leotiomycetes*) was strongly correlated with temperate litter mass loss. Our findings highlight the central role of fungi in mediating HFA effects and suggest that both litter chemistry and climate-driven changes to microbial communities will shape future decomposition outcomes. As climate change alters plant species distributions and soil microbial assemblages, these interactions may become increasingly decoupled but also has recoupled trends, with significant implications for ecosystem carbon dynamics.

**ABSTRACT**

Soil microbial carbon use efficiency (CUE) is an important parameter in describing the assimilation efficiency of microbial organic carbon as a key indicator for measuring the potential of soil carbon sequestration. Previous studies have shown that drought can significantly affect microbial CUE, which is crucial for the carbon cycle in forest ecosystems. However, the mechanisms of microbial CUE on soil carbon stability under drought conditions are not well understood. In this study, a throughfall exclusion experiment was conducted in subtropical *Phyllostachys edulis* plantations (CK, control; T, throughfall exclusion). The results showed that drought increased microbial CUE by 9.12% ($p<0.05$) and 2.56% in 0-10 cm and 10-20 cm soil layers, respectively. Soil organic carbon (SOC), soil particulate organic carbon (POC), soluble organic carbon (DOC), and easily oxidized organic carbon (ROC) all significantly decreased, while the proportion of mineral-associated organic carbon (MAOC) in SOC increased by 4.1% and 6.3% ($p<0.05$) in the two layers, respectively. Microbial CUE was positively correlated with POC/SOC ratio and MAOC/SOC ratio, indicating that variation of SOC components substrate quality was an important factor driving microbial physiological changes. Redundancy analysis (RDA) further showed that soil polyphenol oxidase (PPO) and cellobiohydrolase (CBH) enzymes were the main factors driving changes in microbial CUE. SOC increases with microbial reproduction, CUE and turnover rate. Our results suggested that drought indirectly regulates the storage and transformation of SOC by affecting microbial community structure and function, which would have a profound impact on the carbon cycle of forest ecosystems.

*simona.castaldi@unicampania.it

**ABSTRACT**

The BIOSFeR[3]a project examines the relationship between species and functional diversity that drives key processes in the carbon (C) and nitrogen (N) cycles and related greenhouse gas (GHG) fluxes in natural ecosystems, focusing on the comparison of coniferous versus broadleaved forests. It also explores the differential effect of fire, on post-fire soil C and N cycling, losses, and greenhouse gas fluxes in these two plant community typologies. For this task we analyzed and compared 21 forest stands of Coniferous (Pinus nigra J.F. Arnold) and 16 forest stands of broadleaved (Fagus sylvatica L.) located in the Maiella Natural Park, in the mountain region of Abruzzo in Italy, located at about 1000 m. a.s.l. The area experienced strong fire events in 2017 and 2023. We characterized the site and sampled plant and soil samples one year after the last fire event, both in control unburned sites and in burned plots, in October 2024. Soil physical-chemical properties, chemical fingerprint, soil biodiversity, key C and N processes, 13 enzyme activities, and $CO_2$, $N_2O$ and $CH_4$ fluxes were determined. Control site data revealed a clear difference in soil microbial species coherent with the observed functional diversity, under the two plant communities, characterized by quite different chemical and microbial fingerprint, resulting in a more "open" C and N cycle in broadleaved stands compared to coniferous ones. Fire significantly and differently altered soil diversity and functions in the two plant communities, increasing post-fire C and N losses, significantly more pronounced in relative terms under coniferous cover. Data indicate that forest losses due to fire induce stronger radical changes in terms of reduction of C and N retention and GHG emission in coniferous than in broadleaved forests.

# Age-related shifts in soil microbial community structure and metabolic pathways in Picea schrenkiana var. Tianschanica plantations

**Yu Wang, Liu Li*, Yuan Yuan and Xiaoliang Gu**

*Xinjiang Agricultural University (College of Forestry and Landscape Architecture, Urumqi, China)*

*Leona@xjau.edu.cn

**ABSTRACT**

Soil microorganisms participate in and regulate the conversion and cycling processes of soil nutrients and energy. *Picea schrenkiana* var. *Tianschanica* are the most widely distributed trees and correspond to the largest volume of tree species in the mountain forests of Xinjiang, yet the impacts of stand age on soil microbial communities remain understudied.

On the basis of information such as altitude, slope aspect, and slope position, four *Picea schrenkiana* var. *Tianschanica* plantations of different ages (30-, 40-, 50-, and 60-year-old) were selected. The soil samples collected at the same depth at each sampling point were used as nonrhizosphere soil. We analysed bacterial and fungal communities across 48 stands using high-throughput sequencing and metagenomic profiling.

The diversity of soil bacteria did not significantly differ among stands of different ages, but significant differences in community structure and species composition were detected. The structural differences were significant between the 50-year-old and 30-year-old 60-year-old plantations , and stand age explained 37% of the differences (Adonis, $P < 0.05$). The diversity index and evenness index of the soil fungal community first decreased but then increased with increasing stand age, and those of 40-year-old plantations were significantly lower than those of 50-year-old and 60-year-old plantations ($P < 0.05$) . The soil fungal community structure significantly differed between young and middle-aged forests, and stand age explained 29% of the differences (Adonis, $P < 0.05$). Mantel analysis and redundancy analysis revealed that alkali-hydrolysable nitrogen (explanation rate: 15.50%) and pH (explanation rate: 31.00%) were the main factors affecting the diversity of bacterial and fungal communities and the dominant communities at the phylum and genus levels, respectively, and soil bulk density (explanation rate: 19.90%) and alkali-hydrolysable nitrogen (explanation rate: 20.80%) were the main factors affecting the differential species and metabolic pathways of soil bacteria and fungi in *Picea schrenkiana* var. *Tianschanica* plantations, respectively.

These findings highlight the critical role of soil nitrogen dynamics in shaping microbial communities during stand development, providing insights for the sustainable management of boreal coniferous forests.

## ABSTRACT

Soil microbial communities are strongly shaped by tree species and environmental conditions, but it remains unclear whether shifts in microbial community composition lead to corresponding changes in microbial functions. To address this, we used multiple sampling strategies to determine whether spatial variability outweighed functional and compositional differences of soil microbial communities from beech and spruce forests. Spatial variability in composition of microbial community sampled from the same forest plot was much greater as compared with functions related to respiratory and hydrolytic enzyme activity. Much larger spatial variability was observed for enzymatic activities than for microbial respiration. Effects of spatially remote sites exceeded depth effects on microbial community composition, whereas depth had a stronger impact on enzymatic activities. Explanatory power of soil properties was stronger for variation in bacterial than fungal community composition. We demonstrated that microbial communities in forest soils are spatially distinct in composition but their functional redundancy is sufficient to maintain basic ecosystem services independently on community composition.

## ABSTRACT

Vegetation and their interactions with soil microorganisms are central to maintaining soil organic carbon (SOC) dynamics. Yet, understanding of how vegetation diversity, microbial communities, and carbon dynamics during natural restoration in degraded mountain ecosystems remains insufficient. Our study examined five restoration phases in Beichuan County, Sichuan, located in the Longmenshan seismic belt: Y2022 (2 years), Y2020 (4 years), Y2018 (6 years), Y2013 (11 years), and Y2008 (16 years), following a widespread landslide that exposed soil leaching layers. Vegetation surveys and metagenomic sequencing were performed to identify the correlation between plant diversity, carbon cycle–related functional genes, and microbial taxa. The vegetation diversity survey reveals significant differences in temporal trends across the three vegetation types. The SOC and particulate organic carbon (POC) contents increased significantly, while mineral-associated organic carbon (MAOC) content reached its maximum in Y2013. Metagenomic analysis along the restoration gradient revealed that IC fixation and methanogenesis initially increased and then declined, whereas OC degradation exhibited the opposite trend, and methane oxidation ($CH_4$-OX) showed continuous increase. The reductive tricarboxylic acid cycle was the dominant pathway in IC fixation, and hemicellulose-degrading genes were the most abundant in OC degradation, yet their dynamics diverged during restoration. Microbial community analysis identified 391 carbon cycle–associated populations, and PCoA revealed significant differences in community structure across restoration stages, with Y2022 most divergent from other time points. Network analysis shows that module number increases initially and then decreases during restoration. From Y2022–Y2020 to Y2018–Y2013, functional modules shifted from $CH_4$-OX and IC fixation to diverse IC fixation pathways and OC degradation. By Y2008, these two processes remained central, with the Calvin-Benson-Bassham cycle becoming a stable pathway for IC fixation. Correlation analysis between vegetation and microbial diversity revealed that the three vegetation types were significantly negatively correlated with carbon–associated microbial diversity. In fact, pairwise plant–microbe relationships were predominantly positive, e.g., *Choerospondias*, *Rubus coreanus*, and *Miscanthus floridulus*. Mantel tests showed microbial and plant diversity both significantly correlated with MAOC ($P < 0.001$), the latter also significantly affected soil POC ($P < 0.001$). And dissolved organic carbon was a key environmental factor for microbes involved in IC fixation and OC degradation, along with soil TP and TK. This study elucidates the interlinkages among vegetation diversity, microbial communities, and carbon cycling during post-earthquake ecosystem recovery, providing a robust scientific foundation for guiding ecosystem restoration and soil carbon management strategies.

**ABSTRACT**

During the past decade, the Amazon has experienced severe prolonged periods of drought (Papastefanou et al., 2022), leading to the mortality of trees and a reduction in the carbon storage of the world's largest rainforest ecosystems (Aleixo et al., 2019). The Congo Basin, the second largest rainforest ecosystem has absorbed the greatest value (-0.61Gtons) of $CO_2$ relative to the Amazon (-0.1 Gt) and the Southeast Asia, which has emitted more $CO_2$ than it had absorbed (+0.49Gt $CO_2$) in the past decade (Hubau et al., 2020). However, the greatest annual rate of net forest loss in 2010–2020, i.e., 3.9 million ha was recorded in Africa, (FAO UNEP, 2020). Congo Basin is understudied (White et al., 2021). Its future is fragile due to uncertainty of climate change and biodiversity (Beekmann et al., 2024). Natural forests are threatened, therefore, their conservation, restoration and sustainable solutions as forest plantations need to be encouraged.

Human activities as oil exploitation may affect their resilience, as shown by the potential impact of $H_2S$ emissions on soil bacterial and fungal community structure and diversity of forest plantations in the Congolese coastal plains (Koutika et al., 2020; Koutika et al., 2024). This is demonstrated by the strong positive correlation of sulphur to the prevalent bacteria *Actinobacteria* which exhibit a great ability to decompose organic residues, dominant in polluted areas (Xu et al., 2016) Conversely, the prevalence of Ascomycota fungi, negatively correlated to sulphur, withstanding environmental stresses (Egidi et al., 2019), may diminished this ability in the long term (Koutika, 2024).

Mining or oil exploitation may harm the resilience of forest ecosystems. Further investigation need to be conducted: (i) Archaea composition to further confirm the negative impact of $H_2S$ emissions, likely from oil exploitation, on forest ecosystems in Central Africa; (ii) Comparing the resilience of the forest plantations in Central Africa, South America, Southeast Asia, and European Union to human activities and climate change; (iii) raise awareness of human activities such as oil exploitation, mining on the resilience of forest ecosystems, to avoid severe and irreversible impacts on climate change, biodiversity and ecosystem services (Pascual et al., 2023).

*jiangyy73@mail2.sysu.edu.cn

**ABSTRACT**

Wildfires are a fundamental ecological force, now intensified by global climate change and anthropogenic activities. While their effects on macro-organisms are well-documented, the response of soil microbial communities, Earth's largest biodiversity reservoir, remains poorly understood at a global scale. Existing research is geographically constrained and has yielded conflicting results, creating critical knowledge gaps concerning the influence of factors like fire severity and soil depth, and hampering our ability to predict post-fire recovery. To address this, we synthesized a global dataset of bacterial raw sequencing data from 27 studies, encompassing over 2,100 samples from 87 locations. This study investigates how key fire characteristics (e.g., severity) and environmental context (e.g., soil horizon) mediate wildfire's effects on the structure and recovery of soil microbial communities. This global synthesis offers crucial insights into the vulnerability and resilience of belowground ecosystems, providing a scientific foundation for their management in a world increasingly prone to fire.

This global synthesis reveals that wildfires significantly reduce soil bacterial alpha diversity (Richness: -21.0%; Shannon: -9.8%) and increase community dissimilarity (8.2%). At the genus level, 36 taxa were enriched while 23 were depleted; notably, *Effusibacillus*, *Domibacillus*, and *Cohnella* exhibited massive surges (15–21-fold), whereas *UTCFX1*, *Actinomycetospora*, and *CCD24* suffered drastic declines (65–74%). These impacts are highly context-dependent: they are most pronounced in surface soils and under moderate-to-high fire severities, while subsoil horizons remain largely unaffected. Critically, we found that post-fire recovery is incomplete. Although community composition (beta diversity) tends to converge with unburned states after a decade, alpha diversity remains significantly suppressed even >10 years post-disturbance. Variance partitioning identified climate and soil pH as the dominant drivers regulating these vulnerability and recovery patterns globally.

This study offers global insights into the ecological consequences of wildfires on soil microbiomes, filling critical knowledge gaps to guide adaptive management strategies that effectively balance fire risk mitigation with the preservation of belowground biodiversity and associated ecosystem functions.

**ABSTRACT**

Wildfires disrupt soil structure and alter microbial diversity, reducing ecosystem resilience and delaying natural recovery. Restoring native soil microbiomes may enhance plant fitness and promote the degradation of toxic combustion by-products such as PAHs and PyOM. To identify key bacterial taxa with potential for microbiome- based remediation, we investigated wildfire-driven shifts in soil bacterial communities across a pine–oak forest in Mexico. Sixteen soil samples were collected from burned and unburned areas representing three post-fire recovery stages. Bacterial communities were characterized using 16S rRNA Illumina MiSeq sequencing and QIIME1, complemented by physicochemical analyses and culture-based isolation followed by MALDI-TOF identification.

Time since wildfire emerged as a major determinant of community composition, with significant variation along pH and elevation gradients. Burned and unburned soils differed in the relative abundance of Actinobacteria and Acidobacteria and showed enrichment of thermotolerant and pollutant-degrading taxa. Although 50% of species were shared between conditions, co-occurrence network analyses revealed higher connectivity in unburned soils, suggesting greater community stability. Pyrophilous genera such as *Massilia*, *Arthrobacter*, and *Blastococcus* were detected, with *Arthrobacter* and *Blastococcus* forming part of the core microbiome and highly connected network modules.

Culture-based analyses yielded 275 bacterial isolates, of which 126 were identified and assigned to 50 species.

Burned soils exhibited higher cultivable diversity than unburned soils. Dominant species included *Achromobacter xylosoxidans*, members of the *Enterobacter cloacae* complex, and *Bacillus cereus*. Notably, several isolated taxa were not detected by amplicon sequencing, highlighting the complementarity of cultivation-dependent and - independent approaches.

Overall, these results emphasize the value of integrating sequencing, network analysis, and culturable microbiome approaches to identify key bacterial taxa for microbiome-based restoration strategies in fire-prone ecosystems.

**ABSTRACT**

Nitrogen (N) enrichment is a pervasive environmental change known to affect the diversity and productivity of ecosystems. In grasslands, experiments have shown that the positive effect of plant diversity on productivity are robust to nutrient enrichment. Whether this result apply to forests and the underlying processes involved is unknown. Using a large-scale tree diversity experiment manipulating N addition, we quantify tree diversity effects on productivity and the impact of N addition on this relationship. Under ambient conditions, we found positive biodiversity-productivity relationship resulting from direct positive effect of tree species richness and indirect effect of tree species richness via its positive effect on symbiotic fungal richness. In contrast, N enrichment weakened the positive effect of diversity on productivity by promoting productivity in monocultures and reduced symbiotic fungal richness in mixtures. The effects of functional identity in root-fungal collaboration traits via fungal community composition on productivity were robust to N enrichment. Our results provide direct experimental evidence that N enrichment weakens biodiversity-productivity relationship in forest and underscores the importance of tree diversity and fungal communities in maintaining forest function under environmental changes.

## ABSTRACT

Wildfires alter the physical, chemical, and biological properties of soils, compromising fertility, structural stability, and microbial biodiversity. Recolonization of the soil microbiome is a key step in the recovery of soil functioning after fire, yet early post-fire dynamics remain poorly understood because most studies characterize ecosystems months to years after burning. Here, we collected ten soil samples from Lago Peñuelas National Reserve (Valparaíso, Chile) under two dominant vegetation types (native and exotic). Soils were subjected to a simulated fire (350 °C for 30 min) in a controlled combustion chamber, and recolonization was assessed by reintroducing microbial communities isolated from non-burned soil extracts associated with each vegetation type. We monitored microbial responses at four post-inoculation time points (1, 15, 30, and 60 days). Bacterial and fungal community shifts were characterized using 16S rRNA gene and ITS metabarcoding, respectively.

Carbon and nitrogen contents were measured by IRMS-EA, and microbiome functional activity was quantified using MicroResp™ to assess substrate-induced respiration across multiple carbon sources. We observed a clear temporal succession of the bacterial community, with increasing richness and evenness over time. On day 1, Bacillota families (e.g., Bacillaceae and Planococcaceae) predominated and community evenness was low; by day 14, Beijerinckiaceae (Alphaproteobacteria) became most prominent; on day 30, Comamonadaceae, Caulobacteraceae, and Alcaligenaceae (Pseudomonadota), together with Spirosomaceae (Bacteroidota), were enriched; and by day 60, Xanthobacteraceae (Pseudomonadota) and Isosphaeraceae (Planctomycetota) increased. In contrast, fungal evenness declined through time: Mucoromycota contributed strongly at the beginning of the assay but progressively decreased, whereas Ascomycota became dominant. Across the recolonization process, the C/N ratio decreased overall and catabolic activity declined for most substrates, suggesting that burned litter and soil organic matter provides only transient support and that new carbon inputs are required to sustain soil functioning. Overall, our results show how post-fire environmental conditions and microbiome succession jointly shape soil catabolic activity, a key process for functional soil restoration and ecosystem recovery.

Moreover, they highlight the role of source microbiota in steering post-fire successional trajectories and underscore the ecological potential of native microbial communities for restoration strategies in fire-degraded ecosystems.

## ABSTRACT

Soil multifunctionality represents the capacity of soils to sustain multiple ecosystem processes simultaneously and is strongly regulated by soil microbial communities. However, how environmental change modifies microbial diversity–multifunctionality relationships across soil depths remains insufficiently resolved. Here, we conducted a reciprocal soil-column translocation experiment between a temperate forest and cropland in northeast China to disentangle the relative effects of environmental change and soil depth on soil multifunctionality and its microbial drivers. Soil translocation generally reduced multifunctionality, with markedly stronger declines in forest soils than in cropland soils, particularly in surface layers. In contrast, deeper soils exhibited greater functional stability, indicating a depth-dependent resistance to environmental perturbation. These declines in forest soil multifunctionality were closely associated with reductions in microbial biomass, especially bacterial biomass, following translocation. Across treatments, soil multifunctionality was more consistently associated with bacterial diversity and community composition than with fungal diversity, underscoring the dominant role of bacteria in sustaining multiple soil functions. Random forest and structural equation modeling further revealed ecosystem-specific controls on multifunctionality: forest soils were primarily regulated by soil carbon availability and moisture, whereas cropland soils were mainly constrained by soil nitrogen. These contrasting drivers reflect fundamental differences in resource limitation and nutrient cycling strategies between forest and agricultural systems. Overall, our results demonstrate that soil horizon exerts a stronger influence than soil translocation on microbial diversity–multifunctionality relationships. Forest soils are functionally more sensitive to environmental change, whereas cropland soils maintain lower but more stable multifunctionality. This study highlights the critical roles of soil depth, microbial biomass, and ecosystem-specific resource limitation in predicting soil functional responses to environmental change.

## ABSTRACT

Soil microbiota regulates biochemical processes such as the transformation and mineralization of organic matter, nitrogen fixation and carbon sequestration. Deadwood is an important element of forest ecosystems, but the impact of windthrows and deadwood on the microbial and enzyme activity, content and diversity of soil bacterial and fungal communities has been little studied. We partly filled this gap by conducting studies in Podzols, Retisols and Phaozems of old-growth broad-leaved forests (Central European Russia) in areas of mass and isolated windthrows, under fallen trunks of seven tree species and in background environments. In each of the four biotopes, soil samples were taken from the top 5 cm of horizon A under fallen tree trunks (deadwood) that were in an intermediate stage of decomposition and lay tightly on the soil surface, as well as in an area of mass windthrow without deadwood and in the background forest. Soil was collected under the trunks of *Acer platanoides, Fraxinus excelsior, Populus tremula, Tilia cordata, Ulmus glabra, Quercus robur,* and *Picea abies.* Soil physical and chemical characteristics were defined for 120 samples. Microbial characteristics included microbial biomass carbon determined by substrate-induced respiration, the rate of $CO_2$ production by microorganisms using a gas chromatograph (basal soil respiration), and the activity of four extracellular enzymes: β-1,4-glucosidase, N-acetyl-D-glucosaminidase, leucine aminopeptidase, and phosphatase, using the fluorogenic substrate method. For 63 soil samples quantitative PCR (DNA-Technology, Russia) and profiling microbial and fungal communities using 16S and ITS1-3 sequencing (Illumina, USA) were performed. Retisols differed from Podzols in texture, and thickness of horizon A, although they did not differ in bulk density and C and N content; all other chemical characteristics were lower in Podzols. Microbial and enzyme activity was higher in Retisols than in Podzols. Retisols and Phaozems did not differ in microbial and enzyme activity, but the values of physical and all chemical characteristics (such as C and N content, pH, CEC, available P and K) were significantly lower in Retisols. In loamy soils, fallen trunks reduce carbon, nitrogen, and calcium retention, as well as microbial and some enzymatic activity, but do not affect phosphorous availability and phosphatase activity. The bacterial DNA content was higher in loamy soils, while the fungal DNA content was higher in sandy soils. Under fallen trees on loamy soils, a decrease in both bacterial and fungal DNA content was observed. In sandy soils, the DNA content in samples taken under and near tree trunks did not differ, but depended on the species of fallen tree. The species diversity of fungal and bacterial communities was significant higher in loams than in sands; trunks of different tree species had different effects on the taxonomic composition of the soil microbiota under the trunks.

## ABSTRACT

Wildfires are major drivers of soil alteration in Mediterranean mountain ecosystems. This study presents preliminary results from control and burned plots on Monte Morrone (Majella, Abruzzo) following two wildfire events in 2017 and 2023. Soil samples were analyzed for texture, bulk density, pH, cation exchange capacity (CEC), exchangeable cations, carbon and nitrogen content, enzymatic activity, and FTIR-DRIFT spectra to assess short- and medium-term fire impacts on soil structure and function.

Soils across all plots are dominated by silty clay. Burned sites show increased sand content (14.2% in 2017 burn; 8.1% in 2023 burn vs. 7.4% in controls), suggesting post-fire sediment redistribution and erosion. Bulk density increased progressively in burned soils, reaching 1.17 g $cm^{-3}$ in the 2023 plot, reflecting compaction due to aggregate collapse and ash deposition. pH values were significantly higher in burned plots (7.80 in 2017; 7.92 in 2023 vs. 7.76 in controls), consistent with ash-derived alkaline inputs (1).

Chemical analyses indicate reductions in organic carbon and nitrogen, mirrored by decreased CEC. FTIR-DRIFT spectra reveal loss of labile organic functional groups and enrichment in aromatic, pyrogenic structures, indicating qualitative and quantitative changes in soil organic matter. Enzymatic activity declined in burned soils, particularly carbon- and nitrogen-related enzymes (glucosidases, cellulases, proteases, NAG), reflecting substrate depletion and altered soil conditions (2). Phosphorus- and sulfur-cycling enzymes also decreased, with partial recovery of some carbon-related enzymes in 2023, although activity remained below control levels.

Overall, wildfire did not drastically change soil texture but caused persistent modifications in physical structure, chemical properties, and microbial functionality. These findings highlight a post-fire ecosystem undergoing gradual biogeochemical reorganization, providing critical insights for soil recovery and management in central Apennine mountain environments.

## ABSTRACT

The status of microbial resource limitation plays a central role in regulating ecosystem carbon (C) cycle. Tree mycorrhizal associations are increasingly known to regulate soil biogeochemical processes due to their differentiate nutrient acquisition strategies and litter quality, while its effects on saprotrophic microbial resource limitation remain poorly understood. In this study, we collected soil samples from 35 plots with a natural gradient of ECM tree dominance (defined as the proportion of EcM tree basal area relative to the all trees) in a subtropical mountainous forest. A full factorial C, nitrogen (N) and phosphorus (P) addition experiment were conducted to infer soil microbial resource limitation based on the responses of microbial growth. The activities of exocellular enzyme were also determined to explore the possible links between ecoenzymatic stoichiometry and microbial resource limitation. C addition induced a systematic increase of microbial growth, and C plus P addition elicited even stronger responses in all soils, suggesting that microbial growth in this subtropical forest was primarily limited by C and secondarily limited by P. With increasing EcM tree dominance, C limitation showed no significant trend, while microbial P limitation decreased. Ecoenzymatic stoichiometry indicated that microbes in this forest were mainly P limited, but this P limitation did not vary with EcM tree dominance. These results suggest that ecoenzymatic stoichiometry cannot reliably represent microbial resource limitation for growth. Variation in microbial P limitation was positively associated with leaf P content and soil N availability, but negatively associated with the proportion of labile P and the relative abundance of phosphate-solubilizing microorganisms. These findings highlight the mycorrhizal association in shaping microbial secondary P limitation, which may have implications for the maintenance of forest productivity and soil C sequestration potential.

**ABSTRACT**

Variability in snow cover regulates patterns of freeze–thaw cycle (FTC) frequency in temperate forest soils, with direct consequences for soil structure and microbial activity. By manipulating snowpack conditions, we modify FTC frequencies to quantify their effects on soil aggregate stability and microbial processes. We are implementing these experiments in northern and southern Wisconsin across two soil orders: Alfisols, characteristic of deciduous forests, and Spodosols, characteristic of coniferous forests. Our design includes forest–soil pairings that are diagnostic of one another, alongside pairings in which forest vegetation occurs on soils not typically associated with that forest type, enabling us to analyze how vegetation, soil properties, and winter climate interact to shape soil aggregation. This research aims to clarify how freeze–thaw dynamics under variable snow conditions influence soil structure and to characterize the microbial mechanisms underlying aggregation responses.

# Impacts of Mistletoe Infection on Soil Hydrology and Chemistry in Abies and Pinus Ecosystems

**Lizardo Reyna-Bowen[1*], Ewa Słowik-Opoka[1], Małgorzata Stopyra[1], Anna Klamerus-Iwan[1]**

[1] *Faculty of Forestry, University of Agriculture in Kraków, Kraków, Poland*

*joselizardo.reynabowen@urk.edu.pl

**ABSTRACT**

Mistletoe (*Viscum album*) infestation has well-documented physiological effects on host trees, yet its influence on soil processesremains insufficiently quantified. Increasing evidence indicates that parasitic plants can modify below-ground environments indirectly through alterations in canopy interception, water redistribution, and litter quality.

Our study was conducted in southeastern Poland, where mistletoe remained uncommon until approximately six years ago. Its recent and rapid proliferation in this region has introduced a new, clearly identifiable ecological factor affecting soil conditions allowing mistletoe to be examined as an emerging driver of soil hydrological and biogeochemical change. The expansion of mistletoe-bearing shoots within coniferous canopies dominated by Abies and Pinus modifies key soil-forming fluxes. Changes in throughfall chemistry, altered particulate inputs, and the presence of evergreen broadleaved biomass within a needle-dominated overstory create distinct pathways of influence on soil moisture dynamics, nutrient availability, and organic matter turnover.

This study therefore addresses a critical knowledge gap by quantifying how a newly established parasitic pressure alters soil hydrological responses and chemical properties under otherwise comparable environmental and stand-structural conditions.This study evaluates how mistletoe infection affects soil moisture dynamics and soil chemical properties within Abies and Pinus forest ecosystems. By comparing soils beneath healthy and infected trees of the same species under identical environmental conditions, we aimed to isolate the role of mistletoe as a factor influencing soil behaviour.

In Abies stands, soil moisture dynamics showed clear differences between zones. Although soils beneath infected trees maintained higher volumetric water content overall, they also exhibited significantly faster week-to-week moisture decline. This pattern indicates reduced soil moisture stability and suggests that mistletoe indirectly affects soil hydrology, especially during dry periods when infected trees appear to exacerbate moisture fluctuations. In contrast, soils beneath healthy Abies trees retained more stable moisture conditions over time. These findings highlight the sensitivity of Abies ecosystems to biotic stressors and point to mistletoe as an amplifying factor that alters short-term soil water dynamics.

Pinus ecosystems displayed a contrasting response. Soil moisture levels remained relatively stable regardless of tree health condition, reflecting both the inherent physiological resilience of Pinus species and the moderating influence of a denser ground-cover layer. This vegetation likely contributes to maintaining soil moisture while preventing strong differences between healthy and infected zones.

Soil chemical indicators including soil organic carbon, electrical conductivity, hydrolytic acidity, and cation sorption capacity showed no significant short-term differences between healthy and infected trees in either forest system. However, strong correlations among several chemical variables suggest potential pathways for long-term changes. Previous findings indicating mistletoe-driven increases in potassium and conductivity emphasize the need for continued monitoring.

Overall, the study demonstrates that the presence of mistletoe primarily affects **soil moisture dynamics**, with particularly pronounced impacts in Abies forests. Although short-term soil chemical properties appear stable, the identified relationships among soil variables indicate possible long-term implications for ecosystem nutrient balance and soil functioning.

These findings demonstrate that mistletoe should be treated as an emerging biotic driver of soil-process modification in coniferous forests, underscoring the need for its explicit inclusion in future assessments of soil hydrological functioning and nutrient cycling.

## ABSTRACT

Fire is a natural disturbance in many forested ecosystems around the world. Fires combust and alter existing organic matter, producing pyrogenic (or fire-affected) organic matter (PyOM), which tends to be more persistent than unburned organic matter and represents an important global carbon (C) pool. However, climate change is altering fire regimes worldwide, often increasing fire frequency and severity. How these changes will affect PyOM and subsequent C cycling remains poorly understood. In particular, what will happen to existing PyOM when subsequent fires occur?

To measure the net effects of a second fire across different depths and fire intensities, we used 2-mm-sieved unburned jack pine (*Pinus banksiana*) biomass, and jack pine PyOM pyrolyzed at 450°C and 550°C. To represent burial at different soil depths, the samples were situated at 0 cm, 1 cm, and 5 cm within an ashed and washed sand matrix, representative of the sandy soils typical of jack pine stands. High and low heat flux profiles, programmed to mirror measured data from a log burn (Luo et al., 2025), were dosed from a cone calorimeter to the sand matrix, simulating different fire intensities. We then analyzed the resulting materials for a range of properties, including tracing $CO_2$ fluxes from a 12-week microbial incubation.

We found that higher initial PyOM production temperatures, which reflect the conditions of the first fire, protected more PyOM from combustion during the second fire, across all depths and heat-flux treatments. This pattern was more evident for buried PyOM (1 cm and 5 cm) than for surface PyOM, likely due to near-complete combustion of surface materials. We also found that higher initial PyOM production temperatures led to lower mineralization following the subsequent fire.

Together, these findings indicate that heat generated from fire, location (depth) of sample, and initial PyOM production temperature all interact to affect the persistence of organic matter during and after repeated fires. These effects should be considered when evaluating the net C effects of fire on soil organic matter stocks in the context of changing fire regimes.

# The decomposition and stabilization of microbial residues in forest soil

**Chao Wang[1*], Xu Wang[1], and Edith Bai[2]**

[1] *Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang China*

[2] *Changchun Normal University, Changchun, China*

*E-mail: cwang@iae.ac.cn

**ABSTRACT**

Microbially-derived nitrogen (N) has been considered as one of important contributors to soil organic N, but few studies have quantified the rate of necromass N decomposition. Here, via an in situ incubation of 15N-labeled necromass, we found that ~20% of the initial 15N stabilized in the soil as non-living organic N after eight years of incubation. Bacterial, fungal, and actinobacterial necromass N showed similar decomposition pattern and mean residence time. The decomposition of microbial necromass N was best simulated by a two-pool model where a labile pool decomposed rapidly, and a more recalcitrant pool decomposed at a much slower rate. This finding contrasted with the decomposition of plant litter N, which was better simulated by a single-pool model. The stabilization of necromass N in soils after more than two years suggests the important contribution of microbial residues to soil organic N, which is most likely due to mineral protection from decomposition.

# Icelandic old birch woodlands have valuable soil carbon reserves

**Sólveig Sanchez[1*], Jóhann Thorsson[1], and Olafur Arnalds[2]**

[1] *Land and Forest, Iceland (Gunnarsholt, Iceland)*

[2] *Agricultural University of Iceland (Faculty of Environmental and Agricultural Sciences, Reykjavík, Iceland)*

*solveig.sanchez@landogskogur.is

**ABSTRACT**

Mountain birch (*Betula pubescens*) is the single native woodland-forming tree species in Iceland. The woodlands are mostly found on Andisols, which are the country's main soil order. Icelandic birch woodlands have undergone a long history of severe degradation over the past millennium, reducing their cover by 90% since the human settlement approximately 1,200 years ago. Deforestation led to widespread land degradation and erosion, resulting in barren land. Today, only 1.5% is covered by native woodlands, and 45% of the land area is degraded. Therefore, the conservation and restoration of native woodlands are highly relevant and a focal point for institutions focused on land restoration, including Land and Forest, Iceland. In this study, we explored the effects of birch woodlands on soil dynamics, with emphasis on carbon reserves. We selected 10 study areas across the country with woodland chronosequences from non-forested to 60+ years old woodlands. The woodland soils are typical Andisols, with high carbon content and water retention, with allophane, ferrihydrite, and mineral-organic complexes dominating the colloidal fraction. The results demonstrated a significantly increasing trend in carbon content (%) and carbon stocks (kg/m$^2$) with increasing birch age. Old birch woodlands (+60 years old) were important soil carbon reserves at a national level, with significantly higher reserves than younger woodlands. Their high carbon values are partly explained by their andic soil properties. Dust deposition of vitric materials at 50-1,000 g/m$^2$/yr affects soil carbon dynamics, leading to a rising soil surface and, consequently, increased carbon burial. We estimated that up to 0.026 kg/m$^2$/yr of carbon is buried in areas in the vicinity of active dust sources. This is especially applicable, as birch woodlands collect near-surface atmospheric dust efficiently, increasing the carbon stocks buried in the deeper layers of birch woodland soils. Our study highlights the relevance of the carbon sinks in old woodland soils, calling for the restoration of birch on a national scale, in addition to the conservation of existing woodland soils. Restoring birch woodlands to 5% of the country (increasing their cover by 3,000 km$^2$) would lead to soil carbon sequestration equal to 7% of the country's current $CO_2$ emissions. Thus, birch woodland restoration serves as an important climate change mitigation tool.

# Ecological Stoichiometry of Plant-Soil Systems in Pinus sylvestris var. mongolica Plantations in the Semi-Arid Region of Northeast China

**Yi Yang [1,2] and Hui Li [1,2*]**

[1] *College of Forestry, Shenyang Agricultural University, Shenyang 110866, China*

[2] *Research Station of Liaohe-River Plain Farmland Shelterbelt Ecosystem CEN, Shenyang Agricultural University, Shenyang 110866, China*

*E-mail Address: yyi20001111@163.com

**ABSTRACT**

*Pinus sylvestris* var. *mongolica* is a keystone species in China's "Three-North" Shelterbelt Program. The nutrient balance within its plantation ecosystems is critical for regional forest sustainability. However, the spatial patterns and key drivers of carbon (C), nitrogen (N), and phosphorus (P) stoichiometry in the plant-soil system of Mongolian pine plantations across the semi-arid region of Northeast China remain poorly understood. To address this, we established ten sampling sites along a latitudinal gradient in the semi-arid Northeast. We collected leaf samples and soil samples from two depths (0–20 cm and 20–40 cm) from mid-aged plantations (approximately 15 years old). Total C, N, and P concentrations were measured, stoichiometric ratios were calculated, and their spatial patterns, interrelationships, and homeostatic characteristics were analyzed. Our findings revealed that: (1) plant leaves C, N, and P concentrations ranged 391.86–545.87 $g \cdot kg^{-1}$, 12.25–23.35 $g \cdot kg^{-1}$, and 0.72–1.87 $g \cdot kg^{-1}$, respectively, showing a unimodal pattern with increasing latitude. In contrast, plant leaves C:N, C:P, and N:P ratios (ranges: 19.24–35.39, 300.37–667.11, and 10.70–27.60, respectively) exhibited a “decrease-then-increase” trend along the same gradient. (2) Soil total carbon (TC), total nitrogen (TN), and C:N ratios generally increased with latitude, with significantly higher values in the topsoil (0–20 cm) than in the subsoil (20–40 cm). Soil total phosphorus (TP) did not show a consistent latitudinal trend. (3) Correlation analysis indicated strong positive correlations among soil C, N, and P in both layers, and between leaf N and P. Leaf C:N was negatively correlated with leaf N:P. In the topsoil, mean annual temperature was negatively correlated with soil C, N, and P, and environmental factors were closely linked to soil nutrient contents. In the subsoil, soil C:N was positively correlated with pH, while soil C:P was negatively correlated with leaf C, indicating stronger coupling between environmental factors and soil stoichiometry in this layer. (4) Homeostatic analysis showed that leaf C, C:N, and C:P shifted from homeostasis to weak homeostasis and finally to sensitive states with increasing latitude. In contrast, leaf N and P generally exhibited strict homeostasis, except for leaf P at the lowest-latitude site (Z1), which was sensitive to soil P availability. This study elucidates the spatial patterns, vertical differentiation, and environmental drivers of plant-soil stoichiometry in Mongolian pine plantations in semi-arid regions. It also highlights the nonlinear response of leaf nutrient homeostasis to latitudinal gradients, providing a scientific basis for the nutrient management and sustainable cultivation of plantation ecosystems in water-limited environments.

# Land-use intensity restructures soil organic matter pools and stabilization pathways across forest–agriculture landscapes

**Louis-Pierre Comeau[1]*, Claudia Goyer[1], Cameron Wagg[1], Jess Vickruck[1], Kirsten Hannam[1] Brandon Heung[2],**

[1] *Agriculture and Agri-Food Canada, Government of Canada*

[2] *Dalhousie University, Truro Nova Scotia Canada*

**ABSTRACT**

Understanding how soil organic matter (SOM) pools respond to land-use intensity is central to predicting carbon (C) and nutrient cycling in forested landscapes under climate change. While total soil organic carbon stocks are commonly assessed, less is known about how land-use intensification alters SOM partitioning, biological accessibility, and long-term stabilization mechanisms at landscape scales.

We conducted a broad-scale soil survey across forest–agriculture mosaics in Atlantic Canada, encompassing wetlands, mature and young forests, perennial pastures, forage-based rotations, and annual cropping systems spanning a gradient of increasing soil disturbance. At each site, soils were sampled to 30 cm depth and characterized for total SOC stocks, physically fractionated SOM pools (labile particulate, intermediate, and mineral-associated organic matter), oxidizable carbon (POX-C), microbial DNA yield, enzyme activities, soil fauna, and ancillary soil physical and chemical properties. Selected SOM fractions were further evaluated for thermal stability and radiocarbon age to assess persistence.

Total SOC stocks declined systematically with increasing land-use intensity, but this response was disproportionately driven by losses of labile and intermediate SOM fractions, while mineral-associated carbon showed greater resistance to disturbance. Forested systems maintained larger and older stabilized SOM pools, whereas intensively managed croplands exhibited younger, biologically accessible carbon with reduced thermal stability. Microbial biomass, enzyme activity, and soil fauna abundance closely tracked changes in intermediate SOM pools, highlighting strong coupling between biological communities and SOM accessibility. Spatial modeling further revealed that land-use history and disturbance intensity were among the strongest predictors of SOC distribution at the regional scale.

Our findings demonstrate that land-use intensification fundamentally reorganizes SOM pools and stabilization pathways, with implications for long-term soil carbon persistence and nutrient cycling under a warming and increasingly disturbance-prone climate. Integrating SOM fractionation and biological indicators into monitoring frameworks improves our ability to detect early degradation signals and to design land management strategies that sustain soil carbon and forest soil health.

**ABSTRACT**

Agroforestry ecosystems are an efficient strategy for enhancing soil nutrient conditions and sustainable agricultural development. Soil extracellular enzymes (EEAs) are important drivers of biogeochemical processes. However, changes in EEAs and chemometrics in rubber-based agroforestry systems and their mechanisms of action are still not fully understood. Distribution of EEAs, enzymatic stoichiometry, and microbial nutrient limitation characteristics of rubber plantations under seven planting patterns (RM, rubber monoculture system; AOM, Hevea brasiliensis-Alpinia oxyphylla Miq; PAR, Hevea brasiliensis-Pandanus amaryllifolius Roxb; AKH, Hevea brasiliensis-Alpinia katsumadai Hayata; CAA, Hevea brasiliensis-Coffea Arabica; CCA, Hevea brasiliensis-Cinnamomum cassia (L.) D. Don, and TCA, Hevea brasiliensis-Theobroma Cacao) were analyzed to investigate the metabolic limitations of microorganisms and to identify the primary determinants that restrict nutrient limitation. Compared with rubber monoculture systems, agroforestry ecosystems show increased carbon (C)-acquiring enzyme (EEAC), nitrogen (N)-acquiring enzyme (EEAN), and phosphorus (P)-acquiring enzyme (EEAP) activities. The ecoenzymatic stoichiometry model demonstrated that all seven plantation patterns experienced C and N limitation. Compared to the rubber monoculture system, all agroforestry systems exacerbated the microbial limitations of C and N by reducing the vector angle and increasing vector length. P limitation was not detected in any plantation pattern. In agroforestry systems, progression from herbs to shrubs to trees through intercropping results in a reduction in soil microbial nutrient constraints. This is primarily because of the accumulation of litter and root biomass in tree-based systems, which enhances the soil nutrient content (e.g., soil organic carbon, total nitrogen, total phosphorus, and ammonium nitrogen) and accessibility. Conversely, as soil depth increased, microbial nutrient limitations tended to become more pronounced. Partial least squares path modelling (PLS-PM) indicated that nutrient ratios and soil total nutrient content were the most important factors influencing microbial C limitation (−0.46 and 0.40) and N limitation (−0.30 and −0.42). This study presented novel evidence regarding the constraints and drivers of soil microbial metabolism in rubber agroforestry systems. Considering the constraints of soil nutrients and microbial metabolism, intercropping of rubber trees with arboreal species is recommended over that of herbaceous species to better suit the soil environment of rubber plantation areas on Hainan Island.

**ABSTRACT**

Climate warming is altering biogeochemical cycles, leading to changes in soil nutrient availability. As nutrients limit the growth of plant and microbial communities, warming-induced changes will have important implications for the ecology of forest ecosystems. To assess this, we quantified soil organic matter and available nutrients along a 1700 m elevation gradient in South Korean temperate forests on Mount Baekun and Mount Jiri. The gradient represents a 10ºC change in mean annual temperature and forms a climosequence in which all soil forming factors except temperature are constrained. We sampled soils from >70 permanent forest census plots and quantified concentrations of nitrogen (N), phosphorus (P) and other essential nutrients. We predicted that (1) N availability would decline with elevation due to temperature constraints on N fixation and organic matter decomposition, and (2) P availability would increase with elevation due to weaker weathering and pedogenically younger soils. Consistent with our expectations, we find a strong shift from P deficiency at low elevation to N deficiency high elevation. Organic matter concentrations increase with elevation, indicating slower decomposition at lower temperature. Total, organic, and available forms of P increase with elevation, indicating that warmer soils are more strongly weathered and leached of P. Total N increases with elevation, but the N:organic P ratio decreases, indicating greater availability of P relative to N at lower temperature. Exchangeable cations (calcium, magnesium and potassium) and soil cation exchange capacity also increase with elevation, supporting a weaker degree of weathering in colder soils. Overall, these results indicate that climate warming will increase N availability and reduce P availability in temperate forests. This imbalance in nutrient availability has important implications for forest nutrition and ecosystem stability in a warming world.

# Nature-based solutions for mitigating climate change: from rangelands to forests

**Scott X Chang**[1*]

[1] *Department of Renewable Resources, University of Alberta, Edmonton, Alberta, Canada*

[*] E-mail Address of Presenting Author: sxchang@ualberta.ca

## ABSTRACT

Global climate change is characterized by rising temperatures and more frequent extreme weather events. Reducing anthropogenic sources of greenhouse gas (GHG) emissions and increasing carbon sequestration in terrestrial ecosystems are among the measures needed to mitigate climate change. Nature-based solutions (NbS) have become central to climate change mitigation efforts because they harness ecological processes to reduce net GHG emissions, increase carbon sequestration, and support ecosystem sustainability. This presentation will discuss the mitigation potential of NbS across rangelands, agroforests, and forested ecosystems, based on research conducted in the research group over the last decade. Proper management of grasslands, converting marginal agricultural lands to agroforests, and conserving plant diversity in forests prevent substantial carbon losses and re-establish long-term ecosystem function. Despite their high potential, the effectiveness of NbS is influenced by many factors, including soil quality, management intensity, and climate variability, underscoring the need for robust monitoring and governance frameworks to ensure the permanence of sequestered carbon and ecosystem integrity. Collectively, NbS can significantly contribute to climate change mitigation as part of a broader, multi-sectoral strategy.

**ABSTRACT**

Phosphorus (P) availability is a key regulator of soil microbial activity and nutrient cycling in forest ecosystems, yet the mechanisms governing its vertical heterogeneity along soil profiles remain insufficiently understood. To address this knowledge gap, we designed a depth-resolved investigation across ten forest sites spanning a broad latitudinal gradient in Northeast China. At each site, a complete soil profile was excavated from 0 to 60 cm and subdivided into six depth intervals to capture vertical variation in biogeochemical and microbial processes. This study integrates complementary measurements of phosphorus supply, mineral constraints, and microbial nutrient demand. Phosphorus bioavailability will be is quantified using diffusive gradients in thin films (DGT), together with concurrent DGT measurements of Fe, Al, and Mn to characterize mineral-associated and redox-sensitive controls on phosphorus supply. Phosphorus pool composition will be assessed using sequential Hedley fractionation to distinguish between labile, moderately labile, and residual P pools. Microbial nutrient demand and acquisition strategies will be evaluated through microbial biomass stoichiometry (MBC, MBN, MBP) and extracellular enzyme activities associated with carbon, nitrogen, and phosphorus cycling. To provide ecological context for depth-dependent functional responses, bacterial and fungal community composition will be characterized using 16S rRNA gene and ITS sequencing across soil depths. By integrating geochemical fluxes, phosphorus pool structure, microbial nutrient demand, and microbial community composition across soil profiles and sites, this experimental framework is designed to elucidate the mechanisms controlling vertical patterns of phosphorus bioavailability in forest soils and their implications for soil biogeochemical functioning.

## ABSTRACT

The slow natural decomposition of eucalyptus logging residues is a key constraint to the wide application of the technology for returning these residues to the forest. Microorganisms are the main participants in the decomposition process of logging residues. The development of efficient decomposing microbial resources is expected to be a breakthrough in solving the technical bottleneck of efficient reforestation with eucalyptus logging residues. This study set up a 36-month in-situ decomposition experiment of eucalyptus logging residues, analyzed the key role of core microorganisms in the decomposition of logging residues through metagenomic binning technology, and verified their role by constructing synthetic microbial communities. The results showed that the key stage of residue decomposition was 24 months, during which the microbial decomposition and transformation efficiency was the highest, and the activity of decomposition enzymes and the accumulation of microbial residue carbon (alkyl carbon, amino sugar) reached the peak. Moreover, the decomposition process followed a pattern of "bacteria dominance in the early stage - fungal drive in the later stage", and the contribution of fungi to lignin degradation significantly increased in the middle and later stages. A total of 634 high-quality metagenomic assembled genomes (MAGs) were obtained through metagenomic binning, which mainly belonged to Pseudomonadota, Actinomycetota, and Acidobacteriota. Further analysis indicated that three MAGs from the genera Puia, Conexibacter, and Afipia were the core strains for the decomposition of eucalyptus logging residues and played a key role in the process. By constructing synthetic microbial communities based on core strains and non-core strains and inoculating them into eucalyptus logging residues, the key role of core microorganisms in the decomposition of eucalyptus logging residues was verified through microcosm experiments. The results showed that the synthetic microbial community containing core strains significantly improved the decomposition efficiency of logging residues, with a weight loss rate of up to 87.73%, while the weight loss rate of the blank control (CK) was only 2.92%. This result confirmed that core strains greatly enhanced the decomposition efficiency of eucalyptus residues by regulating the synergistic effects among strains. The research results have important guiding significance for the rapid decomposition of difficult-to-decompose natural products such as straw and the maintenance of soil quality.

## ABSTRACT

The prediction of soil organic carbon (SOC) responses to land-use changes remains uncertain, primarily due to the inadequacy of current models in incorporating alterations in its stable microbial-derived components. Evaluating microbial necromass carbon (MNC), a crucial and persistent fraction, offers a significant opportunity to enhance the accuracy of these predictions. This study systematically quantified the differential impacts of management-driven land use change (LUC-), and ecologically restorative land-use change (LUC+) on soil carbon fractions by integrating 517 pairs of global observations using meta-analysis and spatially explicit prediction methods. Ecological restoration (LUC+) significantly boosted all carbon fractions, with microbial necromass carbon (MNC) rising by 41.45%, contributing heavily to a 30.91% increase in total soil organic carbon (SOC) and raising the MNC/SOC ratio. Fungal and bacterial necromass carbon also grew by 42.92% and 38.95%, respectively. Conversely, anthropogenic disturbance (LUC−) led to a 19.14% SOC loss but increased the MNC/SOC ratio by 10.59%. This suggests that disturbance rapidly depletes labile, plant-derived carbon, while more persistent microbial residues become a larger part of the reduced SOC pool.The meta-regression analysis reveals that soil depth, pH, and climate zone are pivotal regulatory factors, while the duration of land-use conversion (LUC_year) has significant differential impacts: it is beneficial under ecological restoration (LUC+) and detrimental under human-managed conversion (LUC-). From 2001 to 2024, global land-cover changes show that human-driven transitions (7.10 million hectares) outpaced ecological restoration (2.02 million hectares) by 3.52 times, mainly due to wetlands and shrublands converting to croplands and urban areas. A Markov chain model predicts a net loss of soil organic carbon (SOC) at 0.29 Pg C per year, totaling 22.1 Pg C by 2100. Conversely, microbial necromass carbon (MNC) is expected to increase by 1.46 Pg C per year, with bacterial necromass carbon (BNC) showing strong resilience. Tropical regions are likely to experience significant SOC loss, while mid-to-high latitude areas and regions with ecological engineering will see microbial carbon growth. This study highlights that land-use changes not only affect soil carbon quantities but also alter their chemical makeup and stability, providing essential insights for policy development.

# Soil Organic Carbon Stocks and Controlling Factors in Planted and Natural Mangrove Forests Developed on Acid Sulfate Soils

**Nghia Van Nguyen[1*], Thia Hong Le[2], Binh Thanh Nguyen[2]**

[1] Institute of Environmental Science, Engineering and Management, Industrial University of Ho Chi Minh City, 12 Nguyen Van Bao, Hanh Thong District, Ho Chi Minh City, Vietnam

[3] Faculty of Technology, Dong Nai Technology University, Bien Hoa City, Vietnam

*E-mail: nguyenvannghia@dntu.edu.vn

**ABSTRACT**

Mangrove ecosystems are among the most efficient blue carbon sinks globally, yet the mechanisms controlling soil organic carbon (SOC) accumulation remain insufficiently understood, particularly in mangrove systems developed on acid sulfate soils. This study quantified SOC stocks and their vertical distribution and identified key controlling factors using an extensive dataset collected from the Can Gio Mangrove Biosphere Reserve, southern Vietnam. A total of 98 soil profiles were sampled across planted and natural mangrove forests, with soil collected at six depth intervals (0–25, 25–50, 50–75, 75–100, 100–125, and 125–150 cm) to capture SOC dynamics throughout the soil profile. For the layer 0-150 cm, total SOC stocks ranged from approximately 579 to 893 t C $ha^{-1}$, depending on forest type. Notably, SOC stocks increased with depth, indicating that subsoil layers constitute a dominant and stable carbon reservoir in mangrove ecosystems. Planted mangrove forests stored, on average, 36% more SOC than natural forests, a difference attributed to higher root biomass production, greater root turnover, and enhanced belowground carbon inputs that promote carbon burial and stabilization in deeper soil layers.

Multivariate analyses demonstrated that soil acidity associated with acid sulfate soils was the primary factor governing SOC accumulation, likely through suppression of organic matter decomposition under strongly acidic conditions, while no significant relationships were observed between SOC stocks and salinity, tidal inundation frequency, or land subsidence. These findings provide globally relevant evidence that soil chemical constraints, rather than hydrological variability alone, play a decisive role in regulating long-term carbon storage in mangrove ecosystems, with important implications for blue carbon accounting and climate mitigation strategies worldwide.

**ABSTRACT**

The capacity of forests to sustain carbon sequestration under elevated ($eCO_2$) is theoretically constrained by the "Progressive Phosphorus Limitation" (PPL) hypothesis. Unlike nitrogen, phosphorus (P) supply relies on slow geological weathering, creating a potential bottleneck. Here, we combine a global meta-analysis with a process-based coupled model to project forest P trajectories through 2050. Contrary to PPL predictions, we find that $eCO_2$ accelerates P cycling dynamics to meet increasing demands. Specifically, $eCO_2$ drives a 21% expansion in root biomass and a 19% improvement in P use efficiency. This root proliferation triggers an 18% surge in biological P weathering (+180 Gg P $yr^{-1}$), which effectively offsets the intensified P removal from biomass harvest (+188 Gg P $yr^{-1}$). Consequently, shifts the P budget towards a surplus in most regions, reducing global anthropogenic fertilizer requirements despite higher forest productivity. These findings demonstrate that "biological mining" enables forests to uncouple carbon accumulation from external nutrient inputs, safeguarding their climate mitigation potential.

## ABSTRACT

Dissolved organic matter (DOM) is a significant component of soil organic matter. It plays a crucial role in forest ecosystems because DOM migration is the main factor of SOM accumulation in the subsoil and its runoff to groundwater and adjacent streams. The former is occurred by precipitation and sorption of DOM on mineral surfaces and its transformation to mineral-associated organic matter**,** the latter, on the contrary, originates from the dissolution of SOM. Thus, DOM dynamics controls carbon flows and connects the pedosphere with the hydrosphere. An investigation of optical characteristics, such as absorption and fluorescence spectra, is an easy, available and highly reproducible way to make qualitative and quantitative analyses of DOM.

Soil and adjacent streams waters were sampled in Ust-Kulom region of Komi Republic, Russia. There is a middle taiga bioclimatic zone, the study site forest is defined as the moss-covered bilberry spruce forest, the parent rock is a cover loam. According to World References Base of Soil Resources soils are classified as Albic Retisols. Water extracts from soil horizons were prepared with ultrapure water. Absorption spectra were recorded on a Shimadzu UV-1800 spectrophotometer (Japan), fluorescence ones are obtained as excitation-emission matrices using a Shimadzu Spectrofluorophotometer RF-6000. Dissolved organic carbon (DOC) content was determined by a Shimadzu TOC-L CSN analyser. Absorption and fluorescence spectra were measured in the water extracts from the fresh soil samples and water ones. Spectral data were corrected and processed by parallel factor analysis (PARAFAC). In addition, an experimental study of DOM sorption in equilibrium conditions was conducted. The parent rock from the three-meter depth was sampled, dried and sieved through 2 mm. Water extracts of soil horizons were added to the parent rock samples and shaken. Then, DOC content and optical characteristics were measured again.

PARAFAC modelling revealed that forest litter and upper mineral horizons DOM is enriched with humic- as well as protein-like components. Subsoil DOM contained more protein-like material due to precipitation and sorption of humic-like substances during DOM downwards migration, which proved by the sorption equilibrium experiment. Therefore, protein-like DOM components are more labile and recalcitrant enough to reach the subsoil of Albic Retisols and accumulate there. DOM of adjacent streams has close composition as that of albic horizons and forest litter with a big proportion of humic-like structures although they are more microbially processed. Therefore, DOM migration to adjacent streams, tentatively, comes through forest litter and albic horizons.

**ABSTRACT**

Although the sensitivity of litter decomposition and soil organic carbon (SOC) stocks to nitrogen deposition is well-documented, the transformation of litter into SOC and its subsequent stabilization remains poorly understood, particularly through microbial (MRC) and plant residue carbon (PRC) pathways. The response mechanisms of this process to nitrogen deposition are limited by traditional understory-based simulations that overlook canopy processes. To fill this knowledge gap, we combined an in-situ $^{13}$C-labeled litter decomposition experiment with a long-term field study comparing understory (UN) and canopy N addition (CN) in a temperate forest. We identified a bimodal pattern of litter-derived SOC formation, governed by a shift from early-stage MRC to late-stage PRC dominance. This shift facilitated sustained litter-derived mineral-associated organic carbon (MAOC) accumulation, progressively enhancing the stability of litter-derived SOC throughout decomposition. CN not only enhanced microbial carbon use efficiency by improving litter quality but also accelerated microbial turnover rate compared with UN, leading to greater litter-derived MRC formation. Similarly, CN promoted higher litter-derived PRC formation by stimulating lignin release from litter, whereas UN elevated PRC by inhibiting peroxidase-mediated lignin degradation. Litter-derived MAOC accumulation was driven solely by PRC under UN but jointly by MRC and PRC under CN, resulting in more effective enhancement of litter-derived SOC stability under CN. Our findings, for the first time, systematically elucidate the dynamics of litter-derived SOC formation and stabilization mediated by microbial carbon pump, along with their divergent response mechanisms under UN versus CN, underscoring the importance of considering canopy processes for accurately predicting forest soil carbon sequestration.

# Contrasting effects of roots and arbuscular mycorrhizal fungi on soil carbon storage reveal divergent pathways in forest carbon cycling

**Xin Guan[1, 2]; Nadia Soudzilovskaia[2]; Jiang Jiang[1*]**

*[1]Collaborative Innovation Center of Sustainable Forestry in Southern China of Jiangsu Province, Nanjing Forestry University, Nanjing 210037, China*

*[2]Centre for Environmental Sciences, Hasselt University, Hasselt, 3500, Belgium*

**ABSTRACT**

Roots and mycorrhizal hyphae are major pathways through which plant carbon enters soils, yet their relative roles in regulating soil carbon storage remain poorly resolved. In particular, it is unclear why enhanced microbial activity associated with belowground plant inputs can lead to either soil carbon accumulation or loss. Here, we combined a field-based ingrowth core experiment with microbial, biochemical, and biomarker measurements and a process-based carbon dynamic model to disentangle the effects of roots and mycorrhizal hyphae on soil carbon dynamics in subtropical forest stands of different ages.

After 15 months of in situ incubation, root presence led to a net increase in soil organic carbon, driven primarily by gains in mineral-associated carbon, whereas mycorrhizal hyphae resulted in a net loss of soil carbon. Roots increased microbial biomass and promoted the transfer of plant-derived carbon into microbial biomass and mineral-associated pools, while maintaining a slow but persistent recycling of mineral-associated plant-derived carbon through microbial biomass. In contrast, mycorrhizal hyphae reduced microbial biomass but enhanced extracellular enzyme activities and microbial turnover. Model-based flux analysis revealed that mycorrhizal hyphae accelerated the conversion of microbial biomass into residues while suppressing the recycling of mineral-associated plant-derived carbon through microbial biomass, thereby routing carbon toward short residence-time pathways and mineralization.

Together, our results demonstrate that the direction of soil carbon change is determined by whether microbial processing is coupled to mineral protection. Roots promote soil carbon accumulation by coupling microbial processing with mineral-associated stabilization, whereas mycorrhizal hyphae promote soil carbon loss by decoupling microbial processing from mineral recycling and stabilization. These findings provide a mechanistic framework for reconciling contrasting effects of belowground plant inputs on soil carbon storage and highlight the need to explicitly distinguish root and mycorrhizal pathways in models of ecosystem carbon–climate feedbacks.

**ABSTRACT**

Soil organic carbon (SOC) stability fundamentally depends on interactions between organic matter and mineral surfaces, forming mineral–soil organic matter interfaces that act as a central hub of the global terrestrial carbon cycle. While these interfaces underpin long-term carbon sequestration in forest ecosystems, their stability under accelerating climate change and increasingly frequent extreme events remains poorly constrained. Here, we integrate a comprehensive literature synthesis with transect-based field sampling, site-level experiments, and controlled laboratory incubations to examine how acute climate changes e.g. short-term droughts and intense precipitation events alter SOC dynamics. We focus on redox-sensitive organo-mineral associations, particularly manganese-associated and iron-bound organic carbon (Mn-OC, Fe-OC) and mineral-associated organic carbon (MAOC), which are critical yet vulnerable pools. Our results demonstrate that climate extremes disrupt mineral-SOM interfaces through coupled geochemical feedbacks: drought-induced oxidation destabilizes reduced Fe-OC phases, whereas extreme rainfall promotes reductive dissolution and mobilization of Mn-OC. These processes shift carbon from mineral-protected, stable pools into more labile, microbially accessible forms, increasing the risk of soils transitioning from carbon sinks to carbon sources. By linking molecular-scale mechanisms to ecosystem-scale observations, this study provides a geochemistry-based framework for assessing SOC vulnerability under future climate scenarios. Our findings offer actionable, mechanistic insights to inform sustainable forest soil management aimed at enhancing the stability of soil carbon storage in a changing climate.

# Reduced below-ground carbon allocation triggers contrasting nitrogen dynamics in rhizosphere and bulk soil of alpine coniferous forests on the eastern Tibetan Plateau

**Dengjie Zhou[1*] and Ziliang Zhang[1]**

[1] *School of Life Science and Technology, Northwestern Polytechnical University, Xi'an 710129, China*

*E-mail Address of Presenting Author: zhoudengjie2022@163.com

**ABSTRACT**

Below-ground carbon allocation (root-derived carbon inputs) is a key mechanism regulating nutrient cycling in forest soils; however, a systematic understanding of how reductions in below-ground carbon allocation induced by global change or anthropogenic disturbances affect soil nitrogen dynamics remains limited. Here, we combined a meta-analysis across global forests with a girdling experiment conducted in alpine coniferous forests on the eastern Tibetan Plateau to elucidate the relative impacts and underlying mechanisms of reduced below-ground carbon allocation on soil nitrogen dynamics. Meta-analysis showed that overall, girdling significantly increased soil nitrate nitrogen and inorganic nitrogen contents, while reducing microbial biomass nitrogen content and fine root biomass. Field experiment results showed that girdling significantly increased inorganic nitrogen contents, net nitrogen mineralization rates, and nitrification rates in both rhizosphere and bulk soils of natural and plantation forests. However, responses in natural forests were gradual and persisted for a longer duration, whereas plantation forests exhibited rapid but short-lived responses. Girdling reduced microbial biomass nitrogen content and nitrogen availability in rhizosphere soils of both forest types, while in bulk soils it led to increased microbial nitrogen content and nitrogen availability or alleviated the early negative effects. The dominant drivers of changes in nitrogen availability differed between forest types: microbial attributes primarily regulated nitrogen availability in natural forests, whereas enzyme activities were the main explanatory factors in plantation forests. Path analysis further indicated that changes in rhizosphere soil nitrogen availability were jointly regulated by microbial properties and extracellular enzyme activities, whereas those in bulk soils were synergistically controlled by soil physicochemical properties and microbial factors. These findings suggest that reduced below-ground carbon allocation in coniferous forests of the eastern Tibetan Plateau tends to shift nitrogen cycling toward a more closed state in rhizosphere soils but a progressively more open state in bulk soils. This study highlights differential response mechanisms of soil nitrogen cycling to changes in below-ground carbon allocation across forest types and between rhizosphere and bulk soils, providing a scientific basis for predicting forest soil nitrogen cycling under global change.

## ABSTRACT

Methane ($CH_4$) is one of the greenhouse gases (GHGs) emitted from paddy soil ecosystems. Together with other GHGs, such as carbon dioxide ($CO_2$) and nitrous oxide ($N_2O$), it may induce global warming and climate change (IPCC 2001). Among anthropogenic GHGs, methane is estimated to account for 14% of the $CO_2$-equivalent emissions; rice paddy emits 60 Mt C $year^{-1}$, particularly from Monsoon Asia (IPCC 2007). When fresh organic matter is fertilized just before flooding in paddy rice cultivation, the soil becomes abnormally reduced conditions to create root-rotting, then produces $CH_4$ gas. In this study, we compared the amount of $CH_4$ gas generated and the effect of steel-making sludge and application timing and rate on $CH_4$ emission in pot experiments.

Dephosphorized slag, converter slag, and ferrous materials were used as iron-containing materials and applied to river sand and gray lowland soil (1:1). The treatments consisted of a chemical fertilizer plot, a sludge plot applied with dried sludge only, and a combined sludge-ferrous material plot. Rice was grown for 3 months. The degree of hydrogen sulfide generation, Eh transition and methane gas release were measured from the beginning of cultivation, degree of root-rot and yield and yield-components of rice were examined at harvest. We also measured the amount of ferrous in the soil after 1, 2 and 3 months of transplanting and the amount of free iron in the soil after harvest. Another pot experiment was conducted to examine application timing and application rate of slag.

The degree of hydrogen sulfide generation was enhanced in all the plots where dried sludge was applied, and there was no difference in the degree of root-rot caused by the application of each iron-containing materials. The combined use of iron-containing materials reduced methane release. Free iron and ferrous were highest in the dephosphorized slag combined plot. The amount of ferrous reached a maximum 2 months after transplanting in each slag combination plot. These results suggest that ferrous eluted from iron-containing materials can improve plant growth by dry sludge, and suppress methane release, and that dephosphorized slag is particularly effective among tested materials. When slag was applied 1 and 2 months before transplanting, $CH_4$ emission was reduced to compare with immediate application on transplanting, while more $CO_2$ was emitted from pots with slag applied 1 and 2 months before transplanting to compare with immediate application on transplanting timing. When application rate increased twice as recommended, $CH_4$ emission was reduced comparing to recommended rate, while more $CO_2$ was emitted from pots with double rate of slag application. Rice yield was not affected by application rate and timing. These results suggested that steel-making slag is feasible mitigation option to reduce $CH_4$ emission from paddy field.

# Effects of Alternate Wetting and Drying (AWD) on Driving Factors Controlling $CH_4$ Emissions from Rice Paddy Soils

**Crosetto L.[1*], Sleutel S.[2], Said-Pullicino D.[1]**

[1] *Department of Agricultural, Forest and Food Sciences, University of Torino - Italy*

*lucia.crosetto@unito.it

## ABSTRACT

Alternate Wetting and Drying (AWD) is a water-saving irrigation technique increasingly adopted in rice systems as a climate-smart alternative, offering potential to reduce methane ($CH_4$) emissions. However, mitigation outcomes remain variable, suggesting that the effectiveness of AWD depends on how soil characteristics and residue management influence microbial activity and redox conditions. We hypothesize that the contrasting microbial and redox dynamics occurring during AWD cycles can lead to a hysteresis effect on net $CH_4$ emissions. This effect may depend on soil texture and residue incorporation depth, which influence redox stratification and substrate availability in the soil profile.

A mesocosm experiment was conducted using two soils of contrasting textures (coarse and fine) and two crop residue incorporation depths (shallow: 0–10 cm; deep: 20–30 cm), in a full factorial design. Following an initial continuous flooding period, two AWD cycles were implemented, progressively lowering and raising the water table in 10 cm increments. During these cycles, $CH_4$ fluxes and $\delta^{13}C\text{-}CH_4$), soil redox potential at multiple depths, and porewater chemistry (including $Fe^{2+}$, DOC, dissolved CH4, and $\delta^{13}C\text{-}CH_4$) were continuously monitored.

Preliminary results suggest a nonlinear and asymmetric $CH_4$ response to drainage and reflooding phases, consistent with a hysteresis effect. Redox potential increased during drainage, temporarily suppressing methanogenesis and partially enhancing $CH_4$ oxidation. However, emission reductions varied across treatments. Deeper straw incorporation (20–30 cm) resulted in higher $CH_4$ emissions during drainage phases when the water table dropped below –10 cm, compared to shallower incorporation. This suggests that under dry conditions, anoxic microsites at depth, enriched in labile organic carbon, can maintain active methanogenesis, while reduced water-filled pore connectivity may hinder oxygen penetration and $CH_4$ oxidation. Moreover, isotopic analyses ($\delta^{13}C\text{-}CH_4$) aim to distinguish the relative contributions of microbial and physical processes and transport mechanisms to the observed fluxes.

These findings highlight the importance of vertical interactions between redox conditions and carbon availability in determining $CH_4$ responses to AWD. While AWD shows potential for mitigation, its effectiveness may be sensitive to residue management and soil physical properties. This study contributes to a process-level understanding of $CH_4$ dynamics under AWD and informs strategies to optimize its implementation for climate mitigation in rice systems.

*E-mail: michaelzionadam@gmail.com

**ABSTRACT**

This study employed Open Top Chambers (OTCs) to investigate the responses of $CH_4$ fluxes with respect to soil Carbon (C) pools and microbial activity in rice soil exposed to different levels of elevated ozone concentrations (e[$O_3$]). Treatments included: (i) UC = ambient [$O_3$] under open field condition (30 ± 5 ppb), (ii) CC = ambient [$O_3$] under OTC (30 ± 5 ppb), (iii) EO40 = elevated [$O_3$] under OTC (40 ± 5 ppb) and (iv) EO60 = elevated [$O_3$] under OTC (60 ± 5 ppb)]. Rice soil under EO60 conditions showed reductions of 19%, 20%, 26%, and 37% in readily mineralizable carbon, potassium permanganate-oxidizable carbon, water-soluble carbohydrate carbon, and microbial biomass carbon, respectively, over CC. The rhizospheric methanogen population declined by 12% under e[$O_3$] compared with CC. Furthermore, $CH_4$ emissions were reduced by 39% under EO60 compared to CC on a seasonal basis. This research employed path analysis using the Partial Least Squares-Path Modelling (PLS-PM) method to differentiate the factors influencing $CH_4$ emissions under varying levels of e[$O_3$]. The PLS-PM model indicated that methanogens directly affected $CH_4$ emissions, with a more pronounced effect under e[$O_3$] than CC. These insights are valuable for understanding soil-plant-microbe dynamics in an $O_3$-enriched environment, which can help reduce $CH_4$ emissions from rice under changing climatic conditions.

# Effect of dry direct-seeded and seedling-transplanted rice cultivation on methane emissions from a paddy field in Hokkaido, Japan.

**Mariko Shimizu[1*], and Arata Nagatake[1]**

[1] *Civil Engineering Research Institute for Cold Region (Hokkaido, Japan)*

* shimizu-m@ceri.go.jp

**ABSTRACT**

Rice paddies are one of the major anthropogenic sources of atmospheric methane ($CH_4$). The area of dry direct-seeded rice is increasing in Hokkaido, although puddled transplanted rice remains dominant. However, literature reporting $CH_4$ emissions from direct-seeded rice cultivation systems is extremely limited compared to that regarding transplanted rice in Japan. To evaluate the effect of different rice cultivation systems on $CH_4$ emissions, a six-year field experiment was conducted from 2017 to 2022 in a paddy field on peatland dressed with mineral soil in central Hokkaido.

In the paddy field selected for this study, transplanted rice was cultivated from 2016 to 2018 and in 2021, whereas dry direct-seeded rice was grown in 2019, 2020 and 2022. For the transplanted rice cultivation system, the field was flooded before the puddling in mid-May. Seedlings were transplanted in late May, and harvested in mid-September. For the dry direct-seeded rice cultivation system, seeds were sown into dry soil after tillage in mid-May. The field was flooded for a few days after sowing, and then drained. When the rice had grown two to four leaves, the field was flooded again and then managed in the same way as with transplanted rice cultivation. Dry direct-seeded rice was harvested in late September. Rice straw was left in the field and incorporated in the following spring in both cultivation systems. $CH_4$ fluxes were measured using a closed chamber method at three to four replications during the growing season. Groundwater levels were recorded 1.5 m below the surface.

$CH_4$ emissions during the rice growing season were 29.6±3.0,39.2±18.7, 17.5±3.8,48.9±22.6,38.3±25.0,2.6±1.5 gC $m^{-2}$ from 2017 to 2022, respectively, and showed large interannual variability regardless of the rice cultivation systems. The cumulative duration of flooding for the dry direct-seeded cultivation system was 66 – 79 days, and was shorter than that for the transplanted rice cultivation system (83 – 94 days). The flooding duration had no apparent correlation with $CH_4$ emissions. On the other hand, $CH_4$ emissions had a weak positive correlation ($r = 0.62$, $p = 0.19$) with precipitation from August 20 to September 19 of the previous year. $CH_4$ emissions also had a positive correlation ($r = 0.97$, $p < 0.01$) with the average groundwater level in September of the previous year and a positive correlation ($r = 0.91$, $p < 0.05$) with volumetric soil water content in the Ap2 horizon after the harvest in the previous year. Our results suggest that lowering the groundwater level below the Ap2 horizon and drying soil in autumn could decrease $CH_4$ emissions in the following growing season from a paddy field regardless of whether dry direct-seeded or seedling-transplanted rice cultivation is adopted.

## ABSTRACT

Cow manure is a globally abundant byproduct of livestock farming. It plays a critical role in closing the nitrogen (N) cycle in agroecosystems through its application on farmland as an N source for crops. Given that cow manure compost (CMC) has low decomposability and persists in soil over multiple cropping seasons, understanding its long-term N dynamics is essential for sustainable crop production and environmental conservation. However, most studies investigating CMC N dynamics have been limited to periods under three years in continuous paddy or upland environments. A critical knowledge gap exists regarding its behavior in a paddy-upland rotation (PUR) system, where a unique, repeated cycle of soil reduction (paddy) and oxidation (upland) may profoundly influence N dynamics. In this study, we aimed to quantitatively track the six-year N dynamics of CMC in a soybean-introduced PUR system using $^{15}$N-labeled CMC.

Microplots were established in paddy and upland fields at Kawatabi Field Center (38°74'N, 140°75'E) in a cool climate region of Japan, and were annually cultivated with rice or soybeans from 2019 to 2024. The $^{15}$N-labeled CMC was applied only in 2019, the initial year of the study period, and the annual distribution of its derived N (Ndfc) to crops and soil was investigated until 2024. Non-labeled CMC was applied annually from 2020 to 2024. The effect of annual rice-soybean PUR was evaluated in comparison with the continuous paddy (CP) treatment. We also investigated the influence of soil type, namely Fluvisol and Andosol, on the Ndfc dynamics under both management practices.

Results showed that more than 50% of Ndfc remained in the soil six years after the $^{15}$N-labeled CMC application in all treatments, with the residual ratio decreasing gradually over time. No significant differences in the residual ratio were observed among the treatments throughout the study period. Supported by its high residuality in the soil, the Ndfc uptake by crops continued throughout the six-year study period in all treatments, although the uptake ratio declined annually. In the PUR, soybeans exhibited lower Ndfc uptake, while subsequent rice showed higher Ndfc uptake compared to rice in the CP. The increase in Ndfc uptake by rice after soybean cultivation was more pronounced in the Fluvisol than in the Andosol.

In this study, we directly tracked CMC N (Ndfc) over six years, revealing that both the PUR treatment and soil types influenced the Ndfc dynamics, particularly the crop uptake. These findings suggest that the CMC application strategy should be adjusted based on the management practices and soil types. Longer-term investigations are required to accumulate observations of the effects of the PUR on the soil Ndfc residual ratio. Furthermore, physicochemical analyses of the Ndfc in the soil are also indispensable to clarify the mechanism of these long-term dynamics.

## ABSTRACT

The global accumulation of plastic waste necessitates urgent circular economic solutions. A novel "plastic to fertilizer" technology has been developed to chemically recycle bio-based poly(isosorbide carbonate) (PIC) via ammonolysis, yielding urea as a nitrogen source and isosorbide (ISB) as a potential biostimulant (Abe et al. 2021, Agrahari et al. 2025). While previous studies confirmed the efficacy of these degradation products in artificial growth media, their performance in actual agricultural soils—particularly paddy soils, which are a major agricultural soil type globally—remains to be verified. The objective of this study was to evaluate the fertilizer effectiveness of PIC degradation products compared with commercial urea in soil culture.

We conducted a pot experiment using Fluvisol collected from the plow layer of a paddy field in Miyagi, Japan (soil texture: light clay, pH 5.2, total N: 1.86 g/kg). Komatsuna (*Brassica rapa* var. *perviridis*) was cultivated under four treatments: (1) PIC degradation products, (2) commercial urea, (3) commercial urea with ISB, and (4) a no-nitrogen control. For all N-source treatments, nitrogen was applied at a rate equivalent to 0.5 g N per pot to ensure comparable conditions.

The results demonstrated that the application of PIC degradation products significantly increased plant height, leaf number, fresh/dry biomass, and nitrogen uptake compared with the control ($P < 0.05$). Crucially, these agronomic outcomes were statistically equivalent to those obtained with commercial urea, indicating that the recycled material performed just as well as the conventional fertilizer. Although ISB was hypothesized to act as a biostimulant, no significant additional growth-promoting effects were observed in this study. This suggests that ISB may undergo rapid biodegradation by the active microbial community inherent to the paddy soil environment, preventing it from exerting long-term biostimulant.

In conclusion, this study provides the first evidence that chemically recycled PIC functions effectively as a nitrogen fertilizer in paddy soil conditions. These findings strongly support a circular economic model that repurposes plastic waste into valuable agricultural resources, offering a sustainable nutrient management pathway for crops grown in agricultural systems while mitigating plastic pollution.

## ABSTRACT

The 2011 Fukushima nuclear power plant accident caused contamination of farmland soils in the coastal areas of Fukushima Prefecture. To restore agricultural production, contaminated surface soil was removed and replaced with decomposed granite soil (masa soil), which was collected from nearby mountains and was a low-fertility sandy loam. Therefore, rapid improvement of soil productivity in these reconstructed fields is required. At the same time, effective use of cattle manure compost could help establish a crop–livestock farming system that reduces dependence on chemical fertilizers. This study aimed to evaluate the potential of cattle manure compost for improving the fertility of low-fertility masa soil.

A small-scale plot experiment was conducted continuously from 2024 to 2025 in a paddy field at the Field Science Center, Tohoku University using masa soil, and the rice plants (CV. Tsukiayaka) were cultivated there. Manure compost was applied at rates of 0, 3, 6, and 12 kg/m$^2$, with five replications. In 2024, the basal chemical fertilizer consisted of 4–10–10 g/m$^2$ (N–$P_2O_5$–$K_2O$), and transplanting was performed on May 29. Additional nitrogen fertilizer (3 kg/10a) was applied on June 25 and July 16, respectively. In 2025, the experiment continued with the repeated application of the manure compost and basal fertilizer at 6–10–10 g/m$^2$ (N–$P_2O_5$–$K_2O$) and transplanting on May 30. Nitrogen topdressing (4 g/m$^2$) was applied on July 3. Each year, soil redox potential, plant growth, yield, and the nutrient composition of plants and post-harvest soils were measured.

The results showed that cattle manure compost had both short-term and repeated application effects on rice growth and yield. In the first year, heavy compost application (6 and 12 kg/m$^2$) caused temporary growth disorders in rice. Although dry matter weight tended to increase with higher compost application rates, growth disorders resulted in similar dry weights between the 6 and 0 kg/m$^2$ plots, and larger variation was observed in the 12 kg/m$^2$ plot. The 3 kg/m$^2$ treatment showed the most balanced growth and stable dry matter accumulation. In the second year, tiller number and dry matter weight increased with higher compost rates, indicating that the negative effects of heavy compost application were temporary, and that the repeated application effects gradually improved soil fertility and rice growth.

In conclusion, cattle manure compost application improved soil fertility and crop productivity over time, although heavy application temporarily suppressed rice growth. Based on these findings, two management strategies are proposed: (1) Moderate compost application (3 kg/m$^2$) is recommended to maintain stable rice growth and minimize the risk of early growth disorders; and (2) Heavy compost application (12 kg/m$^2$) may be an alternative for long-term soil fertility improvement, despite its short-term negative effects. Continuous monitoring of soil chemical and biological properties is required to clarify the long-term sustainability of compost use in paddy fields.

**ABSTRACT**

Soil organic matter in paddy fields plays important roles such as maintenance of soil fertility for rice production and mitigation of or adaptation to global warming through soil C sequestration. To better understand the situation in Asia, this study aimed to evaluate the amounts and persistence of SOC in multiple fractions and to elucidate their determining factors using the total of 253 paddy soils across 7 Asian countries under different climatic and geological conditions. SOC was fractionated into four fractions based on their physicochemical properties: (1) coarse light fraction (LF) derived from plant residue, (2) coarse heavy fraction (HF) containing stable aggregates, (3) fine NaClO oxidizable fraction (OxF), and (4) fine NaClO non-oxidizable fraction (NOxF) associated with fine-textured minerals. The C content of each fraction was determined by dry combustion method and $\Delta^{14}C$ values were measured to infer SOC turnover time. The relationships between the amounts of fractionated SOC and soil- and climate-factors were investigated.

The total C content was on average 22.5 gC/kg and ranged in the order of Japan (29.6 gC/kg, n = 73) > Malaysia (27.8, 40) > Philippines (18.5, 37) > Taiwan (18.2, 30) > Thailand (18.2, 16) > South Korea (16.5, 25) > Nepal (15.1, 32). The averages and percentages of fractionated C for all the samples were OxF (8.9 gC/kg, 43 %) > NOxF (6.9, 33) > LF (3.3, 16) > HF (1.9, 9), indicating that dominance of fine-grain fractions in soil C storage. The average $\Delta^{14}C$ values of selected samples were OxF (8 ‰) > HF (-54 ‰) > NOxF (-169 ‰), suggesting slow turnover of oxidation-resistant C. Total C and C contents in OxF and NOxF correlated positively with pyrophosphate-extractable Al and Fe (Alp, Fep), oxalate-extractable Al and Fe (Alo, Feo) and clay content ($p<0.01$) and negatively with pH and mean annual temperature ($p < 0.01$), indicating strong influence of soil organo-metal complexes and short-range order minerals (reflecting volcanic activities) and soil pH, in addition to temperature. Exchangeable Mg and Ca correlated positively with C content in HF, implying their influence on aggregate formation. Multiple-regression analysis further revealed that roughly 47 and 66% of the C variations in OxF and NOxF were explained by the above variables for all the samples, suggesting stronger control on the stable fraction. Furthermore, the major controlling factors for OxF and NOxF varied across pH ranges: (1) Fep and Alp for pH 4.6–5.5, (2) Alo–Alp, Alp, and Fep for pH 5.5–7.5, and (3) exchangeable Mg and Feo–Fep for pH 7.5–8.4, suggesting distinct mechanisms depending on soil pH. These findings help to better manage SOC levels in paddy fields to achieve sustainable rice production and environmental conservation.

# Decades of intensive rice cropping alter tropical soil fertility

**Kazuki Saito[1*], Tomohiro Nishigaki[2], and Olivyn Angeles[1]**

[1] *International Rice Research Institute (IRRI) (Sustainable Impact through Rice-based Systems Department, Laguna, Philippines)*

*k.saito@cgiar.org

**ABSTRACT**

Sustaining soil fertility under continuous intensive rice cultivation remains a major challenge in tropical Asia, where rice demand continues to increase and year-round cropping systems are expanding. Although triple rice cropping is practiced in several tropical regions, long-term empirical evidence on the effects of decades of intensive cultivation and fertilization on soil properties remains limited. This knowledge gap constrains the development of nutrient management strategies that sustain high productivity while preventing soil degradation. The present study analyzes multi-decadal trends in soil fertility under varying nitrogen (N) fertilizer inputs in a tropical paddy field, using data from the world's longest-running long-term continuous cropping experiment (LTCCE) at the International Rice Research Institute (IRRI) in Los Baños, Philippines. Established in 1962, the LTCCE features triple rice cropping with contrasting N fertilizer treatments. Since 1999, four N treatments (N1–N4: 0, 155, 310, 465 kg N $ha^{-1}$ $year^{-1}$) have been maintained while phosphorus (110 kg $P_2O_5$ $ha^{-1}$ $year^{-1}$) and potassium (70 kg $K_2O$ $ha^{-1}$ $year^{-1}$) were applied uniformly across treatments. Aboveground residues were removed after each harvest. Soil samples were collected from 0–15 cm depth in 1985, 1995, 2005, 2015, and 2019 were analyzed for total carbon (TC), total nitrogen (TN), available nitrogen (AN), available phosphorus (AP), and exchangeable potassium (Ex-K).

TC and TN increased steadily across all treatments, including the unfertilized N1 plot, with higher values generally observed under greater N inputs. In contrast, AN and Ex-K declined over time in all treatments. AN was positively correlated with N input, whereas Ex-K was the highest in the unfertilized N1 plot and the lowest under high-N inputs. AP increased across all treatments until 2005, but subsequently plateaued or declined, particularly under the N4 treatment. The AP accumulation rate between 1985 and 2005 was greatest in N1.

The concurrent increases in TC and TN, even without N fertilization, suggest contributions from belowground biomass and biological N inputs through *Azolla* and N-fixing microbes under triple rice cropping. However, the decline in AN despite rising TN indicates a shift toward more recalcitrant organic matter and reduced N mineralization under intensified rice cultivation, consistent with previous findings (Cassman et al., 1995; Olk et al., 1996). Lower N inputs resulted in higher soil P and K accumulation, likely due to lower plant uptake and export in low-N treatments.

Overall, triple rice cropping can enhance stable soil organic carbon stocks even with residue removal, but it concurrently reduces soil N supply capacity, increasing dependence on external N inputs. The observed imbalance between N, P, and K dynamics highlights the need for site-specific nutrient management guided by regular soil testing and strategies to optimize nutrient cycling in intensifying tropical rice systems.

## ABSTRACT

In Malaysia, paddy is the second largest agricultural land-use after oil palm which covers 647,936 hectares, with most of the soils are acidic. Malaysian paddy farmers rely heavily on government-subsidized program of using ground magnesium limestone (GML) at a rate of 3 tons per hectare for every 3 years. This standard practice of liming, without accounting for the varying acidity levels of different fields, does not address specific soil needs and is therefore unsustainable environmentally. Furthermore, overreliance on GML, a finite resource, raises concerns about long-term availability and unnecessary greenhouse gas emission. Understanding the efficacy of liming materials in increasing the pH of different soil types is essential to address timely pH adjustment for crop requirement. This study evaluates the effects of fine (2 µm) liquid lime (CaCO3) versus l00-mesh (149 µm) GML (CaMg(CO3)2) on soil pH, exchangeable acidity, cation availability, and $CO_2$ emissions, providing insights into their efficiency and environmental impact. Soil samples were collected from major paddy granary areas across Peninsular Malaysia, including Perak, Pahang, and Kedah. These samples were air-dried and sieved through a 2 mm mesh. The soils were incubated at field capacity with equivalent carbonate doses and sampled for pH (1:2.5), $CO_2$ emission and exchangeable acidity at different intervals for 372 days. Meanwhile, exchangeable cations $Ca^{2+}$ and $Mg^{2+}$ in the incubated soils were also sampled. Results show that liquid lime, characterized by its finer particle size compared to GML, exhibited a more rapid reaction in all soil types. Liquid lime achieved a higher increase in soil pH in the early stages of treatment, which stabilized at a plateau throughout the incubation period without any crossover between treatment profiles. In addition, liquid lime markedly reduced both hydrogen ($H^+$) and aluminum ($Al3^+$) exchangeable acidity at a faster rate than GML. After three months, the reduction in $H^+$ concentration in GML-treated soil was similar to that of liquid lime. Furthermore, soils treated with liquid lime demonstrated higher available calcium ($Ca2^+$) levels, an important indicator that the finer particle size contributes to a larger reactive surface area, which subsequently improves the release rate of $Ca2^+$. On the environmental side, although liquid lime was more efficient in acid neutralization, GML treatments consistently produced higher $CO_2$ emissions. In conclusion, liquid lime demonstrated greater efficiency, achieving a rapid pH increase and acidity reduction in the early stages of incubation, making it particularly suitable for urgent soil remediation.

## ABSTRACT

**Introduction:** Paddy rice is a staple food for > 50% of global population, while paddy soils are substantial (> 10%) sources of methane ($CH_4$) emitted anthropogenically. Water saving irrigation is expected to reduce $CH_4$ emission, but water drainage promotes aerobic decomposition and increases risk of soil degradation. Alternative wet dry irrigation management can reduce ca. 55% of methane emission (Minamikawa et al., 2025), while water saving irrigation and dry direct-seeded rice (DDSR) are assumed to decrease $CH_4$ emission by ca. 80%, with increasing emission risks of nitrous oxide ($N_2O$) and carbon dioxide ($CO_2$) from aerobic decomposition of soil organic matter. However, overall impacts of water management on greenhouse gas emission are variable between soil types and climates. Especially, water management practices could affect root exudation of organic acids, the potential substrates for methanogenesis. We tested whether DDSR and water saving irrigation change greenhouse gas emission, root exudation, and soil microbial composition, compared to continuous flooding.

**Materials & Methods:** We compared three water management practices [continuous flooding (CF), water saving irrigation (WS), and dry cultivation (DC)] of the paddy rice systems in Tottori, Fukushima, and Akita prefectures in Japan. The fluxes of greenhouse gas emission ($CO_2$, $N_2O$, and $CH_4$) were periodically measured using the closed chamber method in each plot. Greenhouse gas emission trade-off between $N_2O$ and $CH_4$ were assessed using global warming potential values relative to $CO_2$ [27 ($CH_4$) and 273 ($N_2O$); IPCC]. Mature rice roots were rinsed with distilled water to remove soils and grown in hydroponic systems to collect root exudates. Root surface areas were measured with WinRhizo. Organic acids in root exudates were measured by high performance liquid chromatography. Soil pH, bulk density, soil C and N concentrations, microbial biomass C and N were measured. Prokaryote (bacteria and archaea) and fungal community diversities in soils were assessed. Prokaryote rRNA 16S (V4 region) gene was amplified and fungal rRNA Internal Transcribed Spacer 1 (ITS1) gene was amplified with PCR to compare microbial diversity and relative abundance of methanogenic archaea.

**Results & Discussion:** Soil pH was lower in the DC plot, compared to CF and WS plots. Soil bulk density decreased by dry cultivation without puddling. The $CH_4$ emission fluxes follows the order: CF > WS > DC, while the higher fluxes of $N_2O$ emission were observed in the WS and DC plots, compared to CF plots. However, overall impacts on global warming potentials were still smaller in the DC and WS plots, compared to the CF plot, suggesting a decrease in global warming potentials by water saving irrigation and dry cultivation. Major organic acids released from roots were acetate, followed by malate and citrate. Root exudation rates of acetate, the substrates for methanogenesis, were greater in the CF plot than in the DC and WS plots. The fungal diversity was lower in the CF plot than in the DC and WS plots. The relative abundance of methanogenic archaea was also higher in the rice root of the CF plot, compared to the DC and WS plots. The relative abundance of methanogenic archaea was also higher in the rice root of the CF plot, compared to the DC and WS plots. Despite there being tradeoff between reducing greenhouse gas emission and increasing rice yields, increasing management options for farmers can provide opportunity to get C credit without increasing labor costs at the expense of crop yield.

## ABSTRACT

The application of nanotechnology in agriculture offers a promising strategy for achieving sustainable intensification, yet the efficacy and mechanisms of nano-fertilizers like iron oxide nanoparticles (FeONPs) across varied soil environments remain inadequately explored. This study investigated the dual effects of FeONPs on rice productivity and greenhouse gas (GHG) emissions in three major paddy soils of China: black soil, red soil, and hydragric anthrosol. A two-year pot experiment was conducted with two FeONPs application rates (10 mg·kg$^{-1}$, T1; 100 mg·kg$^{-1}$, T2) applied as basal fertilizer, compared to a traditional fertilization control.

Regarding yield and plant physiology, FeONPs demonstrated significant benefits. The T1 rate (10 mg·kg$^{-1}$) was identified as optimal for yield enhancement. It significantly increased grain yield by up to 61.69% and 74.85% in hydragric anthrosol over two years, and showed a consistent increasing trend (34.93-46.43%) in red soil. This yield improvement was attributed to enhanced photosynthetic performance from the booting to mid-grain-filling stages. Consequently, key yield components such as spikelet number per panicle, seed-setting rate (increased by up to 53.03%), and 1000-grain weight (increased by up to 8.92%) were synergistically elevated.

FeONPs exhibited a strong capacity for mitigating methane ($CH_4$) emissions. The higher application rate (T2, 100 mg·kg$^{-1}$) was more effective, achieving $CH_4$ emission reductions ranging from 24.39% to 60.92% across soils. This suppression was mechanistically linked to an increased abundance of methanotrophic bacteria and a concurrent decrease in dissolved organic carbon availability. Furthermore, FeONPs application, particularly T2, increased soil organic carbon content by up to 4.96%, indicating a potential for soil carbon sequestration.

The impact on nitrous oxide ($N_2O$) emissions was soil- and rate-dependent. While the lower rate (T1) had minor or variable effects, the higher rate (T2) consistently and substantially reduced $N_2O$ emissions by 43.81% to 59.85% in black soil and hydragric anthrosol. The underlying mechanisms were soil-specific. In acidic red soil, FeONPs likely modulated the ammonia oxidation process by influencing ammonia-oxidizing archaea (AOA). In alkaline soils (black soil and hydragric anthrosol), the reduction was associated with the inhibition of ammonia-oxidizing bacteria (AOB) and the promotion of complete denitrification.

In conclusion, FeONPs present a viable nano-enabled strategy for synergistically enhancing rice production and reducing GHG emissions, primarily $CH_4$ and $N_2O$. The effects are mediated through the improvement of plant physiological processes and the regulation of key soil microbial communities involved in carbon and nitrogen cycling. For optimal outcomes, application rates should be tailored to specific goals: the 10 mg·kg$^{-1}$ rate is recommended for maximizing yield, whereas the 100 mg·kg$^{-1}$ rate is more effective for GHG mitigation. This study provides critical insights for the precise and soil-specific application of FeONPs to support climate-smart rice cultivation.

## ABSTRACT

Rice (*Oryza sativa* L.) cultivation is a major source of methane ($CH_4$) emissions, requiring effective mitigation strategies. Pot-grown seedlings (pot seedlings) may reduce $CH_4$ emissions by enhancing early root establishment and oxidation activity at the initial stage of rice growing, thereby increasing $CH_4$ oxidation; however, it remains unclear. A field experiment was conducted to evaluate the effect of seedling tray type on mitigating $CH_4$ emission during rice cultivation. An early-maturing (*Jomyeong 1*) and late maturing cultivar (*Shindongjin*) were selected, and both bed seedlings (conventional seedlings as control) and pot seedlings were prepared. $CH_4$ emissions were monitored during the seed bed preparation stage and the whole rice cultivation period using the closed chamber method. In addition, rice growth characteristics, grain yield, and yield-scaled $CH_4$ emissions were investigated during the cultivation period. Furthermore, an incubation experiment was conducted to determine $CH_4$ oxidation potentials in soils and roots at major rice growth stages. Our results showed $CH_4$ emissions were negligible during the seedling tray stage for both conventional seedlings and pot seedlings. During the whole rice cultivation, pot seedling treatments effectively decreased $CH_4$ emissions by 36% and 9% (early and late maturing varieties, respectively) compared to the control, indicating effective reduction on $CH_4$ emissions. Regardless of cultivar, grain yield showed higher in the pot seedling treatments than in the controls, which might be associated with increased the number of grains per panicle and improved the ripening ratio. Yield-scaled $CH_4$ emissions were reduced under pot seedling treatments, showing reductions of 8-47% relative to the control, indicating a better sustainable option. Overall, biomass productivity at the initial stage of rice growing significantly increased by 78% and 40%, at the early-maturing and late maturing cultivar, respectively compared to the control, indicating better growth conditions. Our study revealed a negative correlation between the number of grains per panicle and $CH_4$ emissions, suggesting that greater carbon allocation to grain formation may reduce substrate availability for methanogenesis, thereby lowering $CH_4$ emissions. In the incubations, root oxidation potential was higher than the control. Overall, transplanting pot seedlings promoted early root growth in rice, which likely enhanced root activity and increased $CH_4$ oxidation potential, thereby reducing overall $CH_4$ emissions. Therefore, pot seedling transplanting could be a promising strategy for mitigating $CH_4$ emissions while maintaining grain productivity in rice cultivation.

# Transplanting Date Potentially Modulates Post-Season Methane Emissions via Residual Root Carbon Inputs in a Mono-Rice Paddy Field

**Yeomyeong Lee[1], Sohee Yoon[1], Jasmin Melendez[1] and Sang Yoon Kim[1,2*]**

[1] *Department of Agricultural Chemistry & Interdisciplinary Program in IT-Bio Convergence System, Sunchon National University, Suncheon 57922, Republic of Korea*

[2] *Department of Agricultural Life Sciences, Sunchon National University, Suncheon 57922, Republic of Korea*

*sykim@scnu.ac.kr (corresponding)

**ABSTRACT**

Adjucting rice transplanting date is one of the main factors substantially influencing rice growth and biomass prodction by altering meteorological conditions and flooding duration, thereby significantly affecting methane ($CH_4$) emissions in rice paddy ecosystems. Residual root biomass can serve as a potential carbon (C) source for anaerobic decomposition in flooded paddy soils and may stimulate $CH_4$ emissions in the post rice cropping periods. However, the effects of shifting transplanting dates on the quantity and quality of root biomass, and the consequences for $CH_4$ emissions during the following season, remain unclear. A field study was carried out over the three years (2022–2024), in which two rice cultivars (late and early maturing) were transplanted on four dates: May 10 (Time1), May 25 (Time2, locally recommended date), June 9 (Time3), and June 24 (Time4). $CH_4$ emissions, rice growth and psysiological characteristics were monitored throughout the rice cropping seasons. At harvest, root biomass was quantified and its chemical characteristics, including C, N content, and C/N ratio were analyed to evaluate their potential contributions to $CH_4$ emissions in the subsequent rice cultivation season. Regardless of cultivar, cumulative $CH_4$ emissions peaked at Time1, and significantly decreased by 24–87% with delaying transplanting dates in rice cropping season over the earliest date as decreased flooding duration during rice cultivation and rice growth that minimize plant-mediated $CH_4$ transport. Interestingly, mean daily $CH_4$ fluxes were also decreased significantly with delaed transplanting, consistent with the observed reductions in cumulative $CH_4$ emissions despite a shorter flooding duration. These results imply a potential shift in methanogenic activity and intensity, which may be associated with altered soil C availability influenced by residual root-derived C in paddy soils. Regardless of cultivar and investigation year, root biomass at harvest significantly decreased with delayed transplanting, accompanied by changes in C and N composition. Notably, the potential C input from residual roots showed a strong positive correlation with $CH_4$ emissions during the following season, indicating that residual root-derived C in soils could be potential methanogenic substrates, which substantially influence post-season methanogenesis and stimulate $CH_4$ emissions. Our findings suggest the quantity and quality of residual root biomass remaining after harvest should be newly considered one of the key parameters, potentially influencing $CH_4$ emissions during the following cropping seasons in a mono-rice paddy system.

# Feeding the world while mitigating climate change: a global meta-synthesis of agronomic pathways for low-emission rice

**Jean-Martial Johnson[1*] and Kazuki Saito[1]**

[1] *International Rice Research Institute (IRRI), DAPO Box 7777, Metro Manila 1301, Philippines*

*j.johnson@cgiar.org

**ABSTRACT**

Rice sustains half the global population, yet its cultivation is a major source of greenhouse gas (GHG) emissions. Meeting rising demand calls for agronomic interventions that increase yields while curbing GHG emissions. Here, for the first time, we conducted a meta-synthesis of 91 meta-analyses to quantify the effects of 54 rice agronomic interventions, grouped into 14 categories, on yield, $CH_4$ and $N_2O$ emissions, global warming potential (GWP), and GHG emission intensity (GHGI). Biochar consistently delivered co-benefits, increasing yield by 12%, and reducing $CH_4$, $N_2O$, and GHGI by 15-18%. In contrast, residue incorporation and organic amendment raised yields (5% and 19%), but sharply increased CH4 emissions (144% and 76%) and GWP (96% and 65%). No-till or reduced tillage lowered GWP by 15% without a yield penalty. Water-saving technologies cut $CH_4$ emissions by 50% and GHGI by 39%, with a slight yield decline (-3%). Within this category, intermittent irrigation offered the best balance, while non-flooded systems achieved greater emission reductions but incurred larger yield losses (-9%). Inorganic nitrogen fertilizer increased yields by 31% but raised $N_2O$ emissions by 130%. Innovations, including deep placement and enhanced-efficiency fertilizers, reduced $N_2O$ emissions by up to 38% and improved yields by 6%–19%. Symbiotic systems (e.g., rice–duck) reduced $CH_4$, though effects on $N_2O$ were variable. While several agronomic interventions show promise, evidence remains limited for others (e.g., liming, crop establishment, weed management). Assessment of integrated approaches is needed to elucidate synergies and trade-offs, enabling the design of scalable, sustainable rice systems tailored to diverse contexts.

*miguine324@naver.com

**ABSTRACT**

Incorporation of organic amendments, such as rice straw, has been recommended to enhance soil organic carbon (C) sequestration and maintain soil quality in rice paddies. However, rice straw is largely removed from fields for uses such as animal feed, reducing organic C inputs to rice cropping systems. Therefore, alternative organic input sources are required. In this study, the ratoon of rice (newly emerged shoot and root biomass as green biomass), and without ratoon rice as the control where investigated at three sampling locations after rice were harvested in the field (n=168). The chemical properties of the ratoon biomass such as total and dissolved C, nitrogen, moisture content, and the characteristic of decomposition rate were determined by an incubation experiment after ratoon rice were added in paddy soils. Moreover, soil properties such as soil moisture, pH, available nutrients etc. sampled from the fields were investigated to estimate growth-regulating factors for new ratoon biomass. Our results revealed that newly-grown rice ratoon biomass could have a strong potential for enhancing soil organic C in rice paddies. Moreover, C input was significantly increased mainly due to increased shoot biomass input, indicating the promising potential for enhancing soil C. Chemical properties of the newly grown-ratoon biomass were differed at the different sampling locations. The green biomass significantly increased overall soil C accumulations, which assumed approximately 2.3 to 5.8 Mg d.w $ha^{-1}$ (334 kg C $ha^{-1}$ $yr^{-1}$). To identify the key factors triggering rice ratoon growth, soil moisture content was one of the main parameters in this study, showing strong positive correlation ($r=0.412$, $p<0.001$). Conclusively, the newly-grown ratooon biomass could be a potential carbon source in rice paddy ecosystem. However, rational cultivation management strategies should be developed rational soil water and fertilization regimes to maximize soil C sequestration potential by enhancing rice ratoon biomass in paddy ecosystems.

**ABSTRACT**

Continuous flooding (CF) in Malaysian rice paddies under anaerobic soil conditions results in elevated methane ($CH_4$) emissions. Alternate wetting and drying (AWD) and mid-season drainage (MD) introduce periodic soil aeration, which can restructure soil microbial communities and modify methane ($CH_4$) fluxes. A tank experiment using Briah series *(Fine, mixed, isohyperthermic, Typic Endoaquepts)* soil planted with the MR297 rice variety was conducted to compare CF, AWD, and MD treatments arranged in a randomized complete block design. Methane fluxes were measured weekly using non-flow-through static chambers and gas chromatography, and interpolated weekly mean fluxes were used to estimate cumulative seasonal $CH_4$ emissions. Soil samples from the 0–15 cm layer were collected at 58 and 96 days after transplanting for 16S rRNA amplicon sequencing, and microbial community structure was assessed using Bray–Curtis principal coordinates analysis (PCoA), heatmaps of the 50 most abundant genera, and LEfSe biomarker analysis in MicrobiomeAnalyst. Seasonal cumulative methane emissions were 70.24, 30.75, and 15.93 g $CH_4$ $m^{-2}$ under CF, AWD, and MD, respectively, corresponding to methane reductions of 56.21% under AWD and 77.32% under MD relative to CF. Plant height, leaf area, and grain yield did not differ significantly among irrigation treatments, indicating that AWD and MD imposed no yield penalty. PCoA revealed significant separation of microbial communities among treatments at both 58 and 96 days after transplanting (ANOSIM, $P = 0.001$), with CF communities clearly distinct from AWD and MD at 58 days, and AWD showing the most significant divergence at 96 days. Soils under CF were enriched in hydrogenotrophic methanogens, particularly Methanocella (Rice Cluster I) and Methanobacterium (Euryarchaeota), which coincided with higher methane emissions. In contrast, AWD and MD soils exhibited higher relative abundances of methanotrophic taxa such as Methylocystis (Alphaproteobacteria) and Pseudomonas (Gammaproteobacteria), consistent with enhanced methane oxidation and lower net $CH_4$ emissions. Alternate wetting and drying and mid-season drainage substantially reduced methane emissions from Malaysian paddy soil by approximately 77%, while maintaining rice physiological performance and yield. These mitigation effects are closely linked to a functional shift from methanogen-dominated microbial communities under continuous flooding to methanotroph-enriched assemblages under alternate irrigation regimes. Overall, the findings demonstrate that water management practices that steer soil microbial abundance and diversity provide a viable strategy for reducing paddy methane emissions without compromising productivity.

## ABSTRACT

Application of organic matter is increasingly important for soil amendment or resource circulation, while the supply of organic substrates such as cow manure and rice straw residue risks increasing the emission of methane ($CH_4$) and carbon dioxide ($CO_2$) from paddy soils. Despite the potential risk, organic matter application to the paddy fields has the potential to increase soil carbon stocks under flooding conditions. This C input is hypothesized to be greater than C output in Andisols because of their high capacity to store organic matter. To test this, we measured microbial organic matter decomposition rates and calculated soil C budgets in an Andisol paddy soil under different fertilizer and manure management.

We compared three treatments (manure, chemical fertilizer, and no fertilizer application) in Andisol paddy fields at Experimental Farm of Utsunomiya University. Manure application has continued over 44 years. Soil C concentrations after 44 years application were determined by NC analyzer. Gas fluxes and drainage were measured as C output from paddy soils, while rice straw residue, manure, weed biomass were measured as C input to calculate soil C budgets. Gas samples were periodically collected using the closed chamber method to determine $CH_4$ and $CO_2$ fluxes in each plot. The loss of dissolved C through drainage was estimated by measuring the concentrations of dissolved organic/inorganic carbon (DOC/DIC) in the soil solutions.

Soil C concentrations were significantly higher in manure plot (ca. 9.5 %), compared to chemical fertilizer and no-fertilizer plots (ca. 8.4 – 8.9 %), probably due to the highest C inputs (4.0 Mg C $ha^{-1}$). The $CH_4$ fluxes increased with decreasing soil Eh after flooding, while $CO_2$ fluxes displayed the opposite pattern. There was no significant difference in $CH_4$ fluxes between manure and chemical fertilizer plots, while $CO_2$ fluxes were slightly higher in manure plot. This is supported by significantly higher microbial activities of cellulose decomposition and higher microbial biomass. We found that ca. 80 % of annual C output (3.6 to 4.5 Mg C $ha^{-1}$) was derived from $CO_2$ emission during the season after drainage and fall plowing in all plots. Organic matter application increased DOC/DIC concentrations in soil solutions, but DOC/DIC fluxes were even smaller than gas fluxes. Incorporation of fresh rice straw residues by fall plowing activated $CO_2$ emission after drainage, and the annual C outputs were roughly equal to C inputs even in manure plot. This suggests that application of organic matter could maintain soil C storage, but organic matter amendment for long term also increases microbial biomass and decomposition activity, especially in the season after drainage. Our findings highlight the importance of decreasing $CO_2$ emission after drainage to increase soil C storage by manure application in the Andisol paddy fields, while decreasing $CH_4$ emission after flooding also contributes to mitigate global warming.

## ABSTRACT

Rice production in the Lao People's Democratic Republic is fundamental to national food security, but many aspects of its productivity and environmental impacts (such as $CH_4$, $N_2O$, NO, $NH_3$ emissions) are under-explored because systematic monitoring and comprehensive datasets are scarce. To address this, we developed a novel spatially explicit and cost-effective rice crop modelling framework by coupling the Decision Support System for Agro-technology Transfer (DSSAT) model with a particle swarm optimization (PSO) algorithm for data gap-filling to simulate rice growth and associated environmental impacts across Laos, from 2012 to 2022. Utilizing available statistical yield records for model calibration, we quantified rice yields, gas emissions and nitrogen loss pathways under contrasting water regimes in wet-season rain-fed rice systems. At the province level in Laos, fertilizer response curves show that high fertilizer prices relative to rice prices depress the economic optimum N application rate. A national guidance band of 25~30 kg N/ha with province-specific adjustments (reductions in 13 provinces and modest increases in a few) can increase farmers' profits while sustaining high nitrogen use efficiency (NUE). Our findings highlight Laos' potential advantages in advancing green rice production while underscoring the seasonal trade-offs in resource use efficiency and environmental outcomes. The proposed PSO-DSSAT framework offers a transferable tool for supporting sustainable rice management in regions with limited data coverage.

# Pedogenesis Shapes the Basis of Sustainability of Paddy Soils

**Ganlin Zhang***

*State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China*

*E-mail: glzhang@issas.ac.cn

**ABSTRACT**

Paddy soils are widely distributed in the world especially in East and Southeast Asia, Africa and Latin America, feeding more than a half of global population which means have contributed substantially to global food security. The sustainable use of this precious soil resource is extremely important for the generations to come. Though regular rice soil management practices including irrigation, plowing and fertilization affect fundamentally rice productivity, the assessment of the sustainability of rice soils is often neglected.

Through extensive studies in various paddy soils regions of China, we find that long term soil changes, i.e., soil changes through pedogenetic processes are dramatic and have fundamental impacts on soil health conditions, in terms of their changes in soil components and nutrient-binding capacity as well as their resilience in respond to possible artificial management. Clay loss, iron transformation and translocation, lowering of cation exchange capacity all indicate a potential yet invisible degradation, while generating secondary nutrient dissipation to environment and causing neighboring water quality changes.

It is an obvious task to examine long term changes of soil quality through the perspective of soil genesis of paddy soils for a sound soil health assessment.

# Methane production potentials and methanogenic communities in winter-flooded rice paddy soils

**SUN Zhijie, HUANG Jing, MO Yongliang***

*College ofEnvironmental Science and Engineering, China West Normal University, Nanchong 637000, China*
*E-mail: mo@cwnu.edu.cn

**ABSTRACT**

Winter-flooded rice paddies are important methane emission sources. As the second most prominent greenhouse gas after carbon dioxide, methane exerts a significant impact on global warming. Therefore, investigating the methane production potential of winter-flooded rice paddy holds considerable scientific significance. Soil samples from the 0-l0 cm layer of winter-flooded rice paddy were collected during the rice tillering stage for anaerobic incubation. Methane concentrations were dynamically determined using gas chromatography (GC) to calculate methane production rates, while high-throughput sequencing were employed to determine the changes in microbial communities. The results indicated that winter-flooded rice paddy soils possessed significant methane production potentials. The methane production rates first increased and then decreased over time, with the maximum rate reaching 24.32 ng g_1 day_1. After 34 days of incubation, the relative abundance of methanogens in the soils showed a converging trend: the relative abundance of the methanogen genus *Methanobacterium* decreased, whereas that of *Methanosarcina* exhibited a substantial increase, suggesting that the latter may have played a crucial role in the methane production process. The decrease in methane production rate may reflect the substrate limitations as well as the methane consuming processes in oxygen restricted environments. Thus we further checked the changes in the communities of sulfate-reducing bacteria (SRB), aerobic methane-oxidizing bacteria (MOB), and anaerobic methane-oxidizing bacteria (ANME). SRB showed varying degrees of abundance increase. The relative abundance of Type I MOB significantly increased overall but decreased in some cases, while Type II MOB exhibited a distinct decreasing trend. The relative abundance of ANME declined remarkably. These phenomena imply that these microbial groups may also be involved in methane metabolism, while the methane production process exerted a significant inhibitory effect on most aerobic MOB, ANME, and other microorganisms. Furthermore, soil factors such as temperature, moisture content, pH, and texture exerted varying influences on methane emissions from winter-flooded rice paddy soils. In conclusion, winter-flooded rice paddy soils possess considerable methane production potential, and *Methanosarcina* is the key methanogen.

## ABSTRACT

Rice cultivation in subtropical Asia is a significant source of anthropogenic methane ($CH_4$) while offering potential for soil organic carbon (SOC) sequestration. This study investigated the interactive effects of water management and rice straw practices on greenhouse gas (GHG) emissions and SOC dynamics. Field experiments were conducted from 2024 to 2025 at the Ankang Experimental Farm, National Taiwan University (*Oryza sativa L.* cv. Taoyuan No. 6), employing a multi-channel automated chamber system for high-frequency, continuous monitoring of $CH_4$ and $N_2O$ fluxes. Six management scenarios were evaluated, combining two irrigation regimes conventional flooding (CF) and alternate wetting and drying (AWD) with three rice straw treatments including rice straw removal (-RS), incorporation (+RS), and rice straw cover (RS cover).The continuous monitoring revealed distinct temporal dynamics; straw input (+RS and RS cover) significantly increased $CH_4$ emissions by providing organic carbon substrates (DOC), with temporal shifts in emission intensity between the early and late rice seasons. In contrast, $N_2O$ emissions peaked sharply following fertilization and drainage events, with the RS cover treatment under AWD exhibiting the highest fluxes (21.90 g/ha/day in 2024), indicating complex carbon nitrogen coupling process. Water management proved essential for mitigation; except during periods of extreme rainfall, AWD consistently reduced $CH_4$ emission factors, achieving a 53% reduction in the 2025 season (1.70 kg/ha/day under AWD+RS vs. 3.62 kg/ha/day under CF+RS). Notably, the AWD+RS cover strategy achieved the lowest Greenhouse Gas Intensity (GHGI) of 0.69 t-$CO_2$eq/t grain in 2025, indicating its superior efficiency in minimizing the climate footprint per unit of yield. However, a divergence was observed in long-term carbon sequestration potential; linear regression of SOC stocks (2024–2025) confirmed that AWD+RS successfully promoted significant carbon storage ($y = 3.7x + 57$, $R^2 = 0.43$), whereas AWD+RS cover exhibited no significant temporal trend ($y = -0.42x + 71$, $R^2 = 0.004$). These findings demonstrate that while AWD+RS cover is optimal for immediate emission intensity reduction, AWD+RS incorporation provides a more robust pathway for long - term soil carbon buildup; thus, integrating AWD with optimized rice straw management offers a synergistic solution to balance productivity and soil health while effectively mitigating the climate footprint of subtropical rice cultivation

# Mechanisms of Rice Root Iron Plaque-Induced Greenhouse Gas Emissions in Paddy Soils

**Jinzhi Yao**[1*]

[1] *Key Laboratory of Agricultural Water Resources, Center for Agricultural Resources Research, Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Shijiazhuang, China)*

* jzyao@sjziam.ac.cn

**ABSTRACT**

Rice root iron (Fe) plaque, a ubiquitous mineral coating at the root-soil interface, plays a critical but complex role in regulating greenhouse gas (GHG) emissions from paddy soils. This study integrates findings from multi-scale experiments to elucidate the coupling mechanisms between Fe plaque and the turnover of carbon (C) and nitrogen (N), specifically driving carbon dioxide ($CO_2$), methane ($CH_4$), and nitrous oxide ($N_2O$) emissions. First, regarding $CO_2$, we hypothesized that Fe plaque induces hydroxyl radical (OH) generation, which disrupts the organic carbon protection mechanism. Our results demonstrated that Fe plaque significantly increased OH concentrations via Fenton reactions. This oxidative burst degraded phenolic compounds, thereby disrupting the "enzyme latch" mechanism and accelerating soil organic carbon (SOC) mineralization and $CO_2$ emissions. Second, regarding $CH_4$, we investigated the role of semi-conductive minerals. We found that crystalline Fe oxides (specifically hematite) within the plaque facilitate extracellular electron transfer (EET) between methanogenic archaea (e.g., Methanosarcina) and their syntrophic bacterial partners (e.g., Geobacter). This mineral-mediated electron transfer significantly enhanced syntrophic methanogenesis, leading to elevated CH4 emissions in Fe plaque-rich soils. Third, regarding $N_2O$, we explored the coupling of Fe redox cycling and denitrification. Fe plaque acts as a hotspot for $N_2O$ emissions. Our evidence indicates that Fe(II) accumulated in the plaque serves as an electron donor for denitrification. The process of Fe(II) oxidation-coupled denitrification was identified as the primary driver for the increased N2O release. In conclusion, rice root Fe plaque is not merely a passive barrier but an active biogeochemical hotspot that simultaneously promotes $CO_2$, $CH_4$, and $N_2O$ emissions through distinct abiotic (Fenton reaction, semi-conduction) and biotic (syntrophy, denitrification) pathways. Regulating Fe plaque formation through soil management could be a potential strategy for mitigating combined GHG emissions from paddy agriculture.

## ABSTRACT

Paddy-upland rotation has become common in the world. Since field managements are fundamentally different between upland cropping and paddy rice cultivation, paddy-upland rotation must have impacted the soil biological properties, compared with the mono-cropping of paddy rice. However, it has not been investigated well how long-term paddy-upland rotation affects the dynamics and interrelationships of soil microbial communities in the soil. In the present study, we analyzed the dynamics of abundance and composition of bacterial and archaeal communities, mainly focusing on the microbes involved in the redox cycles of nitrogen, iron, sulfur, and carbon (methane), in an experimental field under two- or three-year cycle of paddy-upland rotation in Japan over the course of 11 years.

A long-term experimental field for paddy-upland rotation system in the northeast region of Japan was investigated in 2012–2022. A rotational system has been implemented in the field since 2000, in which rice and soybean have been cultivated every two or three years (rotational plot). As a comparison, a consecutive paddy field was examined in a field neighboring the rotational field (control plot). Bulk soil was taken at 5–10 cm depth before, during, and after rice or soybean cultivation period. The abundances of total bacteria, denitrifying bacteria, canonical ammonia-oxidizing bacteria, ammonia-oxidizing archaea, complete ammonia oxidizing (comammox) bacteria, *Geobacteraceae* (iron reducers), *Anaeromyxobacteraceae* (iron reducers), *Gallionellaceae* (iron oxidizers), sulfate-reducing bacteria, sulfur-oxidizing bacteria, methanogenic archaea, and methane-oxidizing bacteria were quantified by real-time PCR. The composition of bacterial community was analyzed by amplicon sequencing analysis of bacterial 16S rRNA genes.

Quantitative PCR analysis showed distinct fluctuations specific to the respective microbial groups between the paddy-upland rotation. In particular, the abundance of *Geobacteraceae* and *Gallionellaceae* drastically decreased after conversion from paddy rice to upland cropping, but their abundances recovered after re-conversion from upland to paddy rice cropping within a year. The amplicon sequencing analysis of bacterial 16S rRNA genes in the field revealed that community composition in the rotational plots was phylogenetically distant from that in the control plots, but the composition was periodically fluctuated between the years of paddy rice cultivation and upland cropping in the rotational plots. The present study showed that bacterial and archaeal communities have changed their community structures according to the periodic fluctuation of oxic and anoxic soil conditions associated with the paddy-upland rotation by adapting their metabolic activities to the soil conditions depending on their physiological features.

# Domesticated rice alters the rhizosphere microbiome, reducing nitrogen fixation and increasing nitrous oxide emissions

**Jingjing Chang[1*,2], Chunjie Tian[1], Jos M. Raaijmakers[2], and Eiko E. Kuramae[2]**

*[1] State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, 130102, China;*

*E-mail Address of Presenting Author: changjingjing@iga.ac.cn

**ABSTRACT**

Crop domestication has boosted global food security but intensified agricultural reliance on chemical inputs, creating environmental trade-offs in soil ecosystems. Rhizosphere microbiomes drive soil nitrogen (N) cycling, a process central to both crop productivity and greenhouse gas emissions, yet how domestication reshapes these microbial functions remains understudied. Shotgun metagenomics and real-time PCR reveal a higher abundance of N-fixing genes in the wild rice rhizosphere microbiomes. Validation through transplanting rhizosphere microbiome suspensions shows the highest nitrogenase activity in soils with wild rice suspensions, regardless of planted rice type. Domesticated rice, however, exhibits an increased number of genes associated with nitrous oxide ($N_2O$) production. Measurements of $N_2O$ emissions in soils with wild and domesticated rice are significantly higher in soil with domesticated rice compared to wild rice. Comparative root metabolomics between wild and domesticated rice further show that wild rice root exudates positively correlate with the frequency and abundance of microbial N-fixing genes, as indicated by metagenomic and qPCR, respectively. To confirm, we add wild and domesticated rice root metabolites to black soil, and qPCR shows that wild rice exudates maximize microbial N-fixing gene abundances and nitrogenase activity. Preliminary genetic evidence (from QTL mapping) further suggests a host genetic control governing the recruitment of these beneficial microbes, providing a scientific foundation for future breeding strategies aimed at reshaping the rhizosphere microbiome for more sustainable crop production.

# Denitrifier community responses to irrigation and straw management in subtropical paddy soils

**Pei-Ju Lu[1]* and Yo-Jin Shiau[1]**

[1] *Department of Bioenvironmental Systems Engineering, National Taiwan University, Taipei, R.O.C.*

*E-mail Addr ess of Presenting Author: r11622021@ntu.edu.tw

**ABSTRACT**

Rice paddies are important sources of greenhouse gases (GHGs), particularly methane ($CH_4$) and nitrous oxide ($N_2O$). While $CH_4$ emissions dominate under anaerobic conditions, mid-season drainage or intermittent irrigation can enhance $N_2O$ production through intensified nitrification–denitrification cycles. This study investigated the interactive effects of irrigation regime and straw incorporation on $N_2O$ emissions and denitrifying microbial communities in a subtropical paddy field located in Xindian District, northern Taiwan. Four management treatments were established: conventional irrigation (CI), CI with straw return (CI+S), alternate wetting and drying (AWD), and AWD with straw return (AWD+S).

About 0-10 cm of the surface soil samples were collected in triplicate from each practice plot during the sampling campaigns conducted between August and October 2023, before and after the basal, topdressing, and panicle fertilizer applications. Quantitative PCR (qPCR) and functional-gene amplicon sequencing were employed to determine the abundance and composition of denitrifiers (*nirS*, *nosZ-I*) of the colleceted soil samples. In addition, soil physicochemical properties were also analyzed and compared to the dominant denitrifying communities to evaluated their environmental niches with the farming practices.

Results showed that *Bradyrhizobium* was the dominant *nirS* type denitrifier across all treatments. Short-term straw incorporation increased soil labile organic carbon ($S_bOC$) but had limited influence on *nirS* type communities. In contrast, AWD significantly altered denitrifier composition and led to higher $N_2O$ emissions. Furthermore, qPCR results indicated that *nosZ-I* abundance was positively correlated with $S_bOC$, suggesting enhanced $N_2O$ reduction potential under carbon enriched conditions.

Overall, irrigation regime exerted a stronger control than straw return on both denitrifier community structure and $N_2O$ fluxes. These findings emphasize the importance of integrating microbial perspectives into sustainable paddy management strategies that balance $CH_4$ mitigation and $N_2O$ regulation.

## ABSTRACT

Sulfur is one of the main components of important biomolecules, playing a critical role in fundamental biological processes in both plants and microbes. In paddy soils, the dynamics of the sulfur cycle are predominantly governed by microbial activities, which are particularly intense and complex within the anaerobic environment of the rice rhizosphere. Our investigation reveals that the rhizosphere microbiome associated with wild rice (*Oryza barthii*, *O. rufipogon*, *O. nivara*) exhibits a superior capacity for sulfur nutrient mobilization compared to cultivated rice (*O. glaberrima*, *O. sativa*). Metagenomic and metabolomic analyses indicate that the wild rice rhizosphere supports a more diverse and functionally microbial community, characterized by an enriched repertoire of genes involved in key sulfur transformation pathways, such as sulfate reduction, sulfur oxidation, and organic sulfur compound metabolism. This enhanced genetic potential translates into a more dynamic and efficient sulfur cycle, ensuring improved availability of sulfur in soil for plant uptake. Furthermore, interactions between wild rice and the microbial community appear to be more robust and active, showing a positive and tightly coupled plant-microbe feedback relationship. Thus, the wild rice system demonstrates a more favorable and complex level of ecological integration for sulfur acquisition. This study aims to elucidate the underlying microbial mechanisms that confer this superior sulfur utilization in wild rice rhizosphere. By identifying key microbial taxa and defining the specific metabolic networks of wild rice rhizosphere, we seek to develop novel strategies for manipulating the rhizosphere microbiome of cultivated rice. The ultimate objective is to enhance the transformation and utilization efficiency of soil sulfur nutrients in agroecosystems, thereby reducing dependency on synthetic fertilizers and promoting sustainable rice cultivation practices.

## ABSTRACT

Methane ($CH_4$) is a potent greenhouse gas, and rice paddies are its main source of agricultural emissions. The methanotrophs in paddy soil serve as crucial "biofilters" for mitigating $CH_4$ emissions. While rare earth elements (REEs) are traditionally considered non-essential for living organisms, recent studies reveal that due to their similar ionic radius to calcium ions ($Ca^{2+}$) and stronger Lewis acidity, REEs can substitute $Ca^{2+}$ and serve as superior cofactors in methylotrophic and methane-oxidation pathways, thereby modifying conventional carbon metabolism. Nevertheless, how soil REE backgrounds influence $CH_4$ oxidation and shape methanotrophic communities in paddy fields remains poorly understood. This knowledge gap limits the development of REE-based strategies for mitigating agricultural $CH_4$ emissions.

To address this, we collected paddy soils with gradient REE background values spanning different climate zones, including mid-temperate, warm-temperate, and subtropical/tropical for microcosm incubation. Results show that increased REE background values enhance the $CH_4$ oxidation potential and the abundance of the *pmoA* gene, with a significant positive correlation observed between $CH_4$ oxidation potential and REE. In REE-differentiated paddy ecosystems, *Methylobacter* (Type I methanotrophs) dominates in temperate and increases significantly in high-background soils, whereas *Methylocystis* (Type II) represents the most abundant methanotrophs in warm temperate and subtropical/tropical. Variations in $CH_4$ oxidation functional genes are primarily and significantly influenced by mean annual temperature (19.79%) and total REE (11.11%). Active microorganisms involved in $CH_4$ oxidation process were successfully identified through $^{13}CH_4$-DNA-based stable isotope probing (SIP). Metagenomic analysis revealed that *Methylobacter*, *Methylosarcina*, and *Methylotuvimitrobium* are key active taxa, with *Methylotuvimitrobium* being specifically enriched in $^{13}C$-DNA fraction. At the functional gene level, the abundance of genes encoding particulate methane monooxygenase (*pmoA*), the REE-dependent methanol dehydrogenase (*xoxF*), and genes involved in formaldehyde assimilation (*fae*) were significantly higher in soils with high REE background values. Metagenomic binning of $^{13}C$-DNA yielded 122 high-quality metagenome-assembled genomes (MAGs), four of which were identified as methanotroph-related MAGs (including *Methylobacter*, *Methylomonas*, and *Methylocystis*). Comparative analysis of metabolic pathways revealed significant differences in methane oxidation, formaldehyde dehydrogenation, and carbon assimilation pathways between methanotrophs inhabiting high and low REE background soils.

These findings not only deepen our understanding of the role of metallic elements in the global carbon cycle but also provide important theoretical support for developing REE-based strategies to achieve $CH_4$ mitigation in rice paddy production.

# Isolation, characterization and identification of culturable methane-oxidizing bacteria inhabiting paddy field ecosystem

**Susumu Asakawa*, Fumika Oe, Rina Shinjo, Takeshi Watanabe**

*Graduate School of Bioagricultural Sciences, Nagoya University, Nagoya, Japan*

*asakawa@agr.nagoya-u.ac.jp

**ABSTRACT**

Methane is a greenhouse gas and paddy fields are an important source of methane emission. Aerobic methane-oxidizing bacteria (MOB) inhabiting oxic microsites in the paddy field ecosystem play crucial roles in mitigating methane emission from paddy fields. Thus, it is important to reveal ecology of MOB in the ecosystem for prediction and control of methane emission from paddy fields. Communities of MOB in the ecosystem have been investigated well by analyzing genes specific for MOB. However, phenotypic and genotypic characterization of culturable MOB inhabiting the ecosystem mostly remains to be elucidated, which will provide useful information for understanding the ecophysiology of MOB in the ecosystem. In the present study, several strains of MOB were isolated from paddy field ecosystem, characterized, and identified at species level.

Four type I (*Gammaproteobacteria*) and nine type II (*Alphaproteobacteria*) MOB strains were isolated from seven compartments of a Japanese paddy field: floodwater, soil surface, bulk soil, rhizosphere soil, roots, basal stem of rice plants and rice stumps. Among the isolates, two type I and one type II MOB strains were further characterized and identified at species level. An isolate from floodwater, strain Fw12E-Y, belonged to the genus *Methylomonas* (type Ia), but showed distinctive physiological and phylogenetic features from the recognized species of the genus. The name *Methylomonas koyamae* sp. nov. has been proposed for the strain. Strain RS11D-Pr was isolated from rhizosphere soil and belonged to type Ib MOB in the family *Methylococcaceae*. The strain showed morphological, physiological, chemotaxonomic and phylogenetic characteristics distinguishing the strain from related genera of *Methylococcus–Methylocaldum–Methyloparacoccus–Methylogaea* clade in the family. The name *Methylomagnum ishizawai* gen. nov., sp. nov. has been proposed for the strain. A type II MOB strain, SS37A-Re, was isolated from surface soil and belonged to the family *Methylocystaceae*. The strain was closely related to the genus *Methylocystis* phylogenetically, but exhibited distinctive morphological, physiological, chemotaxonomic and phylogenomic features from the members of the genus *Methylocystis*. The name *Methylocystis iwaonis* sp. nov. has been proposed for the strain. We further focused on rice roots as an important hotspot of methane oxidation and isolated two, three and seven MOB strains belonging to the genera *Methylomonas, Methylocystis* and *Methylosinus*, respectively. Among the strains, two and two strains in *Methylomonas* and *Methylocystis*, respectively, represented putative novel species based on the phenotypic and genotypic characteristics. These findings indicate that diversity of culturable MOB in paddy field ecosystem is still open to be explored. Further efforts to cultivate, isolate and characterize MOB strains are needed for understanding ecophysiological features of MOB inhabiting oxic microsites in the ecosystem.

# Organic rice cultivation boosts microbial carbon use efficiency by modulating soil nutrient availability and microbial resource acquisition strategies

**Zhuxiu Liu[1], Junjie Liu[1], and Guanghua Wang[1*]**

[1] *State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin 150081, China*

*E-mail Address: wanggh@iga.ac.cn

**ABSTRACT**

Organic cultivation represents an environmentally friendly agricultural practice with the potential to enhance soil microbial diversities and functions. However, the mechanisms by which soil microbial communities regulate microbial metabolic efficiency under organic cultivation remain to be elucidated. Herein, the rice rhizosphere soil samples from three sites in Northeast China were compared for the differences in soil chemical properties, microbial biomass, enzyme activities, and microbial community diversities between organic and conventional cultivation at different growth stages. We also analyzed the contributions of these factors to the changes in microbial carbon use efficiency (CUE). Results showed that organic cultivation increased soil pH and available nutrient contents, alleviated microbial carbon (C) and nitrogen (N) limitations, and consequently improved microbial stoichiometric homeostasis and CUE. Conversely, microbial enzyme activities were significantly higher in conventional cultivation than in organic cultivation, especially during the later stages of rice growth. This resource allocation strategy of microorganisms led to a reduction in microbial diversity, biomass, and ultimately decreased in microbial CUE. We identified that the content of soil available N and the threshold element ratio for C:N ($TER_{C:N}$) were most important predictors of microbial CUE. Further, network analysis and partial least squares path model (PLS-PM) revealed that the specific microbial assemblies with high *rrn* copy number enhance microbial CUE by increasing biosynthesis (Fig.1). This study underscores the potential of organic farming in enhancing soil microbial CUE to mitigate ecosystem carbon losses, providing valuable insights for optimizing land management strategies to achieve soil carbon sequestration and advance sustainable agricultural practices (Liu et al., 2026).

**Keywords:** Metabolic efficiency; Nutrient limitation; Organic cultivation; Paddy soil

# Coordinated Action of Firmicutes and Bacteroidetes in Rice Straw Decomposition

**Yahai Lu**[1*]

[1] *College of Urban and Environmental Sciences, Peking University, Beijing, China*

*E-mail Address: luyh@pku.edu.cn

**ABSTRACT**

Global carbon storage in terrestrial ecosystems is about 1500 Pg per year, of which over 75-100 Pg carbon is returned to the atmosphere by soil microbial heterotrophic respiration. Rice paddy fields are widely distributed in Asia and provide a staple food for over half of the world populations. The input of plant-derived organic material amounts to 1.7 billion tons per year, most of which are left in fields and undergo anaerobic decomposition. This leads to an annual emission of 24-40 Tg methane into the atmosphere. However, the intricate process of plant biomass degradation by diverse soil microorganisms remains poorly characterized. Here I report a metagenomic research deciphering the mechanism of straw decomposition in a paddy soil.

The chemical analysis of 16-day soil microcosm incubation revealed that straw decomposition could be divided into an initial fast and then slowdown stages based on the dynamics of methane, short chain fatty acids, dissolved organic carbon and monosaccharides. Metagenomic analysis revealed that the relative abundance of glucoside hydrolase (GH) encoding genes for cellulose decomposition increased rapidly during the initial fast stage (3-7 days), while genes involved in hemicellulose decomposition increased in the slowdown stage (7-16 days). The increase of cellulose GH genes in the initial stage was derived mainly from *Firmicutes* while *Bacteroidota* contributed mostly to the increase of hemicellulose GH genes in the slowdown stage. Flagella assembly genes were prevalent in *Firmicutes* but scarce in *Bacteroidota*. Wood-Ljungdahl pathway (WLP) was ubiquitous in *Firmicutes* but not detected in *Bacteroidota*. However, *Bacteroidota* contained the largest proportion of total GHs and the highest number of CAZymes gene clusters (CGCs) across all metagenomes.

Overall, this study revealed a collaborating sequential contribution of microbial taxa and functional genes in the decomposition of straw residues in a paddy soil. *Firmicutes* with the property of mobility, WLP and cellulose decomposition could be mostly involved in the initial breakdown of straw polymers, while *Bacteroidota* became abundant and possibly responsible for the decomposition of hemicellulosic polymers during the later stage.

# Irrigation management drives the niche differentiation and metabolic versatility of ammonia-oxidizing archaea in paddy soils

**Xue Zhou[1*], Junzeng Xu[1], and Yawei Li[1]**

[1] *College of Agricultural Science and Engineering, Hohai University, Nanjing, China*

*E-mail Address of Presenting Author: xzhou@hhu.edu.cn

**ABSTRACT**

Water-saving irrigation is increasingly adopted in rice cultivation to conserve water, improve fertilizer-use efficiency, and mitigate methane emissions. However, the associated drying–rewetting cycles can intensify nitrification, thereby increasing the risk of nitrate loss and nitrous oxide ($N_2O$) emissions. A mechanistic understanding of how irrigation regimes shape ammonia-oxidizing microorganisms is therefore essential for designing effective mitigation strategies. Here, we investigated paddy soils subjected to a decade of contrasting irrigation managements (water-saving irrigation and continuous flooding) using metagenomics, genome-resolved reconstruction, and comparative functional profiling. Metagenomic analyses revealed significantly higher abundances of ammonia-oxidation genes under water-saving irrigation, indicating enhanced nitrification potential. Across all soils, ammonia-oxidizing archaea (AOA) were the dominant ammonia oxidizers. We reconstructed 26 high-quality *Nitrososphaeria* metagenome-assembled genomes (MAGs) and found that water-saving irrigation supported higher AOA *Nitrososphaeria* diversity spanning six family-level clades (including NP, NT-beta, and multiple NS clades), whereas continuous flooding harbored a less diverse assemblage dominated by NT-alpha and a non-AOA *Nitrososphaeria* lineage. Comparative genomics further revealed irrigation- and lineage-linked metabolic differentiation: AOA from water-saving soils showed greater genomic potential for urea utilization and osmoregulation (e.g., $K^+$ transport systems and $Na^+/H^+$ antiporters) and were enriched in carbohydrate-active enzyme (CAZyme) genes, suggesting broader organic nitrogen and carbon acquisition capacities and adaptation to moisture fluctuations. In contrast, AOA from continuously flooded soils were enriched in $Mn^{2+}/Fe^{2+}$ transporters, consistent with adaptation to reducing conditions. Co-occurrence network analysis indicated that AOA in the water-saving module were embedded in consortia linking carbon, nitrogen, and sulfur cycling, showing positive associations with *Nitrospiraceae*, *Blastocatellia*, *Desulfobacterota*, and *Methylomirabilales*, whereas flooded-soil AOA were primarily associated with heterotrophic taxa that may contribute to substrate supply. Finally, irrigation regulated nitrate-reduction pathway partitioning: water-saving soils were enriched in denitrification genes (*nirS*/*nosZ*), whereas flooded soils showed higher *nrfA*, indicating DNRA dominance. Collectively, these results demonstrate that irrigation management imposes strong selective pressure on AOA lineages and their metabolic strategies, reshaping the coupling among nitrification, nitrate-reduction pathways, and broader biogeochemical interactions in fertilized paddy soils.

# Nitrogen fertilization increases rice productivity at the expense of endophytic bacterial community stability and diversity

**Jinyuan Zhang, Xiaojing Hu, Jian Jin, and Guanghua Wang***

*State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin 150081, China*

*E-mail Address: wanggh@iga.ac.cn

**ABSTRACT**

Nitrogen (N) fertilization is indispensable for ensuring global food security by enhancing rice productivity; however, its ecological impact on the intricate assembly of rhizosphere and endophytic bacterial communities remains insufficiently characterized. This study utilized a pot experiment involving two rice cultivars (Longjing 29 and Longjing 39) subjected to four progressive N application rates (0, 40, 80, and 160 mg/kg soil) to systematically evaluate the responses of plant growth and associated microbial communities. Our findings demonstrate that while increasing N levels significantly promoted rice biomass, grain yield, and cumulative N uptake, it simultaneously induced a substantial decline in bacterial alpha diversity across the bulk soil, rhizosphere, and particularly the endosphere. These negative effects were most pronounced during the critical grain filling and maturity stages, suggesting a time-dependent sensitivity of the microbiome to N enrichment. The root endosphere exhibited the highest sensitivity to N inputs. Specifically, elevated N levels favored the expansion of *Proteobacteria* while significantly suppressing key plant growth-promoting bacteria (PGPB) such as *Geobacter*, *Bradyrhizobium*, and *Caulobacter*. Conversely, the relative abundance of potential opportunistic pathogens, including *Aeromonas* and *Stenotrophomonas*, increased under high-N conditions. Furthermore, co-occurrence network analysis indicated that endophytic bacterial communities became significantly less stable and more vulnerable to environmental disturbances compared to those in the rhizosphere and bulk soil. These results reveal a critical ecological trade-off: while intensive N fertilization maximizes short-term rice yields, it disrupts the structural integrity and homeostatic stability of the internal microbial community (Fig.1). Such dysbiosis may compromise long-term plant systemic health and overall N use efficiency. This study underscores the urgent need for optimized fertilization strategies that balance crop productivity with the maintenance of a healthy and resilient crop-associated microbiome in sustainable agricultural systems.

## ABSTRACT

**Background:** Aiming at the problems of frequent seasonal drought and weak productivity in paddy fields in Southwest China. This study focused on the characteristics and functions of rhizosphere microbial communities, the content of rhizosphere metabolites and the driving effects of rhizosphere microenvironment on rice growth and development. The purpose was to clarify the regulation mechanism of nitrogen application under controlled irrigation in paddy fields on rhizosphere microenvironment and rice development.

**Methods:** Randomized block design was used in the experimental area (n=4). A total of five treatments were set up, namely, no N treatment (FCK) under traditional flooding irrigation (FI), and four N application levels under controlled irrigation (CI), including no N application (CCK), low N application (90 N kg $hm^{-2}$, CN1), moderate N application (135 N kg $hm^{-2}$, CN2) and high N application (180 N kg $hm^{-2}$, CN3). The method of combining field experiment and omics analysis. We explored the structural composition, diversity changes and functional expression of rhizosphere microbial communities under different treatments at heading and mature stages; analyzed the species and contents of rhizosphere metabolites and the response characteristics of key metabolic pathways; revealed the driving effect of rhizosphere microenvironment (soil-microbial-metabolite) on plant growth and yield formation of rice.

**Results:** Nitrogen application significantly improved the physicochemical properties of paddy soil under controlled irrigation, and the soil AK, MBN, MBC and $NO_3^-$-N were significantly improved under the treatment of 25% nitrogen reduction (CN2). Based on metagenomic data, N application significantly increased the diversity of rhizosphere microbial communities under controlled irrigation paddy fields. The abundance of dominant microorganisms also changed significantly under different treatments, of which the relative abundance of *Hydrogenophaga* and *Sphingobium* was significantly increased by 107.10% and 84.48% under CN3 treatment ($P<0.05$), and *Nocardioides* was higher under CN2 treatment, with an increase of 16.20%, respectively.The dominant functions of rice at heading stage and mature stage were consistent, of which Amino acid metabolism (12.46%~12.76%) and Carbohydrate metabolism (11.00%~11.96%) had the highest functional abundance. Based on metabolomics results, there was a significant difference in the composition and content of rhizosphere metabolites between heading stage and mature stage of rice. It was showed the content of organic acid decreased and lipid increased from heading stage to mature stage of rice. Meanwhile, the content of Nucleic acids, Carbohydrates and Antibiotics were significantly increased under CN2 treatment at mature stage. Finally, the rhizosphere microenvironment directly or indirectly drives rice growth through the synergistic effect of soil-microorganism-metabolites. Moderate nitrogen application can optimize the rhizosphere microenvironment and positively promote plant growth of rice.

**Conclusions:** This study revealed the comprehensive effects of nitrogen regulation on 'soil-microorganism-metabolite-plant' under controlled irrigation in paddy fields, explored the changes of rhizosphere microenvironment, and proposed the best water and nitrogen regulation mode (CN2) in the main rice producing areas of Southwest China. The micro-ecological mechanism of water and nitrogen regulation in paddy fields on high yield and efficient utilization of water-nutrient of rice was clarified. This will provide theoretical basis and technical support for increasing the productivity of paddy fields and improving the rhizosphere microecological environment.

# Synergistic Effects of Integrated Amendment Practices on Soil Health and Crop Productivity in a Newly Reclaimed Cultivated Land

**ABSTRACT**

Newly reclaimed cropland commonly faces issues such as poor soil structure, low fertility, and insufficient biological activity, which constrain crop production. However, the comprehensive effects of different soil improvement measures on various aspects of soil health and their relationship with crop growth remain unclear. To address this, a field experiment was conducted with the following treatments: chemical fertilizer alone (NPK), bio-organic fertilizer (MF), two integrated improvement measures (MCN and MCN_2), and a blank control (CK). Both the bio-organic fertilizer and the two integrated measures were amended with an equivalent amount of organic matter. The integrated measures comprised an organic material source combined with modified biochar, minerals, and microbial inoculants. The study aimed to investigate the effects of these different treatments on soil physical, chemical, and biological properties as well as wheat growth, and to identify key soil factors driving yield improvement. Measurements at wheat maturity showed that, compared to the NPK treatment, the MCN treatment was most effective in improving soil structure (bulk density reduced by 0.14 g/cm³), alleviating acidification (pH increased by 0.87 units), enhancing fertility (soil organic matter increased by 4.43 g/kg, the ratio of available phosphorus to total phosphorus increased by 3.5%, and calcium content increased by 0.07%), and boosting microbial richness (Observed, Chao1, and Shannon indices increased by 28.6%, 28.3%, and 7.3%, respectively) and activity (activities of β-glucosidase, leucine aminopeptidase, and β-N-acetylglucosaminidase increased by 106.1%, 29.7%, and 60.0%, respectively). LEfSe analysis revealed that the integrated treatments enriched nitrogen-fixing bacteria (e.g., *Mesorhizobium*), organic matter-decomposing bacteria (e.g., *Fibrobacteraceae*, *Pseudohongiellaceae*), and beneficial *Bacillus* strains (e.g., *Blastocatellaceae*). Furthermore, the MCN treatment significantly increased wheat plant height, stem diameter, and yield, resulting in yield increases of 294.3% and 16.5% compared to the NPK and MF treatments, respectively. Correlation analysis indicated that grain yield was significantly correlated ($p < 0.05$) with soil organic matter, total nitrogen, total phosphorus, available phosphorus, calcium, manganese, the Shannon index, and bacterial phyla including *Pseudomonadota*, *Verrucomicrobiota*, and *Actinomycetota*. Yield also showed positive correlations with soil pH and the activities of sucrase, β-glucosidase, leucine aminopeptidase, and β-N-acetylglucosaminidase. Partial least squares path modeling identified the core pathway as "Improvement measures → Enhanced soil fertility (increased organic matter and mineral elements) → Microbial regulation → Yield promotion." In conclusion, the integrated measure combining organic materials with modified biochar, minerals, and microbial inoculants can rapidly improve soil health and crop yield in newly reclaimed cropland through synergistic multi-pathway effects, representing an effective strategy for achieving rapid maturation and ensuring high, stable yields in such soils.

**Key words:**Newly reclaimed cropland, soil improvement, soil health, crop productivity, synergistic effect

**ABSTRACT**

Accumulating evidence underscores the importance of microbial interactions in influencing community dynamics and modifying microbially mediated processes. However, empirical data detailing the effects of these interactions on the communities and activities of aerobic methanotrophs in soil environments are still limited. First, we examined the methane ($CH_4$) oxidation rate and active atmospheric $CH_4$-oxidizing methanotroph communities in two grassland ecosystems. Redundancy, correlation, and random forest analyses revealed that the carbon dioxide ($CO_2$) production rate is a key predictor of active methanotroph community composition and atmospheric $CH_4$ oxidation activity. An incubation experiment with glucose amendment demonstrated that glucose addition enhanced heterotrophic microbial respiration and suppressed atmospheric $CH_4$ oxidation. This study demonstrates that the $CO_2$ production rate is a crucial factor influencing atmospheric $CH_4$ oxidation activity in grassland ecosystems. It also indicates that interactions between methanotrophs and other heterotrophs affect methanotroph activity in these ecosystems. Subsequently, we analyzed in-situ greenhouse gas (GHG) emissions and clarified potential relationships between active microbes involved in methane oxidation and nitrification in grassland soils. DNA-based stable isotope probing (SIP) incubation experiments revealed that competition between active methanotrophs and nitrifiers suppressed $CH_4$ oxidation activity. Lastly, the impact of microbial interactions within and across trophic levels on $CH_4$ oxidation was further substantiated through analyses of methane-driven food webs, employing $^{13}C$-$CH_4$ based SIP and metagenomic sequencing. Metagenomic data and incubation experiments indicated that metabolites from *Hyphomicrobium* (cobalamin) and *Micromonosporaceae* (terpenoid volatiles) respectively promoted and inhibited $CH_4$ oxidation activity. Furthermore, predation on methanotrophs by myxobacteria, protists, and viruses also inhibited $CH_4$ oxidation activity. In conclusion, our findings offer empirical evidence of the substantial impact that microbial interactions have on aerobic methanotrophs and $CH_4$ oxidation activity in soil environments.

# From Genes to Gas: Dynamics of Active Methanogenic Food Webs in Rice Paddies

**Jingjing Peng**[1*]

[1] *College of Resources and Environmental Sciences, State Key Laboratory of Nutrient Use and Management; Key Laboratory of Plant-Soil Interactions; National Academy of Agricultural Green Development, China Agricultural University, Beijing, China*

* jingjing.peng@cau.edu.cn

## ABSTRACT

Methane production in rice paddies is governed by the coordinated activity of bacteria, methanogens and virus rather than by methanogen alone. Integrating time-resolved metatranscriptomics and metagenomcis, we found that carbon flow toward methane is shaped by dynamic interactions among fermentative bacteria, syntrophic partners, methanogens, and their associated viruses, forming a responsive anaerobic food web. Environmental drivers, including temperature, salinity, and nanoplastic contamination, reorganize both transcriptional activity and network connectivity, thereby reshaping methanogenic pathways and methane production rates. We further demonstrate pronounced temporal shifts and pathway flexibility within dominant methanogens, particularly Methanosarcina, underscoring functional plasticity as a key stabilizing mechanism under fluctuating conditions. Notably, virus–host interactions provide an additional layer of regulation on methanogen population dynamics and activity. Together, these findings establish an activity-centered microbial framework for understanding methane metabolism in rice paddies, highlighting the central role of active microbial food webs in controlling greenhouse methane emissions under environmental change.

# The functional divergence and biogeographic patterns of electron-transferring flavoprotein (Etf) in paddy soil

**Zhibin He[1]*, Yahai Lu[1]**

[1] *College of Urban and Environmental Science, Peking University, Beijing, China*

*E-mail Address: zhibin.he@pku.edu.cn

**ABSTRACT**

Rice fields, distributed across diverse climatic zones worldwide, serve as primary agricultural source of atmospheric methane emissions that substantially contribute to global climate change. Methane production through anaerobic methanogens is constrained by thermodynamic limitations during syntrophic oxidation of fatty acid, a process that relies on syntrophs and methanogens. The flavin-based electron bifurcation (FBEB) mechanism, mediated by the electron-transferring flavoprotein (Etf) enzyme, plays a pivotal role in energy metabolism by efficiently overcoming these thermodynamic constraints through enhanced energy transfer. However, the genetic diversity, functional differentiation mechanisms, and biogeographic distribution patterns of EtfAB remain poorly understood. To address these gaps, we integrated advanced computational tools including machine learning algorithms, multi-omics data analysis, and AlphaFold3 software to comprehensively investigate the structural diversity, distribution characteristics, and evolutionary patterns of EtfAB sequence homologs. Based on the sequence-specific features of EtfAB, we elucidate the mechanism underlying flavin-based electron bifurcation mediated in energy metabolism of syntrophs. Additionally, we clarified the global geographic distribution of EtfAB within rice fields and its relationship with environmental factors. These findings will provide critical theoretical insights into the energy metabolism mechanism of methanogens in rice field and improve methane emission predictions.

# Divergent Methanogenesis in Chinese Paddy Soils Driven by Organic Matter Composition under Climate Warming

**Jianpeng Li[1*], Yahai Lu[1]**

[1] *College of Urban and Environmental Science, Peking University, Beijing, China*

*E-mail Address: 2201112226@pku.edu.cn

**ABSTRACT**

Methane ($CH_4$) is a potent greenhouse gas, and microbial methanogenesis in paddy soils represents one of its major agricultural sources. Dissolved organic matter (DOM) serves as the most direct carbon substrate for soil microbes, yet how its inherent composition modulates the response of methanogenesis to warming remains poorly understood. We hypothesize that due to geographic heterogeneity in DOM characteristics, paddy soils will exhibit divergent methanogenic responses to temperature increase, leading to varied feedback under global warming. To test this, we conducted systematic anaerobic incubation experiments using 37 paddy soils collected across major rice-growing regions in China, across six temperature gradients (15℃,20℃,25℃,30℃,35℃,40℃). $CH_4$ production was monitored periodically, and DOM dynamics were characterized via 3D fluorescence spectroscopy. Two distinct response patterns emerged: Pattern I (22 soils) exhibited peak methanogenesis at 30~35℃ followed by a decline at 40℃, while Pattern II (15 soils) showed continuously increasing rates with temperature. These patterns correlated with initial DOM properties: Pattern I soils had significantly higher humification index (HIX), indicating more recalcitrant DOM, whereas Pattern II soils showed higher protein-like fluorescence, suggesting more labile, microbially derived substrates. Furthermore, after incubation at 40℃, DOM transformation pathways diverged significantly from those at lower temperatures, demonstrating that differential microbial utilization of DOM is closely associated with the bifurcation in methanogenic temperature response. This study establishes a significant correlation between DOM characteristics, its differential microbial utilization, and the observed dual-mode temperature response of methanogenesis. Future work integrating microbial community analysis will elucidate the underlying mechanisms and support the development of a predictive classification model, thereby improving the accuracy of $CH_4$ emission projections from paddy ecosystems under climate change.

# Microbial background for mitigating methane emission from rice fields

**Ralf Conrad**

*Max-Planck-Institute for Terrestrial Microbiology, Department of Biogeochemisty, 35043 Marburg, Germany*

* Conrad@mpi-marburg.mpg.de

**ABSTRACT**

Rice production is indispensable for food security, particularly in Asia, yet irrigated paddy agriculture is a major anthropogenic source of atmospheric methane, contributing roughly 8–10% of global emissions. Meeting rising food demand while reducing greenhouse gas outputs necessitates mitigation strategies that do not compromise crop yields. Methane emissions from rice fields result from anaerobic degradation of organic matter and are controlled by interactions among methanogenic production, methanotrophic oxidation, and transport processes mediated by soil and plant systems. Methane production is mainly driven by plant photosynthesis and the anaerobic degradation of organic matter in soil. Mitigation approaches targeting bulk soil focus on reducing the ratio of degradable organic matter to available electron acceptors. Avoiding or optimizing incorporation of rice straw and employing more recalcitrant amendments can significantly suppress methanogenesis. Increasing the availability of oxidants—such as ferric iron, sulfate, or nitrate—can inhibit methanogenic pathways through microbial competition, though nitrogen fertilizers pose trade-offs by potentially enhancing $CH_4$ production and elevating $N_2O$ emissions. Drainage strategies, including alternate wetting and drying, can markedly reduce CH4 formation while maintaining acceptable net global warming potential despite increased $N_2O$ fluxes. Biochar additions may further mitigate $CH_4$ emissions by modulating redox processes and microbial activity. At the level of plant photosynthesis, mitigation centers on restricting root-derived carbon allocation and increasing oxidative capacity. Cultivar selection and genetic engineering can shift photosynthate distribution toward grain rather than root biomass, simultaneously enhancing yield and limiting methanogenic substrate availability. Increasing $O_2$ transport and rhizospheric electron acceptors enhances both aerobic and anaerobic methane oxidation, while microbial manipulation—such as enrichment of methanotrophs or introduction of cable bacteria—shows emerging promise. Overall, the most effective mitigation strategies integrate soil management with plant-focused approaches, emphasizing electron acceptor optimization, organic matter control, and cultivar development. These methods offer substantial potential to reduce rice-associated $CH_4$ emissions without sacrificing productivity.

**ABSTRACT**

It is well known that sunlight exposure in paddy fields stimulates photosynthesis in algae inhabiting surface water, thereby contributing to soil fertility. However, knowledge of soil gas metabolism and microbial community responses in surface soils to light remains limited.

Flooded paddy soils exhibit characteristic stratification reflecting oxygen concentration. The peak daytime oxygen concentration occurs in the subsurface layer, and the diel oscillation in oxygen concentration in the surface soil is significantly greater than that in the surface water. Consequently, photosynthesis and subsequent respiration by microorganisms inhabiting the surface soil are sufficiently intense to influence biogeochemical cycles and microbial ecology.

Under light conditions, the surface soil of rice fields effectively suppresses $CO_2$ flux to the atmosphere, contributing to system recarbonization; algal photosynthesis further facilitates atmospheric $CO_2$ uptake. The dissolved oxygen profiles in the surface layer of flooded paddy soils change rapidly with light conditions, apparently influencing methane flux from the soil surface. Oscillations in oxygen profiles are also likely linked to iron cycling. Stable isotope probing with $^{13}CO_2$ showed that, among prokaryotes, diverse groups beyond cyanobacteria incorporated $^{13}C$ into the soil under light. Among eukaryotic microbes, green algae and diatoms were overwhelmingly dominant, while fungi, amoebae, and cercozoan flagellates also incorporated $^{13}C$, demonstrating a photosynthetic microbial food chain in the surface soil. Overall, our findings suggest that light irradiation plays a significant role in shaping biogeochemical cycles and microbial communities in the surface soil of a flooded paddy field.

# Beyond Nutrients: Minerals as Evolutionary Architects and Signaling Hubs in Soil Microbial Communities

**ABSTRACT**

Minerals have long been regarded primarily as passive sources of nutrients or physical scaffolds in soils. However, our research demonstrates that they actively drive microbial evolution, shape community assembly, and regulate functional gene expression—even under nutrient-rich conditions. Through serial passage evolution experiments, we exposed soil-derived bacterial consortia to a spectrum of nutritive and non-nutritive minerals. The results reveal that mineral substrates consistently restructured communities, notably enriching rare taxa that serve as key agents of niche specialization and metabolic diversification, while abundant taxa maintained core ecosystem functions.

Expanding beyond compositional shifts, metatranscriptomic analyses uncovered that minerals such as kaolinite and olivine act as signaling entities, triggering the upregulation of genes involved in antibiotic biosynthesis, antibiotic resistance, and the degradation of complex organic matter. These responses reflect a form of microbial "memory," where mineral surfaces pre-activate adaptive pathways in anticipation of environmental challenges. Notably, even chemically inert minerals like quartz exerted selective pressures that reshaped community trajectories through physical interface effects.

Together, these findings reposition the mineralosphere as a dynamic microhabitat where abiotic properties govern biodiversity, functional redundancy, and evolutionary innovation. By integrating ecological and molecular perspectives, our work establishes minerals as central players in microbial adaptation—with important implications for soil health, biogeochemical resilience, and strategies in ecosystem management and restoration.

**ABSTRACT**

Ethylene was known to have a strong inhibitory effect on microbial activity, including methanogens. However, ethylene, which is insoluble in water and has a gaseous form, could be utilized as a methanogenesis inhibitor in rice paddy fields. However, the potential of ethephon, which is a precursor of ethylene, as a methanogenesis inhibitor was verified to be utilized in rice cultivation condition. However, it is very unstable under high soil pH over 7. Under the flooded rice paddy, its chemical can convert into ethylene gas within 2-3 days, and therefore, it cannot be directly utilized as an amendment to suppress methane emission in rice field. To develop ethephon as a methanogen inhibitor which can utilize in rice cropping field, an inorganic amendment was developed by mixing with ethephon and polymer for controlling methylene release time. Four different water-soluble polymers (CMC, HEC, HEMC, & PVA) were selected. Ethephon was solubilized in polymer solution (1%, wt $v^{-1}$), mixed with gypsum ($CaSO_4$), and granulated using a disc fertilizer machine. In the flooded incubation test, which applied 1 mg $kg^{-1}$ of ethephon, CMC among the selected polymers was most effective to suppress methane emission, and then followed by HEMC, HEC, & PVA. In ethephon-CMC mixed treatment, methane flux significantly decreased with increasing ethephon application level. Half of methane flux was decreased by 0.5 mg $kg^{-1}$ of ethephon application. One more coating of pure CMC polymer solution on dried ethephon-CMC mixture increased methane suppression effect by 95% over the control. Therefore, the suppression effect of ethephon on methane emission could be more effectively enhanced by improving polymer applying practices. In conclusion, the formulation of ethephon with polymers can increase significantly methane emission, and this formulation could be utilized in developing low methane fertilizers and amendments.

## ABSTRACT

Conventional theory holds that soil flooding enhances denitrification by restricting oxygen diffusion and lowering redox potential, implicitly presuming that carbon and nitrogen availability for denitrification is comparable across soil moisture regimes once anaerobic conditions are established. Here, we challenge this assumption and propose a new mechanistic framework in which soil water status under anaerobic conditions governs the coupling between denitrification and organic nitrogen (SON) mineralization by regulating solute transport and microbial metabolic strategies, rather than denitrification intensity alone. Under strictly anaerobic conditions, we compared nitrogen transformation processes in paddy soils under fresh (60%WHC) and fully flooded (100%WHC) regimes using microcosm incubations. Although denitrification activity was comparable between moisture regimes, flooding markedly enhanced SON mineralization by 1.3–3.7 fold. This pattern indicates that soil moisture redirects nitrogen fluxes by reshaping the functional linkage between denitrification and SON decomposition. Under conditions allowing complete denitrification, SON mineralization was further stimulated, providing direct evidence for a denitrification-induced priming effect on SON decomposition under anaerobic conditions. However, this effect was mediated by distinct metabolic strategies. Flooded soils exhibited higher SON mineralization potential and ammonium assimilation capacity but lower abundances and transcriptional levels of denitrification genes, indicating a “high-mineralization–low gene investment” strategy. In contrast, fresh soils relied on higher denitrification gene expression to sustain comparable denitrification fluxes. Integrated multi-omics analyses revealed the microbial basis of this divergence. *Pseudomonas* served as the core active denitrifier across both moisture regimes, with *Azotobacter* as a secondary contributor, whereas soil moisture reshaped subordinate functional guilds. *Bacillus* and *Gammaproteobacteria* dominated denitrification in fresh soils, while *Schinkia* and *Oxalobacteraceae* prevailed under flooded conditions, reflecting moisture-driven niche replacement. Mechanistically, enhanced SON mineralization was driven by the decomposition of chitin and amino acid–containing compounds. Flooding increased the transcriptional activity of *Anaerolineae* and *Prolixibacteraceae* to promote chitin degradation and enhanced the expression of *Symbiodinium*, *Acidobacteriota*, *Vicinamibacterales*, and *Thermoanaerobaculaceae* to accelerate glutamate and glutamine decomposition. These processes continuously converted complex SON into bioavailable ammonium, supporting microbial biomass synthesis. Overall, this study establishes that under anaerobic conditions, soil moisture does not determine whether denitrification occurs, but instead controls nitrogen fate by regulating the coupling between denitrification and SON mineralization through solute transport and microbial metabolic partitioning.

# Impact of land use and soil types on microbial $N_2O$ reduction potential mediated by nosZ communities

**Xin Xia[1], Yong Li[1]**

[1] *Zhejiang Provincial Key Laboratory of Agricultural Resources and Environment, College of Environmental and Resource Sciences, Zhejiang University, Hangzhou 310058, China*

*E-mail Address: XinXia2025@zju.edu.cn

**ABSTRACT**

Agriculture is the dominant source of global $N_2O$ emissions, how land use and soil type regulate nosZ communities and their role in microbial $N_2O$ reduction remains poorly understood. Here, we investigated how land use and soil type shape soil $N_2O$ reduction potential through the abundance, diversity, assembly, and interactions of nosZI and nosZII communities in paddy and upland soils across coastal China. Paddy soils exhibited significantly higher $N_2O$ reduction potential than upland soils, with soil type further modulating this potential within paddy systems, whereas no significant differences were observed among upland soils. Consistently, the absolute abundances of both nosZI and nosZII were markedly higher in paddy soils, indicating a greater intrinsic capacity for $N_2O$ reduction, although their relationships with $N_2O$ reduction potential differed between land-use types. While α diversity of nosZI and nosZII did not differ between paddy and upland soils, nosZI consistently showed higher diversity and broader ecological niche width than nosZII. Community assembly analyses further revealed a higher contribution of deterministic processes in nosZII communities, suggesting stronger environmental filtering. Co-occurrence network analyses demonstrated that $N_2O$ reduction potential was not associated with the network complexity of individual nosZI or nosZII communities, but was positively linked to enhanced cross-group interactions between nosZI and nosZII in paddy soils. In contrast, such functional coupling was absent in upland soils. Overall, our findings highlight land-use-driven microbial cooperation as a key mechanism regulating spatial variability in soil $N_2O$ reduction potential.

**ABSTRACT**

Soil texture fundamentally governs redox interactions among dissolved organic matter (DOM), methanogenesis, and arsenic (As) mobilization in paddy soils, yet the underlying mechanisms remain unclear. This study combined porewater geochemistry, DOM molecular characterization (3D-EEM and FT-ICR-MS), and microbial analyses (16S rRNA sequencing and metagenomics) to compare coarse loam and fine silt soils in the Jianghan Plain. Loam soils promoted stronger reducing conditions and accelerated decomposition of aromatic, polyphenolic, and nitrogen-rich unsaturated DOM compounds, which acted as key electron donors and ligands, enhancing Fe(III) reduction and As release. These molecular shifts corresponded to significantly higher methane production and porewater As in loam versus silt. Metagenomic and microbial profiling revealed enriched populations of methanogens, anaerobic methanotrophic archaea (*Ca. Methanoperedens*), and Fe/As-reducing bacteria, along with elevated gene abundances for methane cycling (mcrA, fwd) and arsenic transformation (arrA, arsM). Together, these components formed an integrated "methane cycling–arsenic reduction" network. Our findings highlight how soil texture modulates DOM reactivity and microbial redox processes, offering new mechanistic insight into methane-driven As mobilization and groundwater As risks in rice paddies.

**ABSTRACT**

Global agriculture relies heavily on nitrogen (N) fertilizers; however, excessive N fertilizer application causes serious environmental pollution. Developing crop production systems with reduced N fertilizer inputs is therefore essential and could be achieved by harnessing N-fixing microorganisms (diazotrophs) in agricultural soils. Through metatranscriptomic analyses and isolation studies, we discovered previously overlooked diazotrophs, *Anaeromyxobacter* and *Geobacter*, which are well-known iron-reducing bacteria predominant in paddy soils. We hypothesized that the addition of ferric iron oxides, serving as electron acceptors for iron-reducing respiration, could enhance the N-fixing activity of these bacteria in paddy soils. Consistent with this hypothesis, soil N-fixing activity significantly increased after the addition of ferrihydrite or $Fe_2O_3$ to laboratory soil microcosms and iron powder to paddy field soils. Here, with special References to iron-reducing diazotrophs, we performed $^{15}$N-DNA stable isotope probing (SIP) together with $^{15}$N-IRMS analysis of native and iron-applied paddy field soils to (i) identify active diazotrophs and (ii) quantify the amount of fixed N. SIP analysis revealed that *Anaeromyxobacter* and *Geobacter* were the most active diazotrophs in both native and iron-applied paddy soils. In addition, *Bacteroides*, known to exhibit iron-reducing activity, was identified as another active diazotroph in iron-applied soils. IRMS analysis revealed a significant increase in the amount of fixed N in iron-applied soils. Notably, in iron-applied paddy soils, these iron-reducing diazotrophs outcompeted methanogens for carbon substrates, thereby suppressing methane emissions.

Collectively, these results indicated that (i) the newly identified iron-reducing diazotrophs *Anaeromyxobacter* and *Geobacter* are primary drivers of N fixation in paddy soils and (ii) iron application enhances their activity, thereby increasing soil N inputs while simultaneously mitigating methane emissions. This study highlights a novel paddy soil management strategy that improves soil N fertility, sustains rice yields with reduced N fertilizer inputs, and lowers environmental nitrogen and carbon burdens.

## ABSTRACT

Submerged paddy fields are recognized hotspots for methane ($CH_4$) and nitrous oxide ($N_2O$) emissions. While thermodynamic calculations suggest the feasibility of anaerobic $CH_4$ oxidation coupled with $N_2O$ reduction (AMNR), the specific microbial drivers in these oxygen-deficient agricultural environments remain largely unclear. This study hypothesized that conventional aerobic methanotrophs could facilitate the AMNR process in paddy soils. We established microcosms using four typical soil samples collected from different latitudes in China (Acrisols, Gleysols, Luvisols, and Cambisols). Enrichment reactors were maintained with continuous $CH_4$ and $N_2O$ supply for over 400 days to cultivate functional microbes.

Results demonstrated that the AMNR process occurred in all paddy soil samples. A consistently high $N_2O$ reduction rate (5.37-6.24 umol·$g^{-1}$ dry soil·$d^{-1}$) was observed, strongly associated with $CO_2$ formation. The process exhibited two distinct phases: a rapid $N_2O$ reduction phase concurrent with $CH_4$ oxidation, followed by a slower reduction phase. $^{13}C$-$CH_4$ tracing confirmed that $CH_4$ oxidation was tightly coupled to $N_2O$ reduction under oxygen-deficient conditions. Contrary to expectations involving anaerobic methanotrophs like *Candidatus* Methylomirabilis, 16S rRNA sequencing and metagenomic analysis revealed that conventional aerobic methanotrophs, specifically members of the Methylocystis and Methylobacterium genera, were the keystone taxa. These methanotrophs dominated the bacterial community after long-term cultivation. Functional gene analysis indicated that these bacteria harbor the *nosZ* gene, suggesting they can directly reduce $N_2O$. Alternatively, they may support heterotrophic denitrifiers by providing fermentative intermediates as electron donors. Additionally, the stoichiometry of $N_2O$ reduction exceeded theoretical expectations for simple coupling, coinciding with the presence of nitrogen fixation genes (*nifH*, *nifD*) in the enriched methanotrophs, suggesting a potential interplay with nitrogen fixation.

In conclusion, this study identifies that conventional aerobic methanotrophs possess the metabolic flexibility to utilize $N_2O$ as an alternative electron acceptor in hypoxic paddy soils. This mechanism provides a novel perspective on the simultaneous mitigation of two potent greenhouse gases in agricultural wetlands.

**ABSTRACT**

The extensive worldwide prevalence of saline-alkali soils presents a formidable challenge to both food security and environmental stability. Our previous study had well documented that the flue gas desulfurization gypsum long-term amendment saline-alkali paddy fields enhanced the soil microbial diversity and complexity (Liu et al., 2025), the subsequent migration and communication of these communities within the paddy soil - irrigation water - rice plant continuum need further research. Here, we conducted a long-term soda saline-alkali paddy amelioration experiment in China's Songnen Plain, comparing monoculture rice reclamation (PR) and flue gas desulfurization gypsum adding combined with cultivation rice reclamation (FGDG). Using 16S rRNA sequencing of paddy soil, irrigation water layer, and rice plant samples collected over reclamation 1-12 years, we characterized microbial diversity, composition, migration, and function. Results showed that FGDG significantly altered microbial community dynamics, reducing species replacement of beta-diversity in paddy soil and root endosphere alpha-diversity and inhibiting soil-to-root microbial migration while promoting endophytic interactions. Simultaneously, FGDG enhanced the paddy soil and irrigation water layer microbial community molecular ecological network modularity by changing the relative abundance of *Desulfosarcinaceae*, *Thiobacillus*, and *Anaerolineaceae*. Critically, FGDG application suppressed key methane production pathways and simultaneously enhanced sulfur cycling functions in soda saline-alkali paddy soil. Corroborated by soil salinity and nutrient analyses, this functional pivot was driven by FGDG-induced changes in soil chemistry—namely reduced pH and salinity and increased $SO_4^{2-}$, which gave sulfate-reducing bacteria a competitive advantage over methanogens. Our findings demonstrate that FGDG acts as a powerful ecological driver, engineering a stable, functionally specialized microbial ecosystem. This offers a sustainable strategy to improve soil health, mitigate greenhouse gas emissions, and enhance rice health in soda saline-alkali paddies with FGDG reclamation.

**ABSTRACT**

Soil microorganisms are essential for crop performance, and crop rotation is a key practice for shaping soil microbial communities. Rice-mushroom rotation uses the paddy fallow period for edible mushroom production, but how this system modifies the soil microbiome and influences rice yield remains poorly understood. Here, we combined a long-term field experiment with pot assays to compare rice–mushroom and conventional rice–wheat rotations and to quantify their effects on rice biomass, soil properties and soil fungal communities. Rice-mushroom rotation significantly increased rice biomass relative to rice-wheat rotation, and this effect was associated with shifts in the resident fungal community, including higher relative abundance and richness of indigenous soil fungal taxa with plant growth-promoting functions. Moreover, rice-mushroom rotation significantly enhanced soil nutrient status, increasing soil organic carbon, available potassium, total phosphorus and total nitrogen. Relationships between soil properties and community composition indicated that rotation-induced changes in the soil environment were linked to these community shifts. Guided by these patterns, we isolated candidate plant growth-promoting fungi from rice–mushroom rotation soils, assembled synthetic consortia and tested their effects in pots, where they consistently enhanced rice growth. Together, these results show that rice-mushroom rotation improves soil fertility and enriches beneficial fungal groups, and that these microbially mediated changes contribute to the yield advantage of rice-mushroom over rice-wheat rotation.

## ABSTRACT

Paddy fields have been known to provide a steady supply of N to maintain rice growth even without application of chemical N-fertilizer for several years. Biological nitrogen fixation (BNF) which was considered as the primarily nitrogen supply for rice growth has lately been linked to Fe(III) reduction in paddy field. Rice root iron plaque (IP) is crucial in rhizosphere elements cycling and retaining pollutants, but the synergistic interaction between rhizospheric Fe cycle and BNF remains elusive. Herein, rice seedlings with and without IP on rice root were cultured under hydrophonic conditions to explore the extent and the underlying mechanism of IP influencing BNF using acetylene reduction assay and $^{15}N$ labeling DNA-based stable isotope probing (DNA-SIP) combined with metagenomics. IP on rice root surface exhibited a diurnal Fe(III)/Fe(II) redox rhythm. The decreasing proportion of $Fe_2O_3$ and $Fe^{2+}$ on rice root and the increasing proportion of $Fe_3O_4$ and FeOOH revealed a phase transformation of IP during rice cultivation. In the presence of IP, the *nifH* gene abundance and nitrogenase activity were significantly increased by $1.15\times10^{8}$~$1.15\times10^{11}$ copies/g·dw and 134~566 μmol $C_2H_4$/(L·h), which enhanced the $^{15}N$ abundance in rice shoot and root by 36.4% and 23.1% and further facilitated 2.13 and 1.87 times more biomass accumulation than that without IP. The BNF activity was significantly inhibited by dissociating IP or breaking diurnal Fe redox rhythm. DNA-SIP combining *nifH* gene sequencing revealed that *Azotobacter*, *Clostridium*, *Sporolactobacillus*, *Desulfosporosinus*, *Dechlormonas* and unclassified *Ethanoligenaceae* were involved in assimilating $^{15}N$ in the IP-free rice root. *Azotobacter, Burkholderia, Phytobacter* and *Dechlormonas* were recruited by rice root IP to incorporate $^{15}N$ into biomass. Metagenomic binning identified the presence of genes related to BNF and extracellular electron transfer in such diazotrophs recruited by IP, suggesting their genetic potential to mediate synergetic BNF and Fe(III) reduction. The synergistic interaction between nitrogen fixation and Fe redox cycling on rice root shed light on the overlooked yet significantly crucial contribution of Fe(III)-reducing diazotrophs during rice production. Therefore, stimulating iron plaque formation, accelerating rhizopheric Fe(III)/Fe(II) transformation and enhancing the abundance of Fe cycling related diazotrophs might be feasible strategies to promote biological nitrogen fixation, which are needed to further evaluate in field scale.

# Assessing Human Land Use Impacts on Soil Properties and Genesis in the Great Plains Region of the United States

**Elizabeth M. Eroshenko[1*], Adam D. Subora[1], and Judith K. Turk[1]**

[1] *School ofNatural Resources, University ofNebraska-Lincoln, Lincoln, Nebraska, USA*

*leroshenko@unl.edu

**ABSTRACT**

Humans are accelerating soil change beyond natural rates. Some of these changes enhance soil properties, while others drive degradation, impacting ecosystem health and agricultural productivity. Using legacy soil survey descriptions from the 1950s-1980s in the Great Plains Region of the United States, we are resampling these soils 40-80 years later to quantify changes that have occurred over time. Rather than using the soil surface as a References depth, which is an unstable feature subject to erosion and deposition, we will measure changes in soil thickness using more stable features in the soil, such as depth to bedrock, gravels, or texture contrasts that are unlikely to shift within 100-200 years. Preliminary results show that even with native grassland vegetation at a low-slope (3%) rangeland site, about 10cm of erosion has occurred since 1968. In a floodplain soil, an increase in soluble salts was observed, potentially due to incision of the nearby river that lowered the groundwater table and caused salt precipitation such as gypsum. Such processes may hinder future agricultural productivity in affected areas.

We will expand comparisons across depositional and erosional sites in Kansas, Nebraska, and the Dakotas to determine changes in soil properties such as soil depth, structure, and pH. This study demonstrates the value of legacy soil datasets for detecting short-term anthropogenic soil change and provides insights into how human activities have reshaped Great Plains soils over recent decades.

# Multitemporal Mapping of Soil Degradation to Support Environmental Restoration and Land-Use Planning in Minas Gerais, Brazil

**ABSTRACT**

The restoration of degraded areas requires accurate diagnostics of soil degradation dynamics and their relationship with land-use and land-cover changes. In Minas Gerais, Brazil, the expansion and intensification of agricultural and livestock activities have accelerated processes such as loss of soil fertility, increased bare soil, and reduced ecosystem services. This study proposes a multitemporal mapping approach to identify and prioritize degraded areas, supporting public policies for environmental restoration and land-use planning.

A temporal dataset from 2018 to 2024 was analyzed by integrating vegetation spectral indices (Normalized Difference Vegetation Index -NDVI, Soil-Adjusted Vegetation Index -SAVI, and Enhanced Vegetation Index - EVI), land surface temperature, and bare soil indicators, which are sensitive to changes in vegetation cover and soil functionality. Data from dry and rainy seasons were evaluated separately with specific weightings to capture seasonal patterns associated with degradation processes. The Analytical Hierarchy Process (AHP) was applied to integrate the variables and generate priority maps for environmental restoration.

The results identified areas with high temporal variation in spectral indices, reflecting reduced vegetation cover, productivity losses, and increased soil exposure—patterns associated with land-use change and environmental degradation. The findings demonstrate the potential of multitemporal remote sensing to identify degradation hotspots and improve decision-making at the territorial scale. The proposed methodology effectively integrates technical and environmental criteria, providing strategic support for sustainable land management, restoration planning, and environmental policy development in Minas Gerais.

## ABSTRACT

With the escalating global demand for mineral resources, acid mine drainage (AMD) has emerged as a critical environmental concern due to its acidity and heavy metal contamination. To tackle this challenge, this study investigated the integration of montmorillonite (MMT) with electrochemical oxidation pretreatment for AMD, to enhance the removal efficiencies of iron and sulfate, thereby improving the effectiveness of subsequent limestone neutralization. Based on the results of this study, the optimal reaction parameters were determined to be a 5 V electrolysis voltage under heating and static conditions. Incorporating MMT into the electrochemical system significantly enhanced Fe(II) oxidation and sulfate removal, resulting in total Fe and sulfate removal rates of 84.9% and 12.01%, respectively, which were attributed to MMT's adsorption capacity, ion exchange properties, and co-precipitation mechanisms driven by Fe(III) hydroxide formation. Comprehensive characterization using scanning electron microscopy, X-ray diffractometry, Fourier-transform infrared spectroscopy and X-ray photoelectron spectroscopy analyses confirmed the presence of schwertmannite and FeO(OH) in the precipitates, highlighting the increased specific surface area, micropore volume, and structural integrity of MMT. Adsorption experiments demonstrated superior arsenic (As(III)) adsorption efficiencies in precipitates formed through electrochemical oxidation with MMT incorporation, supported by pseudo-second-order kinetic modeling, indicating that MMT had been modified through Fe(III) intercalation. Additionally, the integration of MMT reduced neutralizing agent consumption by up to 68.1%, contributing to a substantial decrease in overall treatment costs. In conclusion, the findings underscore the synergistic interplay between MMT and electrochemical oxidation, presenting a sustainable and economically viable solution for AMD remediation. This integrated approach not only enhances pollutant removal efficiency but also generates environmentally valuable by-products with superior adsorption capabilities.

# Methane Mitigation and Arsenic Immobilization in Paddy Soils by Sulfur-Containing Amendments Applied to Stimulate Sulfate-Reducing Bacteria

**Han Na Kim[1,2*], Jin Hee Park[1], Girish Choppala[2,3], Jong Geon Oh[1], Su Kyeong Shin[1], Seung Jun Lee[1], and Jin Seo Lee[1]**

*hanna2255@naver.com

**ABSTRACT**

Paddy soils inherently produce methane ($CH_4$) under anaerobic conditions, and when the soil is contaminated with arsenic (As), the reducing environment promotes as the formation of highly mobile and toxic As(III). Sulfate-reducing bacteria (SRB) compete with methanogens for electron donors and supplying sulfate sources can suppress methanogenesis while simultaneously the formation of reduced sulfur species that immobilize As. This study investigated the coupled mechanisms of $CH_4$ reduction and As immobilization in paddy soils treated with sulfur-based amendments, including elemental sulfur, gypsum, and schwertmannite. Ten grams of soil were treated with 0.3% of each amendment, followed by 30 mL of 1000 mg/L As(V) under $N_2$-purged anaerobic conditions, and greenhouse gas emissions, As concentration in solution, and As species were monitored for 250 days. To elucidate the As immobilization mechanisms, adsorption experiment were conducted with 0.1 g of each amendment and 50 mL of 50 mg/L As(III) or As(V) for 48 hours. Elemental sulfur, gypsum, and schwertmannite reduced $CH_4$ in soils by 78.7%, 65.5%, and 88.0%, respectively, while immobilizing As by 11.4%, 8.2%, and 22.3% compared with the unamended control. Unlike the control, where As(V) was reduced to As(III), no reduction occurred in the amendment-treated soils because of alternative electron acceptors (e.g., sulfate) thereby limiting the formation of the more toxic As(III) species. Dehydrogenase activity followed the order schwertmannite > elemental sulfur > gypsum, suggesting that higher As immobilization corresponded to lower As toxicity and increased microbial activity. The immobilization of As(III) and As(V) was probably achieved by complexation with sulfur-based amendments as supported by high resolution-transmission electron microscope (HR-TEM) observations. Overall, sulfur-based amendments particularly schwertmannite simultaneously reduced $CH_4$ emissions and immobilized As through surface-bound mineral formation and microbially mediated sulfate reduction, highlighting their potential for mitigating climate and contamination risks in flooded paddy soils.

**ABSTRACT**

Organic amendments such as biochar and compost are widely regarded as stable carbon inputs that enhance soil carbon sequestration and mitigate greenhouse gas (GHG) emissions in paddy systems. However, current assessments typically focus on in-field emissions, often neglecting the climate burden associated with amendment production processes. Here, we conducted a comprehensive life cycle assessment (LCA) to quantify the net global warming potential (GWP) of applying fresh manure, compost, and biochar (12 Mg $ha^{-1}$ dry weight) in a conventional rice paddy, spanning industrial production to field application. Greenhouse gas fluxes were measured using a closed-chamber method, and soil carbon stock changes were integrated into GWP estimates. Relative to fresh manure, compost application reduced net GWP within the cropping sector by 43%, driven by a 25% decrease in $CH_4$ emissions and a 39% increase in soil carbon. However, composting released an additional 34 Mg $CO_2$-eq to produce 12 Mg of compost, generating a 34% increase in net GWP under a full-system boundary. In contrast, biochar treatment transformed the paddy into a net GHG sink, reducing $CH_4$ emissions by 56% and increasing soil carbon by 13%, while the pyrolysis process generated 19 Mg $CO_2$-eq. Overall, biochar reduced net GWP by 28% compared with fresh manure when considering full system impacts. Grain yield did not differ between compost and biochar, although compost improved yield over fresh manure. Consequently, biochar lowered GHG intensity (net GWP per unit grain yield) by 33%, whereas compost increased it by 22%. Our findings demonstrate that although compost confers agronomic benefits and mitigates in-field emissions, its production-phase climate burden substantially offsets these gains. Biochar emerges as a more sustainable amendment for minimizing the global warming impact of rice cultivation when assessed across the entire system boundary.

**ABSTRACT**

Soil erosion is a serious sustainability challenge that causes land deterioration, sedimentation in water bodies, and reduced storage capacity in dam reservoirs, causing severe difficulties in transboundary watersheds with limited data availability, like Mangla. Therefore, this study utilized the Revised Universal Soil Loss Equation (RUSLE) integrated with a Sediment Delivery Ratio (SDR) model. Quantifying the spatial distribution of soil loss and sediment yield, identifying the key environmental drivers, and evaluating their response mechanisms for watershed management. Results show the average annual soil loss of 103.90 tons $ha^{-1}$ $yr^{-1}$, with 64.5% of the region exceeding the tolerable erosion rate (> 25 tons $ha^{-1}$ $yr^{-1}$). Sedimentation yield of 20.75 tons $yr^{-1}$ highlighted the severe problem of siltation in Mangla dam, where the key drivers of soil erosion include topographic factor, where steep slopes increase runoff velocity and erosion potential, cover management factor, where the weak vegetation allows high soil exposure and soil detachment. This cause-and-effect relationship highlights how topography and land cover conditions influence erosion severity. Global and local Moran's I index analysis also confirmed that soil erosion risk exhibits significant spatial clustering, with critical hotspots concentrated in the steep and sparsely vegetated sub-basins. Spatially explicit risk maps pinpoint essential zones of the Kunhar, Neelum, and Jhelum Basins for urgent conservation practices. This work demonstrates the effectiveness of cloud-based geospatial modeling for sustainable watershed management in data-scarce regions. These findings support soil conservation practices like terracing and afforestation and provide actionable insights for hydropower security and achieving SDG 15 (Life on Land).

# Changes in farm business model: Combined effects on soil health, ecosystem services, farm profit, and associated needs for incentives

**Y.C. Wang-Touri[1*], M.C. Kik[2], M.P.M. Meuwissen[1], A.B. Smit[2], and H.W. Saatkamp[1]**

*youssef.touri@wur.nl

**ABSTRACT**

Growing demand to improve soil health and ecosystem services calls for alternative farm business models. Yet such transitions remain challenging because they involve synergies and trade-offs between soil health, ecosystem services, and farm profit. Although these interactions have been conceptually explored (Wang-Touri et al., 2025), few studies assess them holistically in real farm contexts. This research presents a diverse set of alternative business models and evaluates their implications for soil health, ecosystem services, farm profit, and associated needs for incentives.

Through an iterative participatory process, we co-designed alternative business models with six European farms. Each alternative was assessed ex-ante using partial budgeting (Kay et al., 2012) and a structured expert elicitation (IDEA protocol)(Hemming et al., 2018) to evaluate impacts on soil health, ten ecosystem services, and farm profit. Farmers then reflected on the outcomes in semi-structured interviews, discussing their willingness to adopt each option and how stakeholders and policies might influence adoption.

Across the six case studies, seventeen alternatives of varying complexity were identified, including changes to fertilizer strategies, reduced tillage, modified cropping plans, and alley-cropping (agroforestry). Results show distinct synergies and trade-offs across soil health, ecosystem services, and farm profit, with several offering triple gains. More complex changes produced greater improvements in soil health and ecosystem services, while not necessarily creating trade-offs with profit—yet they rarely delivered strong economic gains. Thus, the options with the highest ecological benefits were not the most economically attractive.

These findings lead to two main contributions. First, while additional incentives are not always essential for adoption, supportive measures—financial incentives, training, advisory services, regulatory simplification, and citizen engagement—can enhance uptake. Second, the structured approach developed here offers a novel and transferable method for jointly assessing soil health, ecosystem services, and farm profit, helping identify promising pathways toward more sustainable, resilient, and economically viable farm business models.

# Effect of autumn ratoon biomass on the rice growth and biomass during the following summer season under organic cultivation

**Atana Melingui Elie Desire**[1,2] *, **Keitaro Tawaraya**[3] and **Weiguo Cheng**[1,3]

[1]*The United Graduate School of Agricultural Sciences, Iwate University, Morioka, Japan*

*atana15@yahoo.fr

## ABSTRACT

**Background:** Ratoon rice regenerates as a second crop from stubble left after harvesting the main crop. In northeast Japan, it rarely reaches maturity due to low temperature during autumn and winter seasons. However, autumn ratoon biomass, as similar as rice straw, can supply carbon (C) and nitrogen (N), potentially influencing the rice growth in following summer season and soil C and N dynamics, while contributing C to methane ($CH_4$) emissions and N as a natural fertilizer under organic cultivation.

**Objectives:** This study evaluated the effects of ratoon rice growth over autumn and winter seasons on subsequent summer rice growth.

**Materials and Methods:** The experiment was conducted at Yamagata University Farm using ratoon plants collected after the 2024 harvest season by cylindrical column. Then twenty plants were transplanted into the pots (⌀ 27.0 × h19.5 cm) and assigned to four treatments combining two temperature conditions (ambient outdoor and glasshouse) and light availability: Glasshouse with Light (GHWL), Glasshouse no Light (GHNL), which the pots were covered by black sheet to shade sunlight, Outdoor with Light (ODWL), and Outdoor no Light (ODNL). After winter, all pots were plowed and rice seedlings were cultivated in outdoors under uniform conditions during the 2025 summer. Rice growth parameters and final biomass were measured at maturity. **Results:** As the results, there were no difference of stubble biomass after autumn and winter seasons among 4 treatments, however, the new ratoon shoot biomass was varied significantly. Compared with no light condition, the ratoon rice biomass were increased with light condition at 65% and 28% for glasshouse and natural outdoor conditions, respectively. The ratoon rice growth during the autumn and winter effected summer rice growth. The total biomass were 44.7, 35.7, 29.9 and 22.38 g/pot for GHWL, ODWL, GHNL and ODNL treatments, respectively.

**Conclusion:** These results demonstrate that autumn and winter management strongly influences subsequent rice performance. Higher temperature in glasshouse condition and light availability during off-rice growth season not only directly affected ratoon rice growth, but also indirectly influenced subsequent rice growth and yield under organic cultivation.

# Effects of fertilizers on arsenic accumulation in ratoon rice: implications for human health risks

**Chang-Shiu Li[1], Han-Ting Hsu[1], Bo-Ching Chen[2], and Kai-Wei Juang[1*]**

[1] *Department of Agronomy, National Chung Hsing University, Taichung City, Taiwan*

[2] *Department of Natural Biotechnology, Nanhua University, Chiayi County, Taiwan*

*nchulab508@gmail.com

**ABSTRACT**

Ratoon rice cultivation has received increasing attention in recent years due to its potential to reduce the inputs of labor, seeds, and energy. However, ratoon rice often requires fertilizer supplementation due to its generally lower yield. Furthermore, recent studies have indicated that ratoon rice can effectively reduce the arsenic (As) concentration in rice grain. Therefore, a pot experiment was conducted in the present study to investigate the effect of different fertilizer amendments on As accumulation in ratoon rice with three common Taiwanese rice cultivars—TCS17, TK9, and TK16—as experimental materials. Additionally, the interaction of fertilizer treatments and cultivars with As and iron in the root plaque was evaluated, and the human health risk associated with consuming ratoon rice was assessed. Results showed a significant difference in the effect of rice husk amendment among the three rice cultivars, with TCS17 showing a significant reduction in As uptake. This highlights that different fertilizer amendment strategies must be adopted for different rice cultivars to effectively reduce As accumulation in ratoon rice. Furthermore, fertilizer amendment treatments also significantly affected the concentration of As chelated in the iron plaque. The three rice cultivars showed significant differences in the index As sequestration by Fe oxides in root plaque (IAS), and across all cultivars and treatments, IAS exhibited a significant negative correlation with brown rice As concentration. This suggests that managing IAS is a feasible approach to reduce As concentration in ratoon rice grains. Health risk assessment results further indicated that organic fertilizer and rice husk were effective in reducing the health risk of TCS17, whereas the non-carcinogenic and carcinogenic risks of TK9 and TK16 exceeded the acceptable range under all treatments. Overall, this study clarified the influence of fertilizer and cultivar differences on As accumulation in ratoon rice, highlighting the importance of selecting appropriate cultivars combined with reasonable fertilization strategies to mitigate As accumulation in ratoon rice and its associated health risks.

# Managing water and litter inputs to safeguard wetland soil health: coupled C-N-P responses to drying-rewetting in River Murray floodplain soils

**Rui Yan[1], Zhe H. Weng[1], Mark Farrell[2], Luke Mosley[1]**

*1 School ofAgriculture, Food and Wine, The University ofAdelaide, Urrbrae, South Australia 5064, Australia*

## ABSTRACT

Hydrological volatility is increasing in many river-floodplain wetlands, intensifying drying-rewetting (DRW) transitions that can reshape "soil health" through coupled redox, organic-matter and nutrient feedback (Kingsford, 2011; Zhang and Furman, 2021). Although Birch-type rewetting pulses are well established for upland soils (Fierer and Schimel, 2002; Lopez-Sangil et al., 2018), wetland responses can diverge and depend strongly on litter quality and hydrologic history (Gao et al., 2020).

We synthesize three River Murray soil-column studies testing factorial combinations of water regime (continuous submergence vs DRW) and litter identity to quantify coupled C-N-P outcomes relevant to soil health and downstream water quality. We measured pore- and overlying-water nutrients, soil microbial biomass pools, DOC quantity and UV-Vis indices, FTIR organic-matter signatures, and $CO_2$/$CH_4$ fluxes. Natural-abundance $\delta^{13}C$ of $CO_2$ was used to apportion litter- vs. soil-derived respiration.

Across studies, litter chemistry set the mobilization "ceiling": labile litters (willow and *Themeda*) generated larger DOC and dissolved nutrient pulses, whereas lignin/phenolic-rich red gum constrained short-term mineralization and shifted DOC optical signatures (Moorhead and Sinsabaugh, 2006; Kennedy and El-Sabaawi, 2017). Water regime primarily governed timing and partitioning. DRW consistently suppressed methanogenesis during rewetting and shifted gaseous C towards $CO_2$, consistent with delayed re-establishment of strongly reducing conditions and altered electron-acceptor availability (Knorr and Blodau, 2009; Yarwood, 2018). DRW also amplified short-lived inorganic-N pulses and altered DON trajectories, with elevated eutrophication potential when labile willow inputs were present (Harris et al., 2021). For P, invasive willow increased dissolved P and soil microbial P relative to red gum, while DRW mainly re-timed peaks and strengthened non-additive responses among P fractions (Paranaíba et al., 2020; Skinner, 2022).

Overall, these studies show that "managing water for soil health" requires co-management of hydrology and species-specific litter inputs: DRW governs redox routing and nutrient timing, while litter quality controls the magnitude and composition of mobilised substrates that drive greenhouse-gas balances and episodic DOC export under flooding (Gibbs et al 2022)

# Evaluating Cross-Regional Models for Predicting Soil Carbon and Properties in Taiwan Using Mid-Infrared Spectroscopy and Machine Learning

**Chih-Hao Liao[1]、Cheng-Hsien Lin[1*]、Chien-Hui Syu[2]、Pin-Wei Li[1]**

[1] *Department of Soil and Environmental Sciences, National Chung Hsing University, Taichung, Taiwan*

[2] *Agricultural Chemistry Division, Taiwan Agricultural Research Institute, Ministry of Agriculture, Taichung, Taiwan*

* E-mail: ch.lin@nchu.edu.tw

**ABSTRACT**

Mid-infrared spectroscopy (MIR, 4000-650 $cm^{-1}$) offers rapid, non-destructive, and low-cost analysis of multiple soil properties, making it attractive for long-term soil carbon monitoring and MRV (Monitoring, Reporting, and Verification) frameworks. However, its predictive performance may vary across regions with heterogeneous soil environments. This study integrated 2,780 MIR spectra from a nationwide paddy soil database (TARI, n=1912) and two small-scale sites in Changhua Beidou (MDU, n=468) and Kaohsiung Qishan (QIN, n=400). Soil samples from 0-10 and 10-30 cm were analyzed for MIR spectra and laboratory-measured total organic carbon (TOC), pH, and cation exchange capacity (CEC). A subset of TARI samples was further fractionated to obtain mineral-associated organic carbon (MAOC) and particulate organic carbon (POC). Spectra were corrected using baseline correction, smoothing, and SNV, followed by calibration-validation splitting (70/30) and model development using Partial Least Squares (PLS), Cubist, and Random Forest. Principal component analysis (PCA) was applied to assess spectral variability among regions.

TOC calibration accuracies were consistently high ($R^2$=0.89-0.97), while validation performance differed by region. MDU, with a narrow TOC range (0.39-3.11%), showed moderate transferability ($R^2$=0.64-0.80). QIN, characterized by a wide TOC range (0.15-5.37%), yielded superior predictive performance (validation $R^2$=0.86-0.92). TARI exhibited moderate validation accuracy ($R^2$=0.74-0.77) due to strong cross-regional heterogeneity. Underestimation in TOC <0.4% and >4% occurred across all models, reflecting limited sample representation at these extremes. CEC predictions were robust across regions ($R^2$=0.79-0.93), while pH predictions were inconsistent ($R^2$=0.41-0.82) due to narrow pH variation in MDU and QIN. For SOC fractions, MAOC was best predicted by Cubist+SNV ($R^2$=0.86), whereas POC, with higher heterogeneity, was best predicted by Random Forest ($R^2$=0.85).

PCA revealed that spectral variation was governed mainly by sampling region rather than soil order or TOC concentration. Clear clustering of TARI, MDU, and QIN samples indicated strong regional spectral signatures consistent with model performance patterns, emphasizing the influence of geographic heterogeneity on MIR-based predictions.

Overall, MIR demonstrated strong capability for predicting TOC, CEC, MAOC, and POC; however, model generalization depended heavily on regional data structure. Cubist showed the best cross-site performance, PLS was more stable for homogeneous datasets, and Random Forest excelled for highly heterogeneous targets. Establishing a nationwide MIR spectral library, combined with local calibration and expanded sampling in TOC extremes, will improve cross-regional applicability of MIR-based prediction models for carbon monitoring and MRV applications.

# Integrated remediation strategies by health risk assessment of brown rice approaching technology for As, Cd, Cr, Ni, Cu and Zn-contaminated paddy soils in Taiwan

**Zeng-Yei Hseu[1], Horng-Yuh Guo[2], and Zueng-Sang Chen[3*]**

[1] *Department of Agricultural Chemistry, National Taiwan University, Taipei, Republic of China*

[2] *Division of Agricultural Chemistry, Taiwan Agricultural Research Institute, Taichung, Republic of China.*

[3] *Department of Agricultural Chemistry, National Taiwan University, Taipei, Republic of China*

**: Presentation and correspond author, soilchen@ntu.edu.tw*

**ABSTRACT**

Soil quality (or soil health) is defined as the capacity of paddy soil ecosystems to sustain their biological, chemical, and physical functions. The Soil Quality Index (SQI) has been widely adopted as an integrative tool to quantify the combined effects of multiple soil properties on overall soil quality, particularly for assessing the productivity and health risks of contaminated soils. However, studies that systematically evaluate changes in soil quality following contamination or remediation remain limited. This study assessed variations in soil quality and associated health risk-based assessment (HRA) in Taiwan paddy fields exposed to diverse sources of heavy metal contamination, including illegal industrial wastewater discharge, arsenic-rich irrigation water, industrial-derived metal inputs, and geogenic enrichment from serpentine parent materials. Conventional remediation practices in contaminated paddy soils in Taiwan commonly rely on dilution or soil replacement to meet single regulatory thresholds (e.g., As 60, Cd 3, Cu 200, Cr 250, Ni 200, Zn 600 mg/kg). Although these approaches enable rapid regulatory compliance, they often alter inherent soil properties and negatively affect rice cultivar performance. Therefore, slightly contaminated soils should be regarded as sustainable agricultural natural resources, and remediation strategies should prioritize ecological function, agricultural productivity, and food safety. Establishing a health risk-based assessment framework to guide appropriate remediation technologies and soil management is both pragmatic and innovative. For example, approximately 300 ha of arsenic-enriched (100–500 mg/kg) volcanic paddy soils in northern Taiwan and around 500 ha of irrigation-affected farmland in southern Taiwan exhibit elevated total soil arsenic concentrations, yet inorganic arsenic levels in brown rice remain below 0.3 mg/kg, indicating negligible health risk. In cadmium-contaminated areas near industrial zones (limit: 0.4 mg/kg), the key factors controlling Cd accumulation include soil pH, total Cd concentration, and rice cultivar, with indica varieties posing higher risks than japonica varieties. A health risk-based cultivar selection system was therefore developed to mitigate exposure. Likewise, paddy soils derived from serpentine parent materials in eastern Taiwan naturally contain high levels of chromium and nickel (500–1000 mg/kg); however, their low bioavailability results in minimal metal accumulation in brown rice, and health risk assessments reveal no significant concern, suggesting that soil remediation is unnecessary. For soils with moderately elevated copper and zinc concentrations (300–800 mg/kg), given that metal levels in rice remain within safe dietary intake limits, the use of low-cost soil amendments for in situ dilution and stabilization, combined with comprehensive health risk assessment and adaptive soil management, is recommended. Overall, sustainable utilization of contaminated paddy soils can be achieved through science-based risk communication, targeted remediation interventions, and adaptive soil management that balances environmental quality with agricultural productivity.

**Key Words:** paddy soil, brown rice, heavy metal pollution, health risk-based assessment, soil remediation.

# Effects of broiler litter and inorganic nitrogen on soil chemical indicators under varying row spacings in rainfed, no-till cotton systems

**Sainfort Vital[1], Gary Feng[2], Ardeshir Adeli[2]**

[1]*Mississippi State University*

[2]*Agricultural Research Service, U.S. Department of Agriculture*

**ABSTRACT**

Broiler litter is commonly utilized in cropping systems in the Southeastern United States; however, its effects on soil nutrient indicators under different row spacings in rainfed, no-till systems remain insufficiently characterized. From 2006 to 2009, a field experiment was conducted at the Pontotoc Ridge–Flatwoods Branch Experiment Station (Pontotoc County, Mississippi) on an Atwood silt loam (Typic Paleudalf) within a humid subtropical climate. The study employed a randomized complete block design with a split-plot arrangement, where row spacing (7.5, 15, and 40 inches) served as main plots and fertility management as subplots. Fertility treatments included an unfertilized control, inorganic nitrogen fertilizer (120 lb N $ac^{-1}$ as ammonium nitrate), and broiler litter applied annually at rates of 2, 4, and 6 tons $ac^{-1}$. Phosphorus and potassium were applied in the first year based on soil test recommendations. All plots were managed under rainfed, no-till conditions with standard weed and pest control practices. Broiler litter nutrient concentrations were determined at each application to quantify nutrient inputs. Soil pH, total carbon, total nitrogen, mineral nitrogen ($NO_3^-$ and $NH_4^+$), water-extractable phosphorus, and Mehlich-3–extractable macro- and micronutrients were measured from 2006 to 2009. The main and interactive effects of row spacing and fertility management will be evaluated across years. These results are expected to inform nutrient management strategies for broiler litter application in rainfed, no-till cotton systems in the Southeastern United States.

# Rye–clover cover crop configuration (random vs alternating rows) with poultry litter: soil chemistry and cotton yield in Mississippi

**Sainfort Vital[1], Gary Feng[2], Haile Tewolde[2]**

*[1]Mississippi State University*

*[2]Agricultural Research Service, U.S. Department of Agriculture*

**ABSTRACT**

Cereal rye (Secale cereale) and crimson clover (Trifolium incarnatum) are frequently recommended for mixed cover cropping; however, cereal rye often dominates when seeds are combined and planted as a random mixture, resulting in inconsistent achievement of the intended stand proportion. This study investigates whether an alternative planting configuration, specifically alternating drill rows of rye and clover, leads to different soil and cotton responses compared to a conventional random mixture, and whether these responses interact with poultry litter inputs in Mississippi (Southeastern U.S.). A two-year small-plot field experiment (12 ft × 40 ft) was implemented using a randomized complete block design with a split-plot arrangement and four replicates. Poultry litter (0 versus 2 tons per acre, applied prior to cover crop planting) was assigned to main plots. Subplots consisted of five treatments: winter fallow (no cover crop), cereal rye alone, crimson clover alone, a random rye–clover mixture, and an alternating-row rye–clover configuration (three rows of clover followed by two rows of rye), established by drilling at 7-inch row spacing. Cover crops were planted in mid-October and terminated two to three weeks before planting cotton as the main crop. Measurements included soil indicators at 0–15 cm (2020–2021), cotton yield (2020–2021), and crop nutrient uptake (2021), supported by baseline soil characterization (2019). Split-plot mixed models and planned contrasts will be used to quantify the effects of cover crop configuration and poultry litter on soil nutrient indicators and cotton performance, thereby informing mixture recommendations for rainfed systems.

**ABSTRACT**

Soil quality, either known as "capacity of a soil to function" or "fitness for use" has become an increasingly demanding concept to realize soil's potentiality for both cultivation and environmental management perspectives. Since the last two decades, enumeration of SQI (soil quality index) has dominated by Soil Management Assessment Framework model, with three 3-I's pillars: Identification, Interpretation and Integration of crucial soil quality indicators. However, soil health researchers, especially under rice-growing agroecology, have perceived the important relationship of the developed SQI with other components- grain yield and grain quality, and sometimes with GHG emissions. Summarizing a three-years' study, soil indicators were interconnected under specific soil functions viz. *Nutrients cycling*, *Resistance and Resilience*, *Biodiversity and habitat*, majorly converging soil C, nutrients and microbial indicators to integrate SQI. C-related indices viz., carbon pool, lability index and Carbon management index derived from total organic carbon (TOC) and different C-fractions, revealed that higher values of Carbon pool index (CPI) were expressed by irrigated organic lowland of Cuttack (1.14-1.74%) and upland soils of Hazaribagh (1.09-1.94%) over others; while Carbon management index (CMI) showed an order of: Irrigated organic lowland soil > Upland irrigated soil > Upland rainfed soil > Saline soil. Among soil biological parameters, saline soil of coastal region exhibited lower enzymatic activities compared to other rice ecologies. Irrigated lowland soil showed comparatively higher soil enzymatic activities and microbial biomass N, P, than upland soils. Further, a greater range of AWCD, Shannon and McIntosh Index representing total microbial community and functional diversity indices analysed using Biolog® eco microplates disclosed that irrigated lowland rice soil under organic management had higher richness and evenness of soil microbes in than other rice ecologies. Our findings showed that developed SQI and screened soil indicators is dependent on both crop yield and grain quality parameters in four diverse ecologies of rice-based system belong to eastern India. PCA-based MDS indicators were variable across studied ecologies: TOC, pH, av. N, $C_{min}$, MBC, MBN (long-term organic-fertilized soil), av. P, K, Zn, $C_{min}$, MBP, soil enzymes (upland rainfed and upland irrigated), SOC, EC, av. N, soil enzymes and MBC (coastal rice ecology). Rice grain quality parameters (protein & amylose contents, Fe and Zn) showed association with both SQI and soil indicators, and hence SQ also acted as grain quality predictors. Variable relationships (SQ-GQ-GY) established in different ecologies; more the SQI (>0.70-0.75) a perfect triangular relationship explained.

# Biochar application improves soil health and tomato growth under drip irrigation in acidic soil

**Tingting Chang[1*], and Jianwei Zhang[1], Pinyue Dong[1], Xu Yang[1], Jie Zhang[1], Hengji Qin[1]**

[1] *College of Agricultural Science and Engineering, Hohai University, Nanjing, China*

*E-mail Address of Presenting Author: changtt@hhu.edu.cn

**ABSTRACT**

Excessive application of chemical fertilizers has led to increasingly serious problems of soil acidification and crop growth obstacles. The localized irrigation characteristics of drip irrigation result in the concentration of soil moisture and nutrients, thus affecting soil physicochemical properties. This alteration of soil properties may cause spatially uneven distribution of soil acidification, thereby hindering its remediation. Biochar application can improve soil acidification, but the regulatory mechanisms of biochar on soil acidification characteristics and crop growth under drip irrigation conditions are currently unclear. This experiment set up different biochar application treatments under drip irrigation conditions to study the distribution patterns of uneven soil acidification; it also explored the effects of different biochar application rates on uneven soil acidification under drip irrigation conditions, and its influence on crop growth and water use efficiency. The results can provide a References for soil acidification improvement and the development of water-saving agriculture.

**ABSTRACT**

Long-term excessive application of chemical fertilizers is one of the main factors leading to soil acidification. Studies show that soil acidification extensively affects soil health through disrupting soil structure, causing nutrient imbalances, and reducing microbial activity. Organic amendments are of great importance to improve soil health and plant growth. Different organic amendment treatments under two distinct deficit irrigation regimes were used to remediate an acid soil caused by excessive use of chemical fertilizers. We measured soil pH, organic carbon fraction, aggregate composition, moisture retention, microbiome structure and plant root development, photosynthetic rates, water use efficiency. This work emphasizes the capacity of lignin-based organic amendments to alleviate acidic soil health and sustain wheat productivity under limited water.

# The Potential of Returning Lignified Sesbania and Sun Hemp to the Soil to Increase Soil Organic Matter in Tropical Farmlands

**Chia-Hsing Lee**[1*]

[1] *Department of Plant Industry, National Pingtung University of Science and Technology, Pingtung County, R.O.C.*

*CHLee@mail.npust.edu.tw

**ABSTRACT**

Cultivation of sesbania and sun hemp provides nutrients for subsequent crops; however, their potential to enhance soil carbon sequestration remains uncertain. Unlike previous practices where green manure was incorporated into the soil during its tender stage, this study allowed the plants to mature before being returned to the field. In the first year, experimental fields comprising paddy, upland, and paddy-upland rotation systems were established at the National Pingtung University of Science and Technology. During the second cropping season, Sesbania, sun hemp, and naturally occurring weeds were cultivated for over 10 weeks before incorporation. The results showed that, in paddy fields, rotation with Sesbania or sun hemp resulted in 4.6 and 3.6 t/ha of carbon input more than weeds. Using a decomposition rate of 70% over one year, the estimated increase in carbon sequestration potential was 1.38 and 1.08 t C/ha, respectively. In upland fields, sun hemp incorporation after the cropping season added 2.1 t C/ha more than weeds, with an estimated annual increase of 0.63 t C/ha. Measurements of soil carbon stocks within 30 or 50 cm depths over two years show no significant differences among baseline values, pre-green manure levels, post-green manure incorporation levels, or treatments. It is recommended that the pre-green manure planting timepoint serve as the baseline for monitoring. A linear regression analysis of soil carbon stock changes over two years revealed that, despite high variability leading to insignificant regression and determination coefficients, Sesbania and sun hemp demonstrated higher sequestration rates compared to weeds. The rates were 7.2 and 10.3 t C/ha/30 cm/year, respectively, aligning with trends observed in some international studies. In laboratory incubation tests, early carbon release following green manure incorporation primarily originated from inherent soil organic carbon, with minimal influence from different green manure. This outcome is likely because the green manure had not yet transformed into soil organic carbon, and the carbon input from a single application was insufficient. In the second year, upland fields were cultivated again. For the first cropping season, maize grown under the three treatments exhibited no significant differences in growth vigor, ear length, or yield, indicating that no production-reduction effects occurred. Consecutive typhoons during the second year hindered the growth of sesbania and sun hemp, although sesbania produced more biomass, contributing approximately 0.6 t C/ha more carbon to the soil than weeds.

## ABSTRACT

Conventional rice cultivation systems are extremely water-intensive, requiring 2-3 times more water than other cereal crops (Barker et al., 1999). With rising water scarcity caused by climate change, pollution, and competition from urban and industrial sectors, irrigation sustainability is under increasing threat, jeopardizing food security (Fan et al., 2012). In parallel, paddy fields are major sources of anthropogenic GHG emissions, particularly methane, which is generated in anaerobic conditions and accounts for 5–20% of global $CH_4$ emissions and nearly half of agriculture's total GHGs (IPCC, 2014; Carlson et al., 2017). Water-saving irrigation is a promising strategy to enhance food security and reduce greenhouse gas (GHG) emissions. However, few studies have tested multiple irrigation intensities in a single field experiment, limiting direct comparisons of their agronomic and environmental effects. This study compared continuous flooding with two water-saving methods. Its key innovation lies in a comprehensive, field-scale assessment of impacts on soil quality, crop yield, GHG emissions, and microbial ecology—offering an integrated perspective lacking in prior research. Results showed that Alternate Wetting and Drying (AWD), following International Rice Research Institute guidelines, reduced water use by 23% without affecting yield. Periodic irrigation (PI), applied every nine days, saved 60% more water but caused a 19% yield loss. While CH4 emissions declined under reduced irrigation, increased $N_2O$ emissions offset this benefit, leading to no net reduction in global warming potential. Overall, different irrigation methods had no significant effect on the Soil Quality Index. However, the results indicate that water-saving irrigation may increase microbial physiological stress and alter microbial communities even in the short term. Therefore, this study recommends monitoring changes in soil microbial communities in areas under long-term water-saving irrigation, particularly in regions with higher degrees of water reduction, to ensure soil quality.

**ABSTRACT**

Soil microorganisms participate in almost all soil ecological processes and are crucial for maintaining ecosystem functions and terrestrial carbon, nitrogen, and sulfur cycles. Land use patterns significantly affects bacterial communities and their mediated biogeochemical processes by altering the soil microenvironment. However, further research is needed on how bacterial community structure, co-occurrence networks, and functional genes are coupled in response to different crop planting patterns. This study systematically analyzed the characteristics, network topology, and differences in C, N, and S cycle functional genes and their driving mechanisms in soil bacterial communities under four land use patterns (rice, wheat, maize, and soybean). The results showed that land use pattern significantly altered the relative abundance of dominant bacterial taxa. Functional gene analysis revealed that different land use patterns significantly altered the abundance distribution of C, N, and S cycle functional genes. This study reveals how crop planting patterns drive the reorganization of microbial metabolic potential by altering soil physicochemical properties, providing a References for sustainable nutrient management in agricultural ecosystems.

# Modified biochar enhances the growth of pepper and reduces the accumulation of cadmium in soil contaminated with cadmium

**ABSTRACT**

To address the severe challenge of Cd pollution in agricultural ecosystems, this study developed a novel magnetically modified biochar (MFBC) based on coconut shell waste. Modification significantly increased the specific surface area (496.82 $m^2 \cdot g^{-1}$) and oxygen-containing functional groups on the surface of the biochar. Application of MFBC effectively promoted the transformation of heavy metals in the soil from a weakly acidic extractable state to a residual state. Under the regulation of MFBC, the bioavailability of Cd in the soil was significantly reduced, while simultaneously increasing soil cation exchange capacity and organic matter levels (23.69%–35.40%), significantly improving soil fertility. Pot experiments confirmed that MFBC, by mitigating oxidative stress, increased the root length of bell peppers by 31.56%–39.97% and the photosynthetic rate by 24.10%–54.70%. Simultaneously, MFBC significantly blocked Cd translocation within the plant, substantially reduced Cd accumulation in the fruit, and improved quality indicators such as vitamin C and soluble sugars.

# Organic amendments affect soil organic carbon and water-salt transport under subsurface drainage in a coastal reclamation area

**Yujie Zhang[1], Qiu Jin[1], Anqi Zhang[2], Rongyao Zhang[1], Xu Yang[2], Tingting Chang[2]**

**ABSTRACT**

As an important reserve of arable land, the development and utilization of saline-alkali land in coastal reclamation areas is of great significance to ensuring food security. Applying soil amendments is an effective way to promote the transformation of coastal saline-alkali land into agricultural soil. However, under high salinity and high pH conditions, the process by which soil amendments drive the accumulation of soil organic carbon and water-salt transport in coastal reclamation areas under subsurface drainage systems remains unclear. This study set up five soil amendment treatments on the saline-alkali farmland under subsurface drainage in the coastal reclamation area of Jiangsu Province, China. We studied the effect of different treatments on the increase of soil organic carbon, as well as the distribution and content of organic carbon in soil aggregates of different particle sizes; analyzed the characteristics of soil water-salt transport. The results can provide a References for the application of soil amendments in saline-alkali soils in coastal reclamation areas.

**ABSTRACT**

The underutilization of saline-alkali land is a long-standing problem affecting agricultural production. While subsurface drainage is an effective salt removal technology, long-term use can lead to soil nutrient loss, soil compaction, and reduced soil productivity. Therefore, the improvement of coastal saline-alkali land should consider multiple factors, including desalination and fertilization, to establish a beneficial water-salt synergistic ecological environment. This study set up three subsurface drainage spacings and three organic fertilizer application rates, conducting a field experiment on saline-alkali farmland in the Tiaozini reclamation area of coastal China. The study investigated the temporal processes of soil water and salt transport and the patterns of soil salt leaching/accumulation; it also analyzed the response characteristics of soil physical moisture properties (soil bulk density, soil pore structure, soil water holding capacity, soil aggregate stability, and soil infiltration rate). The results can reveal the regulatory mechanism of soil fertilization and subsurface drainage synergistically on soil water and salt transport and crop growth, providing a References for improving the quality of coastal saline-alkali soil.

## ABSTRACT

Water scarcity starts to restrict the production of wheat, leading to deficit irrigation, which will help save water but may increase the effects of oxidative stress and nitrogen loss, compromising the stability of yield. In this case, biochar-based microbial fertilizer is considered for evaluation as one of the rhizosphere-engineering interventions to save nitrogen and enhance water productivity in regulated deficit irrigation. Controlled 4×4 factorial pot experiment, and combined measurements of soil carbon fractions, inorganic N speciation, enzyme activity, microbial community structure, and wheat physiology and yield formation. As a result, in various irrational states, BMF enhanced the status of soils in terms of carbon and availability of K, and moderately affected soil pH by +0.26, which was evidence of better buffering and nutrient solubility. Microbial ordination showed that there was significant community reassembly when using BMF. Similarly, since it is paramount, BMF found tighter N cycling and lower nitrification pressure changes, where it directed the inorganic nitrogen to increased $NH_4^+$ and decreased $NO_2^-$/$NO_3^+$. The most consistent gains, agronomically, were observed under a moderate × moderate regime of high water-use efficiency of whole-plant grain mass (~18 %) relative to the unamended control of the same moisture status. Generally speaking, deficit irrigation controlled by microbiomes and biochar co-optimization can be considered a climate-intelligent and scalable strategy to achieve water-limiting wheat systems with optimized water application, nitrogen charging, and a stable output in water-constrained environments.

# Soil ridging combined with soil amendments regulates the arsenic-cadmium related geochemical cycles and mitigate its accumulation in rice

**Ting Zhang[1], Gilles Colinet[2], and Shiming Su[1*]**

[1] *Institute of Environment and Sustainable Development in Agriculture, Chinese Academy of Agricultural Sciences, Beijing 100081, China*

[2] *TERRA Teaching and Research Centre, Gembloux Agro-Bio Tech, University of Liege, Gembloux 5030, Belgium*

*E-mail Address of Presenting Author: ting.zhang_0926@126.com

**ABSTRACT**

Co-contamination of arsenic (As) and cadmium (Cd) in paddy soils poses a serious global threat to rice food safety due to their high bioaccumulation in rice grains. As a result from their contrasting geochemical behaviors—As being more mobile under anaerobic conditions and Cd under acidic, oxidized conditions—developing an effective, field-applicable strategy to simultaneously reduce their bioavailability in rice cultivation systems remains a critical need. This study aimed to evaluate and mechanistically elucidate the efficacy of an integrated approach combining ridge cultivation with organic (biochar) and inorganic (calcium-magnesium phosphate, CMP) amendments in an acidic paddy field in southern China (pH 5.17; 66.5 $mg \cdot kg^{-1}$ As and 0.41 $mg \cdot kg^{-1}$ Cd.).

Field experiments using two indica hybrid rice cultivars (IIyou28 and Ruiyou399), supported by microcosm studies, showed that ridge cultivation improved soil aeration, increased redox potential (Eh), and alleviated acidity. When combined with 1% (w/w) biochar or 0.05% P (w/w) CMP, grain As concentrations were reduced by 26.939.7% and Cd by 37.867.6% relative to ridge-only controls, without yield penalties. Microcosm results confirmed decreases in available soil As (26.3–31.2%) and marked reductions in soil solution As (75.6–82.5%) and Cd (to 0.13–0.15 $\mu g \cdot L^{-1}$).

The integrated treatment altered key soil properties, especially pH and Eh, enhancing interactions among Ca, Fe, Mn, and the target metals. Aerobic conditions promoted Fe/Al oxide formation for As immobilization, while Mn (hydr)oxides played a dominant role in Cd sequestration. Geochemical modeling and Aggregated Boosted Tree analysis identified these elemental interactions as primary drivers of reduced metal bioavailability. CMP exerted a liming effect and stimulated nitrification, lowering Cd-risk, whereas biochar delayed nitrogen oxidation and enhanced Mn-mediated stabilization.

Metagenomic analyses indicated that microbial redox cycling of Fe, Mn, and N was a critical control on metal mobility. CMP enriched ammonia-oxidizing genes (*amoA/B*), while biochar increased genes related to Mn (*mntC*) and Fe transport. Key taxa included Bradyrhizobiaceae (abundant in Mn and $Fe^{III}$ transport genes), Nitrososphaeraceae (linked to nitrification), and Caulobacteraceae (Fe transporters).

In conclusion, this study provides a mechanistic and field-validated basis for the integrated application of ridge cultivation with CMP and biochar as a sustainable remediation strategy for As-Cd co-contaminated paddy soils. By improving soil aeration, modifying redox dynamics, and enhancing both abiotic and microbial immobilization processes, this approach effectively reduces heavy metal bioavailability and accumulation in rice, ensuring both environmental and food safety. The findings offer significant implications for large-scale application in similar agroecosystems across Asia and beyond.
