## ABSTRACT

Static closed chambers coupled with gas chromatography are widely used to quantify soil greenhouse gas fluxes. Standardized guidance remains limited for key protocol elements, including chamber volume, closure duration, and mixing conditions. This uncertainty is particularly consequential for short-lived nitrous oxide ($N_2O$) emission pulses triggered by fertilization or rewetting, which can contribute disproportionately to annual budgets. Here, static chamber protocols were evaluated in a subtropical forest soil with an emphasis on resolving event-scale $N_2O$ dynamics.

A factorial field experiment was implemented to quantify the interactive effects of chamber volume, closure duration, and fan operation. Chambers with volumes of 10, 20, and 30 L were deployed. High frequency concentration time series of $N_2O$, carbon dioxide ($CO_2$), and methane ($CH_4$) were measured using a laser-based analyzer, and discrete gas samples were analyzed by gas chromatography under both background conditions and periods with pulse emissions. Protocol performance was assessed using a Flux Credibility Index that integrates goodness of fit, temporal responsiveness, and structural suitability.

Clear trade offs emerged between design parameters and flux resolution. Closure duration strongly affected the ability to resolve event-scale $N_2O$ peaks. Short closures reduced temporal representativeness during the rapid phase after fertilization, whereas long closures increased non-linear behavior and widened differences between online and offline flux estimates. Among the tested configurations, the 20 L chamber provided the most consistent balance by limiting non-linear feedback while retaining sufficient detection sensitivity. These findings support scenario-specific recommendations that align chamber design with monitoring objectives. Overall, protocol harmonization is essential for reducing uncertainty in soil greenhouse gas budgets and enabling robust comparisons across study sites.

## ABSTRACT

Peatlands are major terrestrial carbon reservoirs, and their hydrological degradation and restoration can substantially alter soil carbon transformation processes and associated climate feedbacks. However, the magnitude of carbon emission responses and the underlying microbial regulatory mechanisms following rewetting remain highly uncertain. Here, we conducted a three-year (2023–2025) in situ field study across natural peatlands (NP), rewetted peatlands (RP), and drained peatlands (DP) in degraded peatlands of the Changbai Mountains, Jilin Province, China. We quantified cumulative soil carbon dioxide ($CO_2$) and methane ($CH_4$) emissions and integrated metagenomic analyses with structural equation modeling (SEM) to elucidate hydrological–microbial controls on carbon emissions during the rewetting process.

Across three consecutive years, cumulative soil $CO_2$ and $CH_4$ emissions differed markedly in magnitude and temporal patterns among hydrological regimes, while interannual trends were generally consistent. Cumulative $CO_2$ emissions in NP ranged from 327.90 to 631.81 kg C $ha^{-1}$, which were overall lower than those in DP (441.90–1217.02 kg C $ha^{-1}$), whereas $CO_2$ emissions in RP (353.55–513.66 kg C $ha^{-1}$) consistently fell between NP and DP. These results indicate that drainage persistently enhanced peat soil $CO_2$ release, while rewetting effectively mitigated drainage-induced $CO_2$ emissions over the three-year period, although recovery to natural levels was not achieved. In contrast, $CH_4$ emissions remained consistently high in NP (203.26–297.23 kg C $ha^{-1}$) and were substantially greater than those in RP (11.24–80.51 kg C $ha^{-1}$) and DP (36.41–88.09 kg C $ha^{-1}$), demonstrating that long-term drainage strongly suppressed methanogenesis and that short-term rewetting only partially restored anaerobic conditions, insufficient to recover $CH_4$ emissions to natural peatland levels. Taken together, the net climate effect of peatland rewetting, characterized by the 100-year global warming potential ($GWP_{100}$), is governed by trade-offs between $CO_2$ reduction and $CH_4$ enhancement.

Microbial analyses revealed that hydrological disturbance regulated methane cycling primarily through shifts in functional potential rather than pronounced taxonomic replacement. The methanogenesis marker gene mcrA maintained high abundance in NP but was strongly suppressed under long-term drainage, with RP generally exhibiting an intermediate state indicative of pronounced hydrological legacy effects. In contrast, methane oxidation–related functions exhibited more complex and depth-dependent responses to water table recovery. Metabolic network analyses further showed that drainage reduced the relative contribution of methanogenesis-related modules within the overall metabolic network, promoting functional allocation toward non-methanogenic pathways, whereas rewetting partially restored the dominance of methanogenic pathways in deeper soil layers, while surface soils retained clear drainage characteristics. SEM results collectively indicated that water table position and temperature indirectly regulated $CO_2$ and $CH_4$ emissions by modulating organic carbon availability and key microbial functional groups, highlighting the coupled control of hydrological conditions and microbial processes during rewetting.

Overall, rewetting substantially alleviated drainage-induced $CO_2$ emissions and partially restructured methane cycling functional networks over the three-year period, yet the recovery of carbon emission magnitude and associated climate effects remained constrained by strong hydrological legacy effects. This study provides robust field-based evidence for understanding carbon emission dynamics and microbial mechanisms during peatland rewetting and offers important implications for climate-oriented wetland restoration.

**ABSTRACT**

Soil structure, as the fundamental physical architecture, regulates the production and emission of carbon dioxide ($CO_2$). The effect of soil structure is likely most important but least quantified, mainly due to the difficulty of its direct measurement and the concealment of microscale heterogeneity. Laboratory incubation experiments with disturbed (sieved) and undisturbed (intact) soil cores under different soil moisture levels showed that soil structure disruption (sieving) significantly increased $CO_2$ emissions compared to intact soil. This phenomenon is mainly attributed to the physical protection conferred by the intact soil structure, which constrains the accessibility of substrates (such as organic matter and oxygen) to microorganisms. It was further supported by the evidence derived from X-ray computed tomography that more effective reaction zones (the spatial domains where substrate diffusion flux exceeds microbial consumption flux) can be identified in sieved soil than in intact soil. These findings bridge the gap between macroscopic $CO_2$ fluxes and microscale heterogeneity. Overall, it is necessary to include such key quantifiable physical indexes in future soil carbon models, which is critical to interpret and predict macroscopic soil processes and functions.

# Belowground Cross-trophic Networks Impact $CH_4$ and $CO_2$ Emissions in Degraded Alpine Peatlands

**Dengbo Chen[1, 2], Xue Guo[1, 2*]**

[1] *State Key Laboratory of Regional and Urban Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China*

**ABSTRACT**

Belowground organisms forming complex cross-trophic ecological networks are essential for maintaining peatland carbon stability and energy flow. However, how peatland degradation affects the biodiversity and cross-trophic ecological netowrks of soil communities remains poorly understood. Here, we examined the degradation effects on soil prokaryotes (i.e., bacteria, archaea), fungi and nematodes in alpine peatlands on the eastern Tibetan Plateau, characterized by varying water table depths (indicating degradation levels). We found that peatland degradation, accompanied by significant shifts in soil moisture and pH ($P$ <0.05), reduced the taxonomic richness and phylogenetic diversity of prokaryotes, fungi, and nematodes, particularly in deeper soil layers (20-50 cm). Crucially, peatland degradation weakened potential cross-trophic interactions within bipartite networks of prokaryotes-nematodes and fungi-nematodes, resulting in less than 6.5%-28.8% of unchanged modules. Degradation-induced changes in soil moisture and pH were identified as primary drivers of biodiversity loss and network restructuring. Furthermore, such changes of belowground cross-trophic networks (particularly prokaryote-nematode) were significantly correlated with greenhouse gas emissions, such as decreased $CO_2$ emissions, maintained $CH_4$ emissions (leading to a higher $CH_4/CO_2$ ratio in deep layers), and reduced temperature sensitivity ($Q_{10}$) of soil respiration. These findings underscore the critical need to protect soil biodiversity and cross-trophic netowrks in peatlands, particularly under the threat of climate change, to preserve peatland carbon stocks and maintain ecosystem stability. Our findings highlight that belowground cross-trophic netowrks are pivotal to decipher soil carbon dynamics of degraded peatlands and project the fate of peatland carbon stocks under future climate change scenarios.

## ABSTRACT

Soil respiration (Rs) is the dominant pathway returning carbon (C) as carbon dioxide ($CO_2$) from croplands and a key uncertainty in managed-soil C budgets. Partitioning Rs into heterotrophic respiration (Rh, derived from microbial decomposition of organic matter) and autotrophic respiration (Ra, derived from live plant roots and associated rhizosphere microorganisms) is essential because these components represent distinct processes that can respond independently, or even oppositely, to environmental change. Rs is governed by the coupling of substrate properties, nutrient availability, and hydrologic constraints, yet how these drivers interact to regulate Rh and Ra remains poorly constrained, particularly when straw return and extreme rainfall reshape the context of nutrient effects. Here we integrated complementary field experiments in northeast China using paired croplands with comparable soil organic C quantity but contrasting C quality (high vs. low), and quantified annual Rs, Rh, and Ra under six harmonized treatments (CK, NF, PF, NP, SR, SRF) spanning nutrient additions, straw return, and a contrast between normal and extreme rainfall years. Overall, the high-C-quality soil maintained higher Rs mainly through stronger Rh, consistent with greater substrate C bioavailability and enhanced microbial C-acquisition activity, whereas Ra tracked plant nutrient status and inorganic N supply. Nutrient additions and straw return did not exert uniform effects but were filtered by C quality: in high-C-quality soils, N inputs tended to suppress microbial $CO_2$ release by shifting microbial metabolism from mineralization toward assimilation, while in low-C-quality soils, responses were weaker and aligned with continued microbial nutrient mining under substrate limitation. Straw return generally amplified Rh by providing fresh residues and stimulating hydrolytic processing, yet co-supplied nutrients reshaped this stimulation by lowering straw-induced mineralization and increasing the potential stabilization efficiency of straws in C-quality-dependent ways. In contrast, extreme rainfall imposed hydrologic limitation, such that elevated soil moisture and waterlogging suppressed enzymatic decomposition and diminished the advantage of high C quality in Rh, whereas Ra remained comparatively governed by mineral N availability. Together, these results identify C quality as an overarching driver determining whether nutrient supply enhances, constrains, or redistributes microbial and plant contributions to Rs, and show that straw return and extreme rainfall shift the balance among physical, chemical, and biological controls on cropland $CO_2$ emissions. This synthesis supports C-quality-stratified fertilization and straw management under increasingly frequent extreme rainfall and improves the interpretability of $CO_2$ flux responses in managed soils.

# Effects of Three-Dimensional Surface Area Correction on Soil $CO_2$ Flux and Biomass Accounting in a Gully Landscape

**Peiyu Sun[1*], Yaxian Hu**

[1] State Key Laboratory of Soil and Water Conservation and Desertification Control, College of Soil and Water Conservation Science and Engineering, Northwest A&F University, Yangling, Shaanxi 712100, China

**ABSTRACT**

Soil $CO_2$ flux and biomass accounting in complex gully landscapes is commonly based on two-dimensional (2D) projected area together with slope-based stratification. This practice does not represent true three-dimensional (3D) surface geometry or topographic heterogeneity within land-use units, potentially introducing area-scale bias into regional carbon budget estimates. Here, we investigated a representative gully system (Xiaohegou sub-catchment) in the Wangdonggou watershed on the Chinese Loess Plateau. A high-resolution 3D terrain model was derived from winter UAV–LiDAR, and summer UAV multispectral imagery and point-cloud information were integrated to support gully-scale 3D land-use classification using a Random Forest approach. Land-use labels were mapped onto ground point clouds, and 3D surface areas for each land-use type were computed using a triangulated irregular network (TIN) to correct 2D area estimates. In situ soil $CO_2$ flux measurements and aboveground biomass estimates across land-use types were used to evaluate how 3D area correction affects carbon accounting.Results show that:(1) Differences between 2D and 3D area increase with slope and terrain fragmentation; the largest increases occur on steep gully-wall units, where local area correction factors exceed **3.5**.(2) Treating land-use types as 3D spatial units reveals pronounced within-type heterogeneity in slope composition; a single type can include microtopographic elements beyond empirically defined “suitable” slope ranges, indicating that slope-only stratification cannot ensure area-scale consistency.(3) Surface-area correction changes the magnitude of area-normalized estimates, thereby affecting calculated soil $CO_2$ emission intensity and aboveground biomass; the associated errors are concentrated in steep and fragmented units.Accordingly, extending accounting units from 2D patches to 3D land-use units and applying 3D surface-area correction can help reduce uncertainty in carbon accounting and improve regional carbon budget assessment in complex terrain.

## ABSTRACT

Agricultural soils account for 30% of all global emissions of nitrous oxide ($N_2O$), a potent greenhouse gas with 265 times the global warming potential of carbon dioxide ($CO_2$) (Environment and Climate Change Canada, 2022; IPCC, 2023). Despite many advancements in the fertilizer management sector, $N_2O$ emissions remain highly variable from region to region, highlighting the link between soil physical, chemical, and biological characteristics and $N_2O$ fluxes. Specifically, it remains unclear how soil moisture interacts with soil texture to influence $N_2O$ production pathways including nitrification and denitrification. To address this gap, we integrated continuous ecosystem-scale $N_2O$ flux measurements from 8 agricultural micrometeorological sites across Canada with a controlled soil incubation experiment associated with each site. Field scale $N_2O$ measurements were made using a flux-gradient approach in fields under contrasting best management practices (BMPs) suited for each region. Complementary 24-hour laboratory incubations were conducted using unamended soil from each site, set at water-filled pore space (WFPS) ranging from 40% to 105% WFPS. Isotopomer signatures of $N_2O$ (site pReferences, $\delta^{15}N$, $\delta^{18}O$) were used to determine relative contributions of nitrification- and denitrification-associated $N_2O$ across moisture levels. In field and laboratory experiments, soil moisture emerged as a clear regulator of the magnitude of $N_2O$ flux, but the incubation identified moisture as being a key regulator of the $N_2O$ source pathway as well. The relationship between moisture, SP and $N_2O$ production was highly variably from site to site due to soil texture differences, with heavier clay soils promoting anaerobic conditions and initiating a more rapid pathway change to dominant denitrification at lower moisture levels. Soils with lighter textures produced lower emissions, mostly originating from the nitrification pathway and switched to denitrification over a wider range of moisture and typically at higher WFPS levels. This texture-moisture influence on dominant $N_2O$ pathway coincides with the efficacy of field-scale trials showing denitrification targeted BMPs are most effective at reducing emissions at sites with heavier soils, whereas controlling nitrification is a priority at lighter-textured sites. By explicitly linking field-scale flux-gradient measurements with site-specific, isotopomer-signatures from soil incubations, this study advances our mechanistic understanding of $N_2O$ emissions and identifies soil moisture-texture interactions as critical leverage points for climate-smart fertilizer management under increasing environmental variability.

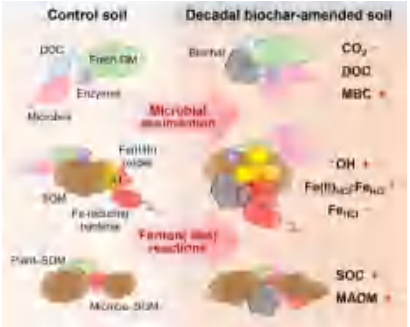
## ABSTRACT

Soil organic carbon (SOC) is pivotal for both agricultural activities and climate change mitigation, and biochar amendment (BA) stands as a promising strategy to enhance SOC sequestration and curb $CO_2$ emissions. However, in agricultural soils with a long-term BA, the roles of biochar in SOC cycling, and its mediation of interactions among microbes, minerals (especially iron (Fe) oxides) and fresh organic matter (FOM) remain largely unclear, particularly under changing environments. To address this gap, we conducted two-step microcosm experiments of soils with and without a decade-long BA history, adding straw as FOM while mimicking different environment conditions.

During a 56-day incubation at constant temperature (25°C) and moisture (60% water holding capacity), long-term BA had reduced FOM-stimulated $CO_2$ emissions by ~11% during, while enhanced SOC accrual. These effects were highly associated with microbially driven Fe reduction and subsequent Fenton-like reactions, where biochar strengthened Fe cycling, extracellular electron transfer, and microbial carbon use efficiency. The enrichment of Fe-C associations on biochar surfaces suggested microscale hotspots for Fe-C complexation, SOC protection and microbial C sequestration. Supplementary soil-slurry experiments with sterilization and Fe(II) spiking further confirmed that microbes were key triggers of hydroxyl radical (•OH) formation while their assimilation of •OH oxidated organic C was elevated in biochar-amended soil (Supporting figure).



To further resolve C turnover mechanisms under climate-change scenarios, we implied $^{13}$C-labelled FOM and incubated soils under elevated temperature (warming, 30°C) and dry–wet cycles (DWC) conditions. Overall, BA soil consistently showed lower total $CO_2$ emissions than control soil, mainly due to suppressed mineralization of native SOC, whereas the mitigation of FOM-derived $CO_2$ emissions was partly diminished by warming and DWC. Specifically, warming enhanced microbial metabolism but reduced C use efficiency, thereby stimulating SOC mineralization, especially from FOM. Intriguingly, newly formed mineral-associated organic carbon (MAOC) increased in the control soil but not in the BA soil, indicating that temperature and biochar jointly modulate the balance between microbial C turnover and the formation of high–organic-carbon-affinity minerals. Under DWC, rewetting tended to mobilize MAOC and FOM, following drought constrained microbial activity and cumulative C mineralization. Overall, these patterns suggest that MAOC may be less stable under DWC, particularly in BA soil. DNA-stable isotope probing (DNA-SIP) further identified active microbes, linking microbial and environmental drivers that regulating the allocation of C from FOM to different SOC pools.

Together, our results show that biochar mediates biotic and abiotic Fe–C coupling, reshaping the balance between microbial C turnover and SOC stabilization, and highlight both the capacity and the vulnerability of BA for soil C stabilization under future climate change.

**ABSTRACT**

Grazing exclusion is widely used to increase soil organic carbon (SOC) in degraded grasslands, but whether SOC continues to accumulate under prolonged exclusion and how this process is shaped by slope aspect remain unclear. Here, we investigated SOC dynamics along a 41-year grazing exclusion chronosequence across contrasting slope aspects in semiarid grasslands. By partitioning SOC into particulate organic carbon (POC) and mineral-associated organic carbon (MAOC), we examined how plant inputs, nitrogen availability, and microbial processes regulate SOC dynamics. SOC exhibited a non-linear trajectory, increasing during the early (0 - 16 yr) to mid (16 - 33 yr) stages but declining during the late stage (33 - 41 yr) of grazing exclusion. Specifically, POC did not continue to accumulate under prolonged exclusion and became increasingly vulnerable to depletion, whereas MAOC was unable to fully compensate for this loss. Slope aspect strongly shaped the magnitude and pathways of SOC responses, the south-facing slope showed greater sensitivity to grazing exclusion, whereas the north-facing slope maintained relatively higher SOC. Overall, these findings demonstrate that the carbon sequestration potential of grazing exclusion is finite and strongly aspect-dependent, providing a mechanistic basis for optimizing exclusion duration and topography-sensitive carbon management in semiarid grasslands.

**ABSTRACT**

The persistence of soil organic carbon (SOC) depends on its partitioning into mineral-associated (MAOC) and particulate (POC) fractions. Yet the combined roles of climate, mineralogy, and land use in shaping these fractions remain unresolved across continental gradients. Here, we analysed 249 Australian topsoils from 65 paired sites along a 550 mm rainfall isohyet. Samples were grouped into four climate–texture clusters (Subtropical Coarse, Subtropical Fine, Temperate Coarse, Temperate Fine) to disentangle the effects of thermal and hydrological regimes, soil properties, and land use on SOC fractions and saturation. Subtropical soils consistently exhibited high stabilisation efficiency (fMAOC ≈ 0.8) despite low SOC stocks, reflecting strong mineral–organic interactions under carbon-limited and water-stressed conditions. Temperate soils stored greater SOC stocks but frequently exceeded predicted MAOC capacity, indicating diminishing stabilisation efficiency. In subtropical fine soils, agriculture elevated fMAOC through microbial activity and nutrient inputs, yet this occurred alongside depleted SOC and POC, highlighting a trade-off between stabilisation efficiency and carbon stock depletion. Across all clusters, land use effects were evident but secondary to climate and mineral properties. These findings challenge assumptions that dryland soils are universally vulnerable, showing instead that subtropical soils stabilise carbon efficiently but in small amounts, while temperate soils store more carbon yet are prone to saturation and management-induced losses. Our climate–texture framework highlights region-specific management priorities: enhancing mineral–organic interactions in subtropical soils and protecting vulnerable carbon stocks in temperate systems.

**ABSTRACT**

Both soil inorganic carbon (SIC) and organic carbon (SOC) are affected by agricultural management. However, the former has received much less attention than the latter when assessing their role in the global carbon cycle, mainly due to the widespread assumption that SIC dynamics proceed at a very slow rate. Nevertheless, growing evidence shows that agricultural practices (e.g., irrigation, amendments, fertilizers) can drive significant and rapid changes in SIC that have not been considered in global carbon budgets, and that could represent potential SIC management strategies.

Among the practices known to influence SIC dynamics are the exogenous supply of $Ca^{2+}$ (e.g., through enhanced weathering or gypsum [$CaSO_4 \cdot 2H_2O$] application) and the introduction of irrigation in drylands. We monitored the effects of these management practices by studying the processes affecting SIC at two scales. The first study compared similar gypsum-containing soils under different management systems—rainfed and irrigated (25 years)—where SOC, SIC, and gypsum contents were measured at two depths. The second consisted of greenhouse and phytotron experiments using several plant species grown in substrates with varying gypsum concentrations. *Thymus* sp., *Rosmarinus* sp., *Brassica napus*, and *Astragalus* sp. were cultivated in pots containing silty loam material (30% $CaCO_3$) mixed with gypsum at 0%, 5%, 50%, and 80%.

In addition to the aforementioned variables, root calcification (observed microscopically) and $Sr^{2+}/Ca^{2+}$ ratios of biogenic calcite were quantified to estimate the proportion of calcite derived from gypsum-$Ca^{2+}$.

Results from the field study revealed changes in SOC turnover compared with the rainfed area, along with an increase in $CaCO_3$ and a decrease in gypsum content. These trends are consistent with previous observations of sulfate and bicarbonate concentrations in irrigation and drainage waters from irrigated watersheds containing gypsum-rich soils.

Similar patterns were detected in the pot experiments, with higher carbonate and lower gypsum contents. Root calcifications were observed in all species, with *Brassica napus* showing the highest degree of root calcification. Increasing gypsum content in the substrate significantly enhanced carbonate formation in both the substrate and roots, confirming that gypsum supplies $Ca^{2+}$ for calcite precipitation, leading to net carbon sequestration. $Sr^{2+}/Ca^{2+}$ ratios of biogenic calcite allowed the use of mixing equations that confirmed this hypothesis, as the proportion of calcite derived from non-carbonate $Ca^{2+}$ increased with gypsum content, reaching about 60%.

Our results are promising, representing a first step toward designing management practices for both rainfed and irrigated systems that promote SIC sequestration—an approach that could be incorporated into future carbon credit schemes.

## ABSTRACT

The sustainability of intensive rice–wheat systems in the Indo-Gangetic Plains is increasingly threatened by soil degradation *driven by organic matter depletion*, structural decline, and nutrient imbalance. This study aimed to evaluate the long-term effects of integrated nutrient management (INM) combining organic and inorganic inputs on soil carbon (C) and nitrogen (N) dynamics, physical properties, and biological activity in terrace soils of Bangladesh. This study assessed long-term effects of INM on soil carbon (C) and nitrogen (N) dynamics, physical properties, and biological activity in terrace soils of Bangladesh through a 32-year field experiment involving compost, cowdung, green manure, rice straw, and varied nitrogen (N) fertilizer rates. Compost application significantly enhanced soil total C and organic C stocks by 10%, microbial biomass C and N by 92% and 96%, respectively, and aggregate stability of 0.50 mm and 0.25 mm particles by 133% and 163%. Bulk density declined by 3%. C and N were concentrated in surface soils, decreasing with depth. Moderate N rates improved nutrient availability, whereas excessive N accelerated organic matter mineralization and reduced C stocks. INM practices consistently improved soil structure, biological activity, and nutrient retention, thereby strengthening climate resilience and productivity in sub-tropical systems. While C sequestration remained modest, continuous organic inputs are essential for sustaining soil fertility. Policy actions should promote organic fertilizers, farmer training on INM practices, and soil health improvement. Widespread adoption of INM offers actionable strategies for food security, soil restoration, and alignment with the UN Sustainable Development Goals.

**ABSTRACT**

Soils could be carbon (C) sinks or sources depending on land use and management changes (LUMC) in different plant-soil ecosystems. Soil nitrogen (N) and its dynamics not only affect plant growth and crop production but also control soil C sequestration. Thus, C and N dynamics affected by LUMC in terrestrial ecosystems contribute not only to global and local environmental problems, including global warming, destruction of the ozone layer, acid rain, and eutrophication, but also to changes in soil fertility and crop production related to human sustainable development. This report examines how soil C and N storage respond to land-use and management changes, and presents a comparison of various plant–soil ecosystems in the Eastern Japan. In Japan, following the introduction of the rice acreage reduction policy, the conversion and abandonment of paddy fields have been increasing year by year. We found that even 40 years after paddy fields were converted into orchards or wetlands, the surface soil C content had not changed significantly. However, in areas converted into vegetation-free parking lots, the soil C content showed a marked decrease. In contrast, when sandy land was converted into vinyl-covered paddy fields, the soil C content increased more than fivefold after 50 years. In the coastal sand dune area, black pine plantation age significantly influenced soil organic C (SOC) and total N (TN) contents in the 0–50 cm depths of sandy soils. Moreover, over the past two centuries, SOC and TN stocks in the 0–50 cm soil depth have exhibited an asymptotic increase with black pine forest plantation age in the sand dunes. Five-year vegetation conversion from pasture to C3 and C4 plants affects dynamics of SOC and TN and their natural stable C and N isotopes via mediating C input and N leaching in same area. These results indicate that changes in soil C and N storage in response to LUMC are largely driven by vegetation type and biomass productivity in plant–soil ecosystems.

# Cover crop quantity and quality jointly drive priming effects and new soil organic carbon formation across soil fertilization histories

**Zhi Liang[1*], Mette Vestergård[1], and Lars Elsgaard[1]**

[1] *Department of Agroecology, Aarhus University, Denmark*

*email: zhi.liang@agro.au.dk

Cover cropping has gained significant attention from researchers and policy makers over the past decade as a promising strategy to increase soil organic carbon (SOC) stocks and mitigate climate change. However, the effects of cover crops on SOC often vary, with some studies reporting negligible or negative outcomes. Uncertainties remain regarding the environmental and management factors controlling carbon (C) inputs and subsequent SOC dynamics, particularly the role of soil nitrogen (N) availability in modulating C sequestration. We previously showed that the quantity of cover crop C was a key determinant of SOC formation in a sandy soil, both directly through new SOC formation and indirectly via priming of native SOC decomposition. The present study evaluates how quantity and quality of cover crop C inputs interact with long-term fertilizer management to influence SOC sequestration in a clayey loam soil.

Using soils from the Askov long-term experiment initiated in 1894 with contrasting fertilization histories (unfertilized = ZERO, mineral = NPK, and animal manure = AM), we performed a 4-month mesocosm study (20ºC) with two $^{14}$C-labelled cover crop residues differing in C/N ratio (ryegrass, C/N=60; red clover, C/N=16), applied at increasing doses (0, 0.1, 0.2, 0.3, and 1.5 mg C kg$^{-1}$ soil). We investigated whether fertilization history and N content of the cover crops affected the formation of new SOC from cover crop C inputs, and whether positive priming effects at low residue-C inputs, previously observed in sandy soil, also occurred in this clayey loam.

The results showed that net C losses induced by cover crop residues were 62-91% of the initially added C across treatments, with higher losses caused by ryegrass than red clover regardless of soil fertilization histories. Yet, isotopic partitioning also revealed greater ryegrass C retention in the soil except for at the highest C addition dose, indicating that the higher C loss in this treatment was primarily driven by stronger positive priming rather than lower stabilization efficiency. Indeed, ryegrass resulted in increasing positive priming effects with higher addition doses across fertilization history, while red clover only triggered weak positive priming effects in ZERO, but not in NPK and AM fertilized soils.

We therefore hypothesized that the positive priming effects induced by ryegrass were driven by microbial N mining arising from imbalanced C-N stoichiometry in ryegrass residue, whereas red clover mitigated excessive native SOC decomposition through more balanced C-N inputs. Ongoing analyses, including fungal and bacterial amplicon sequencing and extracellular enzyme assays, will further elucidate the microbial mechanisms underlying the effects of cover crop quantity and quality on SOC dynamics across fertilization histories.

**ABSTRACT**

Orchard ecosystems play an important role in global carbon sequestration, but have not received sufficient attention. Therefore, tracking the changes of rhizosphere microbial community composition and root exudates of apple on the Loess Plateau, China and revealing their contribution to soil organic carbon (SOC), and its regulatory mechanism, can provide valuable information for carbon sequestration in orchard rhizosphere ecosystems. Our findings highlight that the accumulation of SOC in the rhizosphere of fruit trees mainly occurred in the period of decline rather than in the sapling stage and the full fruit stage. This is because during the growth and fruiting period of fruit trees, vigorous rhizosphere secretions lead to highly active and diverse microorganisms that consume SOC, with amino acids playing a key mediating role. However, in the decay stage, secretions decrease and SOC accumulation from microbial residue carbon, the contribution of fungal carbon is greater than that of bacterial carbon. Importantly, root exudates affect rhizosphere soil organic carbon rather than microorganisms by directly regulating rhizosphere soil physicochemical properties and soil enzyme activity.

## ABSTRACT

Soil organic carbon (SOC) in tropical regions is strongly influenced by high temperatures and abundant precipitation. These conditions create an environment that favors rapid organic matter decomposition, resulting in unique SOC dynamics that differ markedly from those in subtropical and temperate zones. Consequently, tropical soils often exhibit poor plant nutrition and relatively low SOC content. However, information on the chemical composition of SOC in tropical soils and on how this composition relates to soil characteristics and carbon dynamics, especially in Thailand, is still scarce. This study aims to examine the relationships among SOC chemical composition, soil properties, and SOC dynamics in agricultural tropical soils of Thailand. Surface soil samples were collected from a variety of crop fields. We employed three complementary approaches: (i) stable C ($\delta^{13}C$) and N ($\delta^{15}N$) isotope analysis with an isotope ratio mass spectrometer coupled to an elemental analyzer; (ii) density fractionation of SOC using sodium polytungstate; and (iii) solid-state $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy to characterize SOC chemical composition. Our results demonstrated that tropical soil conditions promote rapid SOC decomposition. OC contents were low (6.3–19.1 g $kg^{-1}$), and soils were limited in nutrients and cation-exchange capacity (CEC). The $\delta^{13}C$ values indicated that the OC originated primarily from the existing vegetation. The $\delta^{15}N$ signatures suggested that nitrification was the dominant N-transformation process in most crops, whereas lower $\delta^{15}N$ values in paddy soils reflected denitrification under anaerobic conditions. Density fractionation showed that the high-density fraction (HF; 3.0–14.6 g OC $kg^{-1}$ soil) represented the largest and more stable SOC pool. The free low-density fraction (fLF; 1.0–2.5 g OC $kg^{-1}$ soil) and mineral-associated low-density fraction (mLF; 1.3–3.7 g OC $kg^{-1}$ soil) contained smaller OC amounts. Significant differences in $\delta^{13}C$ among sites were observed for fLF and mLF, but not for HF, indicating that SOC dynamics are mainly confined to the relatively labile fractions, while the more stable pool is comparatively less affected by cultivation across crop fields. The principal component analysis linked alkyl C and n-alkyl C with silt and clay content, CEC, and soil pH in tropical soils. In contrast, di-O-alkyl C and carbohydrate C, which represent labile, easily decomposable SOC, were positively associated with decomposition processes and were predominantly present in fLF and mLF. Carboxyl C and aromatic C, regarded as more stable forms of OC, were primarily found in HF. Overall, this study revealed the chemical composition of SOC and its connections to SOC dynamics and soil properties in Thailand's tropical agro-ecosystems. These findings provide a scientific basis for developing improved soil management strategies aimed at both enhancing crop productivity and increasing SOC stocks in tropical regions.

## ABSTRACT

Soil organic carbon (SOC) and inorganic carbon (SIC) are critical components of terrestrial carbon pools, each playing distinct yet interconnected roles in soil health and the global carbon cycle. Although certain progress has been made in understanding the dynamics of SOC and SIC and their responses to farmland management practices in recent years, challenges remain due to incomplete theoretical frameworks and unclear practical pathways for elucidating SOC–SIC interactions. This mini-review synthesizes recent findings on the spatial distribution, transformation mechanisms, and mutual feedbacks between SOC and SIC in North China's croplands, where semiarid conditions and intensive agriculture create unique carbon cycling dynamics. Evidence suggests that organic amendments, irrigation regimes, and conservation tillage not only influence SOC accumulation but also alter SIC formation through shifts in soil pH, calcium availability, and microbial activity. Conversely, SIC—particularly pedogenic carbonates—can stabilize SOC by promoting aggregate formation and buffering soil acidity. We highlight key knowledge gaps, including the long-term stability of SOC–SIC linkages under climate change and the need for integrated monitoring approaches. Finally, we propose a prospective research agenda combining isotopic tracing, remote sensing, and machine learning to better quantify and manage SOC–SIC synergies for sustainable carbon sequestration in North China's agroecosystems.

## ABSTRACT

Soil organic carbon (SOC) and inorganic carbon (SIC) play critical roles in carbon sequestration and soil health; however, their distributions across soil aggregates under organic amendments remain insufficiently understood. We hypothesized that straw and biochar would promote the formation of macroaggregates, and enhance both SOC and SIC accumulation in macroaggregates. To test this hypothesis, we examined the effects of straw and biochar on aggregate structure, SOC and SIC distribution, and carbon conversion efficiency. Results showed that both amendments reduced the proportion of microaggregates and increased macroaggregate formation, with straw showing a slightly stronger effect. SOC increased under both amendments; the highest SOC content under straw occurred in the 1–0.5 mm fraction (7.3 g $kg^{-1}$), whereas the overall maximum was observed in the 2–1 mm fraction under high-rate biochar (9.4 g $kg^{-1}$). Biochar treatments resulted in larger newly formed SOC accumulation (1.3–3.5 g $kg^{-1}$) and greater conversion efficiency (52–62%) than straw treatment (0.8–1.3 g $kg^{-1}$, 22%). New SOC contributions were consistently highest in the 2–1 mm fraction, with the greatest contribution (36.5%) occurring under high-rate biochar. Relative to the control, both amendments increased SIC content in aggregates >0.5 mm, with biochar showing the greatest increase (3.5 g $kg^{-1}$). SIC distribution differed between amendments, peaking in the 1–0.5 mm fraction under straw but shifting to the 2–1 mm fraction under biochar. A strong positive correlation was observed between newly formed SOC and SIC in aggregates >0.5 mm, suggesting coupled stabilization of organic and inorganic carbon during aggregate formation. Overall, although straw more strongly promoted macroaggregate formation, biochar demonstrated greater potential for enhancing aggregate-associated carbon stabilization and increasing SOC and SIC sequestration in croplands of northern China.

**Keywords:** Soil organic carbon; Soil inorganic carbon, Soil aggregation; Biochar; Wheat straw

# Coupling mechanism of soil organic carbon and inorganic carbon

**ABSTRACT**

Soil inorganic carbon (SIC) in arid and semi-arid regions, especially pedogenic carbonates (PIC), plays a critical role in carbon sequestration and soil health, yet its coupling with soil organic carbon (SOC) fractions and microbial processes remains poorly understood. Here, we develop an integrated framework combining SOC fractions, nutrient status, microbial community structure and soil physicochemical properties to elucidate PIC accumulation patterns and the drivers of organic–inorganic carbon co-stabilization across different region–crop combinations. Field investigations were conducted in two typical cropping zones dominated by major crops in the arid region of Northwest China. Carbon fractions differed markedly among sites. Maize fields in Bole (B–M) had significantly higher PIC and SOC and were dominated by stable fractions, including mineral-associated organic carbon (MAOC) and heavy-fraction organic carbon (HFOC), along with enrichment of SIC, PIC and dissolved inorganic carbon (DIC). Cotton fields in Bole (B–C) were dominated by particulate organic carbon (POC) and lithogenic carbonates (LIC), whereas soils in Wuwei were dominated by labile SOC pools, i.e., dissolved organic carbon (DOC) and light-fraction organic carbon (LFOC). Correlation analyses showed that MAOC and HFOC were positively related to SIC, PIC and DIC, while DOC and LFOC were negatively related to SIC. Microbial diversity was tightly linked to carbon fractions, with fungal diversity more sensitive to coupled shifts in SOC and SIC, and bacterial communities more strongly regulated by inorganic carbon forms and pH. Microbial biomass carbon and nitrogen (MBC, MBN) were positively correlated with SOC, SIC and PIC but not with LIC, indicating greater reliance on pedogenic than lithogenic carbonates. Random forest and partial least-squares path modeling (PLS-PM) identified C:N ratio, cation exchange capacity (CEC), microbial status and MAOC as key mediators of PIC formation. The strong positive association between MAOC and SIC/PIC suggests that stable SOC may promote co-precipitation with carbonates and thus enhance organic–inorganic carbon stabilization. Our results verify a synergistic accumulation of organic and inorganic carbon fractions and highlight the bridging role of microbial diversity and nutrients in PIC formation. SOC and PIC form a positive feedback in dryland croplands, whereas labile carbon and SIC engage in competitive regulation. Coupling between microbial status and stable SOC fractions is a critical leverage point for enhancing carbon sequestration and soil health. These findings suggest that optimized irrigation, fertilization and crop configuration can strengthen the carbon sink function of arid farmlands.

## ABSTRACT

Soil organic carbon (SOC) is key to sustaining agricultural productivity and safeguarding ecosystem services amid daunting challenges from human activities and climate change. SOC embodies a continuum from coarse remnants of plant matter (particulate organic carbon, POC) to resilient mineral-associated organic carbon (MAOC), with each component responding uniquely to environmental factors, making assessment crucial. In our study, we compiled an extensive global dataset comprising 6,668 SOC data points, alongside 3,088 POC and MAOC observations. SOC accumulation is more closely associated with POC. POC shows stronger sensitivity to management and climate change than MAOC, indicating its potentially larger role in driving SOC dynamics under anthropogenic activities and climate change. Random Forest models unveil the strong influence of soil type on the spatial distribution and relative proportions of SOC pools, highlighting its pivotal role in shaping soil carbon composition. Our projections draw a sobering picture: mounting climate pressures lead to troubling decline in global SOC concentration. From 2060 to 2080, SOC loss under various climate scenarios is estimated to reach 0.7-1.2 times the $CO_2$ emissions from anthropogenic sources recorded in 2023 (40.9 Pg). These findings emphasize the urgent need to safeguard carbon reservoirs from the threats of human impact and climate change.

## ABSTRACT

The variations in SOC stock can substantially alter global carbon cycling, with potential to drive significant fluctuations in atmospheric carbon concentrations. Intensive land use changes and agricultural practices—particularly cropping system intensification, tillage operations, and erosional processes—have collectively driven massive carbon losses (40-133 Pg C) from global cropland soils over recent centuries. Although paddy fields account for less than 9% of global cropland area, they store a significant proportion of the global agricultural soil carbon pool (exceeding 14%), playing a pivotal role in the global carbon cycle. In southern China, paddy fields have been converted to upland crop cultivation to alleviate heavy metal pollution and water resource constraints. The organic carbon content in paddy soils exhibit 1.5–1.8 times higher than that of upland soils due to greater inputs of crop roots and litter-derived carbon, slower decomposition rates of organic carbon under anaerobic conditions and the critical role of Fe oxides in stabilizing organic carbon. Additionally, soil pH significantly regulates organic carbon storage in paddy soil systems. The conversion of paddy to upland soils disrupting key biogeochemical processes that regulate SOC cycling. Therefore, understanding these changes is of great significance for managing soil carbon sequestration mechanisms.

SOC can be divided into two primary fractions: mineral-associated organic carbon (MAOC) and particulate organic carbon (POC). Mineral-associated organic carbon (MAOC) plays a critical role in SOC stabilization through both chemical bonding with mineral particles and physical encapsulation within soil aggregates. Research findings indicate that the recalcitrant organic carbon pool, rather than labile organic carbon pools, constitutes the core mechanism governing paddy soil carbon sequestration function. Significant alterations in redox conditions caused by land use changes in rice paddies, particularly through fluctuations in soil moisture regimes, should markedly modulate the stability and transformation of OC-Fe complexes. The impact of conversion of paddy to upland soils on SOC components requires further investigation. The newly recognized ‘iron gate’ mechanism suggests that phenol oxidative activity is mainly controlled by Fe(II) and decreases with water-level decline. This leads to the accumulation of dissolvable aromatics and a reduced activity of hydrolytic enzymes, thereby enhancing SOC preservation. Knowledge of the interaction of Fe oxide with phenol oxidative and hydrolytic enzyme activity when conversion of paddy to upland soils may contribute to our general understanding of SOC stabilization.

Despite the growing understanding of above processes, the specific mechanisms underlying the changes in SOC stocks during the conversion of paddy to upland soils remain poorly understood. In particular, the roles of Fe oxides, soil enzyme activities, and Fe-oxidizing and reducing bacteria composition in this process require further investigation. The objective of the present study was to improve our understanding of the impact of paddy soil land use change on SOC stocks and the underlying factors regulating its persistence. To achieve this, the experiment of converting paddy to upland fields was designed. The aims of the present study were to (1) investigate the reasons of the SOC loss caused by paddy conversion to upland soils, and (2) to explore the mechanisms of Fe oxides in soil organic carbon stock under the conversion from paddy to upland soils. It was hypothesized that: (1) the conversion of paddy to upland soils led the SOC loss, and (2) this conversion would lead to the continuous aging and crystallization of Fe oxides, weakening the binding ability of Fe oxides with organic carbon and the 'iron gate' mechanism, resulting in a decline in SOC.

To address this, long-term rice cultivated fields were partitioned: i) converted to maize-maize (MM) cropping system, and ii) maintained rice-rice (RR) cropping system. Each cropping system included: control (CK), nitrogen, phosphorus and potassium fertilizers (NPK), and NPK combined with straw incorporation (NPKS). The seasonal dynamics of SOC stocks, Fe oxide forms, Fe-bound organic carbon stocks, related enzyme and soil properties have been continuously monitored. Results showed that SOC stocks in the MM cropping system decreased by 9-22% compared with the RR cropping system. The decrease of MAOC (16%) in SOC fractions was significantly higher than that of POC (7%), primarily attributed to the decline of the stocks of complexed ($Fe_{PP}$) (9%–10%), amorphous ($Fe_{HH}$) (9%–31%) Fe oxides, as well as their associated organic carbon stock ($Fe_{PP}$-OC: 5%–15% and $Fe_{HH}$-OC: 14%–33%) after the conversion of paddy to upland soils. After the conversion of paddy to upland soils, the absolute abundance of Fe redox bacteria significantly decreased, with the absolute abundance of Fe-reducing bacteria (FeRB) being substantially higher than that of Fe-oxidizing bacteria (FeOB). The dominant species of FeRB included *Anaeromyxobacter*, *Desulfobacca*, *Syntrophobacter*, and *Syntrophorhabdus*, while the dominant species of FeOB included *Leptothrix*, *Gallionella*, and *Rhodomicrobium*. Specifically, changes in FeRB further influenced Fe(II) levels, thereby driving transformations in Fe oxide forms and their associated Fe-bound OC content. After paddy conversion to upland soils, the ‘iron gate’ mechanism in protecting SOC loss was weakened due to the crystallization and aging of Fe oxide. In addition, increased activity of hydrolase further increased the loss of SOC. According to random forest (RF) model, the DOC, $Fe_{HH}$, $Fe_{HH}$-OC and $Fe_{DH}$ were found to be the most important variables for predicting the SOC, MAOC, POC. Moreover, correlation analysis illustrated that SOC, POC, MAOC gradually decreased with decreasing DOC, $Fe_{HH}$ and $Fe_{HH}$-OC. These findings indicated that the conversion of paddy to upland soils negative impacts SOC stocks by weakening the association between Fe oxides and SOC, underscoring the pivotal role of Fe oxides in SOC loss under paddy land use change.

# Management's Role in Loss of Color and Organic Carbon in Great Plain Soils of the United States

**Isaac Nelson[1*], Peter Tomlinson[1], and DeAnn Presley[1]**

[1] *Kansas State University (Department of Agronomy, Manhattan, Kansas, United States of America)*

isaacjn02@ksu.edu

**ABSTRACT**

Loss of carbon is an important issue that scientists have been trying to address since modern farming techniques became standard. Especially in the central Great Plains of the United States, the 1930's Dust Bowl is a recent catastrophe, but we are still suffering from a century of overworked soil. In the field, color can give us an insight into the nutrient dynamics that are going on in the soil, especially carbon/organic matter. Soil color is traditionally described using the Munsell soil color system with hue, value, and chroma.

During the study period 150 fields varying in management from native grassland, restored grassland, conservation farming, and conventional farming systems were sampled in Kansas. Two pedons were collected per field, for a total of 300 pedons sampled between 2022 and 2024 across Kansas. Soil profile descriptions were completed, and soil samples were collected for the 0-5, 5-10, 10 to the remainder of the A horizon, and by genetic soil horizon thereafter to a depth of 1 m. Bulk density, soil organic C (SOC), water stable aggregation, and particle size were analyzed for each sample.

During the field soil description, the Capsure Munsell Soil Color device was used to measure the moist soil color. In the Munsell system soil is described in hue, value, and chroma. The field descriptions have shown a lighter color value in the top of the A (0 to 5 cm) vs the bottom portion of the A horizon (10-15 cm) that wouldn't be explained by erosion, parent material or difference in mineral soil alone. This was most noticeable in the conservation-ag focused systems which have been no-tilled for 10-30 years at the time of sampling. This was mostly observed in no-till and some conventionally tilled fields. Mixing during tillage may be hiding some of this organic matter and color loss in conventional tillage systems.

However, root depth also matches up well with this loss of color in the top 10 centimeters and can show the role of our cropping systems in deteriorating carbon stores in the topsoil. Comparing how color chip differences appear among differences in cropping system, tillage, and texture can help to explore where carbon loss is happening in our soils.

## ABSTRACT

Nitrification acidifies soil, and the produced $H^+$ are neutralized by inorganic carbon (C) in soil leading to irreversible $CO_2$ emissions. $CO_2$ released by nitrogen (N) fertilizer-induced acidification is partitioned between solid ($CaCO_3$ re-precipitation), liquid (dissolved $HCO_3^-$ and $CO_3^{2-}$) and gaseous ($CO_2$) phases. Therefore, quantifying the effects of N fertilization on $CO_2$ emissions from soil inorganic C is an enormous challenge. $^{14}C$-labeled $CaCO_3$ was used as a model inorganic C to trace the released $CO_2$ caused by acidification by five fertilizers: chicken manure, urea, $KNO_3$, $NH_4NO_3$, and $(NH_4)_2SO_4$ added at three N rates. Cropland soil was homogenously mixed with $Ca^{14}CO_3$ powder and fertilizers, and the emitted $CO_2$ was trapped in NaOH solution to determine total $CO_2$ and $^{14}CO_2$ efflux originated from inorganic C. Fertilization, particularly ammonium-based fertilizers ($(NH_4)_2SO_4$, $NH_4NO_3$), strongly decreased soil pH by 0.35 units over 40 days. All fertilizers except $KNO_3$ increased total $CO_2$ emissions by 21%-490% compared to the unfertilized control soil. The fertilization effects on cumulative $^{14}CO_2$ emission induced by $CaCO_3$ neutralization, corresponded to acidification and decreased in the order $(NH_4)_2SO_4$ > $NH_4NO_3$ > urea > $KNO_3$ > chicken manure. Ammonium-based fertilizers induced the strongest $CO_2$ emissions originated from inorganic C, emitting 1.6-4.5 times more $^{14}CO_2$ than non-fertilized soils during the first nine days. The total $CO_2$ emissions from SIC were proportional to the fertilizer dose applied. Therefore, we conclude that both the choice of N fertilizers and their application rates need to be considered to control $CO_2$ emissions originated from inorganic C. The soil inorganic C losses should be prevented not only because of their irreversible contribution to atmospheric $CO_2$, but also to safeguard ecosystem services of $CaCO_3$, such as organic matter preservation, soil structure stabilization, and C sequestration.

# The Impact of Soil Heterogeneity on Organic Carbon Mineralization

**ABSTRACT**

Soil heterogeneity significantly influences the dynamics of organic carbon mineralization and carbon sequestration effects. To investigate the impact of soil heterogeneity on organic carbon mineralization and its underlying mechanisms in subtropical paddy soil, a laboratory-scale experiment was conducted. The paddy soil was stratified horizontally, and equal amounts of glucose were applied to different layers to create gradients of spatial heterogeneity in soil organic carbon (high heterogeneity, low heterogeneity, homogeneous, and no-carbon control). Diffusion and isolation treatments were set up using different layered materials to monitor the characteristics of organic carbon mineralization and changes in environmental factors. The effects of spatial heterogeneity in organic carbon distribution on mineralization were analyzed. The results showed that both the rate and cumulative amount of organic carbon mineralization decreased with increasing heterogeneity. The homogeneous treatment exhibited the highest mineralization rate, while differences between treatments under diffusion conditions were smaller than under isolation conditions. Diffusion effect on cumulative mineralization in the high-heterogeneity treatment was stronger than other treatments. Regardless of substrate diffusion, the dissolved organic carbon (DOC) and microbial biomass carbon (MBC) contents in layers with added substrate were significantly higher than in layers without substrate, while ammonium nitrogen ($NH_4^+$-N) content was lower. Under diffusion conditions, average DOC content of layers increased, while average MBC, $NH_4^+$-N, and nitrate nitrogen ($NO_3^-$-N) contents decreased. This study demonstrates that soil spatial heterogeneity influences organic carbon mineralization by altering substrate distribution and microbial microenvironments.

# Global warming potential in rice paddy soil applied with different fertilization and tillage management

**Mu seong Kim[1*] and Chang Oh Hong[1]**

[1] Department of Life Science and Environmental Biochemistry, Pusan National University, Miryang, Republic of Korea

*usinoyuri@gmail.com

## ABSTRACT

Previous studies on greenhouse gas emissions from paddy soils have often addressed tillage and organic amendments as independent factors. In this study, eight treatment combinations integrating till and no-till systems with four fertilization types including chemical fertilizer (NPK), NPK+composted manure (CM), NPK+green manure (GM), and NPK+CM+GM were installed. The objective of this study was to evaluate the effect of different fertilizations and tillage managements on greenhouse gas (GHG) emissions, net ecosystem carbon budget (NECB), net global warming potential (net GWP), and greenhouse gas intensity (GHGI) in rice paddy soil. Field experiment (2024–2025) was conducted at the Experiment Farm of Pusan National University in Miryang, Republic of Korea, using rice plant (*Oryza sativa* L.) as the cultivated crop. Total carbon (C) input was greatest with NPK+CM+GM (676 kg ha$^{-1}$), followed by NPK+CM (549 kg ha$^{-1}$), NPK+GM (248 kg ha$^{-1}$), and NPK (41.7 kg ha$^{-1}$). Total nitrogen (N) input was also greatest with NPK+CM+GM (121 kg ha$^{-1}$), followed by NPK+GM (105 kg ha$^{-1}$), NPK+CM (93.1 kg ha$^{-1}$), and NPK (91.4 kg ha$^{-1}$), reflecting the increasing contribution of organic amendments. Carbon dioxide ($CO_2$) emissions were approximately twice higher under till than no-till. In the comparison between NPK and NPK+CM, $CO_2$ emissions with NPK was higher than NPK+CM, implying that total C input did not affect $CO_2$ emissions. Mean value of methane ($CH_4$) emissions across fertilizations were about 20% higher with the no till than till. The trend of $CH_4$ emissions was similar to that of total C input, increasing with higher C input. Nitrous oxide ($N_2O$) emissions increased with increasing total N input. Nitrous oxide emission was the greatest with NPK+CM+GM and followed by NPK+GM, NPK+CM and NPK. The NPK+CM+GM showed the greatest NECB (13.0 Mg ha$^{-1}$), suggesting considerable C sequestration potential. The trend of NECB was similar to that of total C inputs, meaning that high C inputs may lead more C sequestration. Mean value of rice grain yield across all fertilizations was significantly higher under the till system than the no-till system. In both till and no-till, total biomass yields were not significantly different among all treatments, but the mean value of total biomass across fertilizations slightly higher with till than no-till. NPK+CM+GM had the highest value of net GWP but the lowest value of GHGI. In no-till, the values of net GWP and GHGI with NPK, NPK+CM and NPK+GM were similar. In till, net GWP increased from -5.49 to -4.54 and to -4.15 with from NPK to NPK+CM and to NPK+GM, respectively. However, the trend of GHGI was opposite to that of net GWP. A higher value of net GWP suggested a greater overall contribution to global warming. Even though NPK+CM+GM had the greatest NECB, it exhibited the greatest net GWP due to its large greenhouse gas emissions. However, the lower GHGI value with this treatment reflected that its grain yield was substantial enough to offset its higher net GWP.

# Soil Carbon-Nitrogen Pools in Different Land Use Types and Varying Time Scales: Implications for Soil Health and Sustainable Agriculture

**Samuel Ayodele Mesele[1]*, Abosede Busayo Babatunde[2], and Joseph Uponi[2]**

[1] *International Institute of Tropical Agriculture (IITA), Monrovia, Liberia*

[2] *International Institute of Tropical Agriculture (IITA), Ibadan, Nigeria*

*E-mail Address of Presenting Author: s.mesele@cgiar.org

**ABSTRACT**

This study critically examines the comparative effects of various land use types and the duration of no-till practices on soil carbon (C) and nitrogen (N) pools, along with a range of soil health indicators on an Oxic Paleustalf (Ferric Luvisol) within a moist lowland forest ecology. Given the escalating concerns over soil degradation and the urgent need for sustainable agricultural practices, this research emphasises the importance of understanding how different agricultural methods impact soil health in Nigeria and other similar pedoclimatic regions. The study evaluates the influence of conventional tillage, no-till farming, and natural forest ecosystems on vital soil properties. Apart from the various soil and carbon fractions, key indicators such as bulk density, pH, aggregate stability, moisture retention, leaching potential, and nutrient holding capacity were assessed to determine the extent of soil health improvements resulting from notill practice over varying time scales. The findings reveal that while notill practices markedly enhance soil C and N pools, the duration of these practices is critical in manifesting significant impacts on soil health. Notably, the study highlights the potential of notill agriculture to restore soil functions comparable to those of undisturbed ecosystems; however, it also underscores the limitations associated with shorter adoption periods. This research provides valuable insights for agronomists and land managers in mesic forest and savanna ecologies, aiming to develop effective strategies that enhance soil health and agricultural sustainability. Ultimately, the study advocates for tailored land management approaches that not only conserve soil health but also promote resilience in agricultural systems amidst changing environmental conditions.

**ABSTRACT**

Soil acidification is a global problem raising in the last decades mainly because of intensive nitrogen (N) fertilization of croplands and high atmospheric N deposition. The most natural acidification processes are boosted by human induced acceleration of biogeochemical cycles of nutrients and ballast elements, leading to irreversible losses of base cations from soils by leaching and removal with harvest, and to $CO_2$ fluxes into the atmosphere.

In this talk, we will raise the awareness of soil acidification processes mainly related to N fertilization in intensive agriculture. Acidification mechanisms and soil buffering systems will be shortly presented. As rhizosphere is one of the most important hotspots of soil acidification, the processes at root surface and the root-microbial interactions leading to $H^+$ release will be visualized and discussed. Despite microscale of rhizosphere acidification processes, and field scale of N fertilization, the consequences are of global importance. The losses of soil inorganic C (SIC) – mainly $CaCO_3$ – as $HCO_3^-$ leaching and as $CO_2$ release from calcareous soils amount for 7.5 Tg C $yr^{-1}$. Lime application to remediate soil acidity is another direct source of $CO_2$ emission and amounts for 273 Tg C $yr^{-1}$ as $CO_2$ release.

In contrast to C losses as $CO_2$ by soil organic matter by decomposition, the $CO_2$ release by $CaCO_3$ neutralization including lime application are unidirectional and irrecoverable: it is impossible to bring the released $CO_2$ back into soil as $CaCO_3$. Functions of SIC for plant nutrition, soil fertility and agroecosystem stability will be presented. Consequences of SIC depletion and strategies to remediate and control soil acidification will be discussed. Compared to SOC, wherein C stocks can be increased through management and organic fertilizer input, the SIC losses are irreversible and cause significant decline in soil health, ecosystem services, and functions. Concluding, N fertilization induced soil acidification and $CO_2$ losses from inorganic C are major C loss pathways, which jeopardize global efforts to mitigate climate change through SOC sequestration and dramatically decrease soil fertility.

**ABSTRACT**

This study evaluates the impacts of long-term land use - specifically arable agriculture, livestock grazing, and afforestation with windbreaks established in the 1960s - on soil organic carbon (SOC) stocks and prospective carbon sequestration in the Shiraki Plain, Dedoplistskaro Municipality. Soil samples were collected across different land uses and analysed to quantify key soil fertility parameters and to evaluate their correlation with SOC content. The findings demonstrate distinct variability in SOC stocks across land use types. Soils beneath windbreaks, undisturbed for over sixty years, had the highest organic carbon, likely attributable to continual organic matter input via leaf litter and minimal anthropogenic disturbance. Pasture soils exhibited intermediate SOC concentrations, driven by persistent rhizodeposition and reduced mechanical perturbation. Conversely, cultivated soils subjected to frequent tillage and removal or burning of crop residues displayed substantially diminished SOC, reinforcing the hypothesis that improper soil management accelerates long-term soil carbon depletion.

Soils across all land-use types were alkaline and had high carbonate content. They also had high potassium levels but low nitrogen and phosphorus levels. The high concentration of carbonates probably limits the amount of phosphorus available by causing it to precipitate or become fixed in forms that plants cannot readily use. This reduction in available phosphorus can reduce plant growth, which in turn can affect how much carbon remains stored in the soil. The soils were mainly medium- to heavy-clay. They had a high cation-exchange capacity, which helps protect soil carbon by forming stable organomineral bonds.

The results show that windbreak belts are important for carbon storage because they help sequester carbon in the soil. They also provide ecological benefits, such as reducing wind erosion and maintaining soil moisture. Actions such as improving damaged windbreaks, reducing residue burning, maintaining ground cover, and adopting conservation tillage can increase SOC storage on the region's dryland farms by enhancing soil organic matter

## ABSTRACT

Intensification of Mediterranean orchards often accelerates soil degradation and threatens long-term productivity. Alley cover crops are promoted as a climate-smart practice, yet their influence on carbon (C) and nitrogen (N) distribution with depth is still poorly quantified (Montanaro et al., 2017). We assessed the effect of alley cover cropping on soil organic carbon (SOC) and total nitrogen (TN) in 0-1 m depth in six commercial almond orchards in Central Spain: three farms with alley cover crops established for 7 years (CC) and three farms with bare soil managed by tillage and herbicides (BS). In each orchard, six soil profiles (0-100 cm) were opened and four horizons (0 - 10, 10 - 40, 40 - 80, 80 - 100 cm) were identified and sampled. Bulk density, SOC, TN and their stocks were determined, together with cover-crop biomass (biomass) and its C and N inputs (CC_TC, CC_TN). In the surface horizon, SOC contents were very similar under both treatments (10.5 - 10.6 g $kg^{-1}$), with SOC stocks of 11.7 Mg $ha^{-1}$ (CC) and 12.1 Mg $ha^{-1}$ (BS). In contrast, SOC was higher under CC at 10 - 40 cm and 40- 80 cm horizons: 2.34-4.85 g $kg^{-1}$ in BS and 4.83-5.77 g $kg^{-1}$ in CC. SOC stocks ranged 11.89-21.79 Mg $ha^{-1}$ in CC and 17.67-28.07 Mg $ha^{-1}$ in BS. Although SOC at 80-100 cm was higher in BS (6.12 g $kg^{-1}$) than in CC (2.44 g $kg^{-1}$), total SOC stocks in the 0 - 100 cm profile reached 66.5 Mg C $ha^{-1}$ under CC compared with 49.4 Mg C $ha^{-1}$ under BS, a net increase of about 35 %. TN stocks were higher in BS than in CC (5.7 Mg $ha^{-1}$ and 7.8 Mg $ha^{-1}$ in CC and BS, respectively) due to a higher TN stock in horizon 2 of BS, with no significant differences in the other horizons between treatments. Biomass, CC_TC and CC_TN were significantly and positively correlated with SOC ($r = 0.4\text{-}0.5$; $P < 0.001$). These relationships indicate that orchards receiving larger inputs of cover-crop biomass as litter and root exudates, and associated C and N, are related to SOC and TN accumulation and storage > 10 cm depth. Overall, alley cover crops in almond orchards enhanced subsurface C storage and reshaped C-N profiles, highlighting the need to include deeper horizons when quantifying the mitigation potential of perennial cropping systems.

## ABSTRACT

Understanding how land use practices influence soil organic carbon (SOC) chemistry and its interactions with soil aggregation processes is essential for predicting soil structural development and C sequestration potential. Nevertheless, the mechanisms linking SOC chemical composition to soil aggregation processes, aggregate stability, and aggregate-associated C under contrasting land uses remain insufficiently understood. Herein, we aimed to disentangle the relationships between SOC chemical composition and aggregate formation, aggregate stability, and aggregate-associated C under contrasting land uses. To achieve this goal, soil samples (0–20 cm) were collected from sites with comparable pedogenesis, general soil characteristics, and soil classification (Typic Haplustalfs) across seven land uses: forest (FR), pasture (PT), corn plantation (CO), sugarcane plantation (SC), cassava plantation (CA), orchard (OR), and abandoned land (AD). All soil samples were fractionated into five aggregate-size classes (>2000, 500–2000, 250–500, 53–250, and <53 μm) using a wet-sieving procedure. Soil aggregate stability was evaluated by calculating the mean weight diameter (MWD) and geometric mean diameter (GMD). All separated aggregate fractions were analyzed for their C content using a CHN determinator. The chemical composition of SOC was characterized using solid-state $^{13}C$ nuclear magnetic resonance (NMR) spectroscopy. Among the contrasting land uses, the macroaggregate (>2000 μm), 0.05–0.70 g $g^{-1}$, was significantly greater in PT soil, whereas the <53 μm fraction, 0.04–0.12 g $g^{-1}$, was significantly greater in CA soil, compared to the other land uses ($P < 0.05$). The MWD and GMD, ranging from 0.50–3.64 and 0.47–1.35 mm, respectively, were significantly higher in PT soil ($P < 0.05$). The amount of SOC stored in the >2000 μm fraction (0.96–13.34 mg C $g^{-1}$) was significantly higher in the PT soil, whereas that in the <53 μm fraction (0.55–1.90 mg C $g^{-1}$) was significantly higher in the CA soil ($P < 0.05$). Correlation analysis showed that the methoxy C % was positively correlated with the proportion of >2000 μm fraction, whereas the aromatic C-O % was positively correlated with the proportion of <53 μm fraction ($P < 0.05$). The MWD and GMD were positively correlated with the alkyl C % ($P < 0.01$) and methoxy C % ($P < 0.05$) and negatively correlated with aromatic C % ($P < 0.05$). The *O*-alkyl C %, including methoxy C % or carbohydrate C %, was positively correlated with SOC accumulation in the >2000 and 500–2000 μm fractions, while the aromatic C-O % was positively correlated with SOC accumulation in the <53 μm fraction ($P < 0.05$). Overall, the findings highlight that methoxy C % or carbohydrate C % may be considered key chemical components for promoting the formation and SOC accrual of macroaggregates under divergent land uses. Moreover, alkyl C % and methoxy C % are presumably desirable chemical components contributing to soil aggregate stability.

# Soil carbon stocks and sequestration rates in Northern Irish grasslands

**Selva Dhandapani[1*], Chris Chagumaira[1], and Alex Higgins[1]**

[1] *Soil Biogeochermistry and Terrestrial Ecology Research Programme, Agri Food and Biosciences Institute, Belfast, UK.*

*E-mail Address: Selvakumar.dhandapani@afbini.gov.uk

**ABSTRACT**

It is estimated that global grasslands store 236 giga tons of carbon (C) in soil belowground, playing an important role in global climate change mitigation. Maximising soil carbon (C) stocks and sequestration in grasslands is crucial for climate change mitigation in Northern Ireland (NI), as grasslands cover ~95% of farmlands in NI. As part of Soil Nutrient Health Scheme, the most comprehensive regional soil nutrient sampling programme undertaken in the world, we aim to understand the environmental and management factors influencing C storage and sequestration in Northern Irish grasslands. Soil C and nitrogen (N) stocks were measured to a depth of 30 cm across 257 fields that were also surveyed in 2004. We found significant increase in soil C ($p$=0.0005) and nitrogen (p=0.0001) stocks over the last two decades, indicating sequestration. Field topography ($p$=0.0089) and depth ($p$ <0.0001) were significant predictors ofC stocks, while soil type had no impact. Flat fields stored more C (63.68 Mg C/ha) than undulating fields (54.66 Mg C/ha). We also found that adjacent hedgerow soils have significantly greater C and N stocks than the paired field soils, which is more pronounced in the deeper layers. Relative topography of hedgerows to the fields also significantly influenced C and N stocks, with hedgerows that were in lower altitude than fields showed greater soil N stocks, and hedgerows that were at the same altitude level as fields showing greater C stocks than field soils, while other relative topography classifications showed minimal variations. Soil sampling to full depth (up to 1m) is ongoing in these fields. Preliminary results from 162 sites indicate reduction in C stocks with depth: 0–15 cm (62.18), 15–30 cm (41.67), 30–45 cm (38.44), >45 cm (21.01 Mg C/ha), with 64% of soil C stored in the top 30 cm. Using field metadata and soil biogeochemistry data, we are applying modelling approaches to identify ideal management strategies for maximum C sequestration in NI grasslands.

# A Large Carbon Stock in Global Coarse Woody Debris and Its Contribution to Soil Carbon Dynamics

**Yuxin Zhang[1,2,*], Yuanyuan Huang[1]**

[1] Key Laboratory of Ecosystem Network Observation and Modeling, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, 100101, China

[2] University of Chinese Academy of Sciences, Beijing, 100101, China

*E-mail Address of Yuxin Zhang (zhangyuxin243@mails.ucas.ac.cn)

**ABSTRACT**

The global carbon budget framework is critical for formulating effective climate change mitigation strategies. As an important component of the soil carbon pool, coarse woody debris (CWD) stores approximately 8% of global forest carbon. However, its stock dynamics remain poorly understood within the global carbon budget, which could lead to substantial biases in estimating terrestrial carbon sink capacity and future carbon dynamics. To address this knowledge gap, we developed a global box-model framework to simulate CWD carbon stock dynamics, accounting for carbon inputs from aboveground vegetation mortality and outputs from decomposition. Notably, existing studies whether data-driven approaches or Dynamic Global Vegetation Models (DGVMs) have mainly treated CWD decomposition rate as a constant. Yet decomposition rates show pronounced global heterogeneity driven by environmental conditions, climate, wood traits, and biotic processes. Therefore, we compiled 2,477 observations of CWD decomposition rates from the literature and vegetation trait datasets and established a machine learning model to predict the global pattern of CWD decomposition rates. This model incorporates multidimensional drivers, including environmental factors, climate, wood traits, forest attributes, and biotic effects. Our work aims to provide a more accurate estimate of global CWD carbon stock dynamics, thereby offering essential scientific evidence to refine the global carbon budget and enhance the predictive capacity of terrestrial carbon cycle models.

**ABSTRACT**

The soil carbon pool, as the largest carbon reservoir in terrestrial ecosystems, holds approximately twice the carbon stored in the atmospheric carbon pool and two to three times that of the vegetation carbon pool (Zhao et al., 2018). Soil inorganic carbon constitutes a vital component of the soil carbon pool. SIC represents mineral carbon formed during soil weathering, composed of primary and secondary carbonates. Calcium carbonate ($CaCO_3$), as the primary constituent of soil carbonates, significantly influences soil physical structure, chemical properties, carbon sequestration processes, acid-base equilibrium, and productivity (Ding et al., 2025), holding substantial scientific significance in soil environmental research.

A soil chronosequence refers to a set of soils of different ages originating from the same or similar parent material and formed under comparable environmental conditions (Chen et al., 2011). It connects the evolutionary history of soils and translates spatial differences between soils into temporal variations, thereby reflecting the rate and direction of soil formation changes (JIAO et al., 2020). Consequently, establishing soil chronosequence can be used to simulate the processes and rates of SIC leaching.

*Table 1 Table of Profile IDs versus Pedogenic Ages*

| Profile | CX00 | CX01 | CX02 | CX03 | CX04 | CX05 | CX06 | CX07 | CX08 |
|---|---|---|---|---|---|---|---|---|---|
| Soil age | 1100 a | 950 a | 550 a | 350 a | 280 a | 200 a | 170 a | 120 a | 60 a |

This study focused on soil calcium carbonate in coastal regions. By establishing a millennial soil chronosequence, we determined the calcium carbonate reserves at different soil depths and formation ages to investigate the spatio-temporal variation of soil inorganic carbon in coastal areas. Results indicate: (1) SIC Stock are high in the deep soil layer (60~100 cm) and low in the surface layer (0~20 cm).

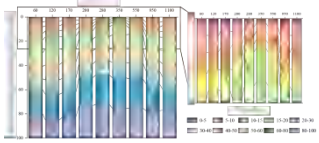

*Figure 4 Percentage of SICs at Each Soil Layer Depth Interval*

(2) According to the function fitting results, the exponential function is the best-fit model for describing the relationship between soil inorganic carbon Stock (SICs) and soil age. SICs exhibit a decreasing trend with increasing soil age.

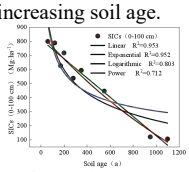

*Figure 5 Model fitting of SICs (0-100 cm) against pedogenic age*

Leaching-driven translocation of SIC to deeper layers is a primary mechanism for its depletion over pedogenic time.

**Graphical ABSTRACT**

## Highlights

180 days of laboratory culture experiment revealed the effects of biochar supported ammonia nitrogen on organic carbon composition and microbial composition.
Ammonia nitrogen supported by biochar reduces soil carbon emission and improves the stability of soil organic carbon.
Biochar supported ammonia nitrogen is a new type of nitrogen fertilizer that can effectively reduce carbon emissions.

## ABSTRACT

Soil organic carbon (SOC) can influence soil carbon emissions and organic carbon (SOC) composition, with soil microorganisms playing an important role. However, the effects of biochar-loaded NH+ 4-N (BN) form on soil carbon emissions and its regulation of changes in soil SOC fractions remain unclear. As a result, a 180-day incubation study was performed utilizing three distinct types of nitrogen inputs: a single application of chemical nitrogen fertilizer (CF), a combination of biochar and chemical nitrogen fertilizer (BF), and biochar-loaded nitrogen (BN). Our results showed that compared to the CF (CK), BF addition increased soil carbon emissions (3.79), while the addition of BN reduced soil carbon emissions (2.26). BN decreased the C-mineralization of recalcitrant and labile C pools. Moreover, BN effectively enhanced the relative stability of soil dissolved carbon. By comparing the functional genes of microorganisms involved in carbon degradation, it was found that S-β-XYS and S-β-GC enzyme activities and gene expression varied significantly. Compared to CF, the activity of S-GC was significantly elevated in both BF and BN treatments at the 180-day. Furthermore, the activity of S-XYS was highest in BN at the 180-day compared to the remaining three treatments. Both S-β-XYS and S-β-GC enzymes regulate this SOC turnover in response to nitrogen input forms. BN considerably enhanced the relative prevalence of Sphingomonas and facilitated the decomposition and utilization of aromatic carbon, thereby influencing the stability of SOC. Overall, BN altered the fractions of SOC composition by modifying microbial community structure and enhancing carbon degrading enzyme activities, thereby reducing carbon emissions in soil environments.

## 1 Introduction

Global climate change, driven by the greenhouse effect resulting from rising CO2 concentrations, has significantly impacted ecosystems worldwide, altering the carbon (C) cycle in terrestrial ecosystems (Reich et al. 2020). The soil carbon pool is the largest and most stable carbon pool in the world (Lal 2004), with a carbon storage capacity 3.3 and 4.5 times greater than that of the atmospheric and biological carbon pools, respectively (Batjes 2016; Lal 2008; Lehmann et al. 2015). Consequently, minor alterations in the soil carbon reservoir can have a substantial impact on atmospheric CO2 levels. In particular, agriculture activities contribute to 17% of global carbon emissions (Delgado-Baquerizo et al. 2017), with CO2 from soil respiration being the largest source of atmospheric CO2 (Bradford et al. 2016; Falkowski et al. 2000; Lal 2008; Lehmann et al. 2015). Soil organic carbon (SOC) serves as the largest organic carbon pool on land (Bradford et al. 2016), whether soil acts as a carbon source or sink for atmospheric CO2 under global warming climate conditions depends on the rate of SOC decomposition (Davidson et al. 2006; Friedlingstein et al. 2020). Thus, it is essential to focus on the stability of organic carbon and soil respiration to help reduce the rise in atmospheric CO2 levels and anticipate climate change.

The terrestrial carbon and nitrogen (C-N) cycles are tightly coupled, with nitrogen inputs significantly impacting the soil carbon pool (Vitousek 1994). The potential for soil carbon sequestration is strongly correlated with N inputs (Bradford et al. 2016; Fang et al. 2017; Hurbert et al. 2020; Liang et al. 2017; Tipping et al. 2016). N input affects soil carbon sequestration potential mainly by altering soil microbial activities, which subsequently influences the microbial-mediated decomposition of SOC and dissolved organic carbon (DOC) (Xiao et al. 2019). N additions can increase soil N effectiveness (Buchkowski et al. 2017; Tripathi et al. 2018; Zhaltsina et al. 2015), which promoted soil C accumulation mainly by decreasing soil respiration (de Vries et al. 2014; Jansson et al. 2010; Liu et al. 2010; Zhang et al. 2018) and stimulating plant carbon exudation (Chen et al. 2019; Chen et al. 2021c; Pessoney et al. 2020; Wu et al., 2024). However, the opposite effect also exists: N addition promotes microbial respiration by increasing organic matter inputs and decreasing N limitation to microorganisms, which hinders soil C accumulation (Allison et al. 2009). There remains uncertainty regarding the decomposition of soil carbon pools (especially SOC and DOC) due to N inputs, and the impact of N inputs on the stability of soil carbon pools is not yet fully understood (Jiao et al. 2021; Feng et al. 2022; Lu et al. 2021). Therefore, studying the effect of N inputs on the soil carbon cycle process is essential for providing an theoretical foundation for the global carbon balance.

It has been found that the quality of exogenous substrate added into soils determines their effect on soil carbon mineralization. Han et al. (2022) found that green manure and straw fertilizers affected soil C mineralization by influencing key microbial taxa involved in soil C mineralization. Yang et al. (2023) suggested that different N applications affected soil C pools, primarily by modifying the abundance of carbon cycle genes and enzymes responsible for the degradation of soil organic carbon (SOC), particularly those related to the breakdown of cutinlike and resistant carbon. Previous studies have extensively explored the effects of various N input forms, such as chemical nitrogen fertilizers, biochar, and biochar combined with chemical nitrogen fertilizer on soil organic carbon cycling (Zhang et al. 2022; Zhang et al. 2023). Zhang et al. (2018b) proposed biochar-loaded NH+ 4-N as a novel form of nitrogen input, which can effectively reduce the emission of the greenhouse gas N2O by adsorbing NH+ 4-N through complexation, cation exchange, and electrostatic attraction. Biochar is a carbon-dense material created via pyrolysis in an environment with limited oxygen, exhibiting a high degree of stability (Leng et al. 2019; Li et al., 2024; Weber et al. 2018). Numerous studies have concluded that biochar offers a promising route to achieving net zero emissions (Cayuela et al. 2014; Lehmann et al. 2021; Nan et al. 2020; Sui et al. 2016). Biochar production and application can effect up to 12% of carbon emissions from human sources (Woolf et al. 2010). However, it is not yet clear how N input forms such as biochar loaded with NH+ 4-N affect organic carbon turnover. Extracellular enzymes secreted by microorganisms directly isolate soil carbon and nitrogen. The remaining portion (up to as large as 40%) can be released into the soil environment (Sinsabaugh et al. 2008). Enzymatic activities are closely linked to the activity of specific carbon degrading enzymes expressed by microbial communities.

Therefore, this study conducted a 180-day soil incubation experiment with the following objectives: (1) to investigate the impacts of biochar-enhanced NH+ 4-N on soil carbon emissions and the fractions of organic carbon, and (2) to shed light on the microbiological mechanisms underlying how biochar-loaded NH+ 4-N affects the stability of organic carbon; (2) biochar loaded with NH+ 4-N affects the activities of carbon-degrading enzymes and microorganisms; and (3) biochar affects microbial utilization of carbon by altering the structure of organic carbon, ultimately influencing soil carbon emissions.

## 2 Materials and methods

### 2.1 Soil and biochar preparation

The soil sample was collected from the 0–20 cm soil layer at the Qingdao Tobacco Resources and Environment Field Scientific Observation and Experimental Station of the Chinese Academy of Agricultural Sciences (36°20′ N, 120°14′ E). After homogenization and drying, the soil was sieved through a 2-mm mesh. The soil utilized in this experiment was classified as Alfisols according to the Alfisols (FAO Soil Taxonomic System), with the fundamental chemical properties prior to the test detailed in Table S1.

Biochar is prepared from biogas, and the preparation process of biogas can be found in previous reports (Zheng et al. 2020; Zheng et al. 2018c; Zheng et al. 2018b). The biochar preparation process is as follows: the pyrolysis temperature is 700°C, the heating rate is set at 5°C per minute, with a residence time of 60 minutes, and nitrogen (N2) is used as the inert shielding gas at a purity of 99.999% and a flow rate of 0.5 dm³ per minute. After biochar pyrolysis was complete, the biochar was pulverized, sieved through a 0.25-mm mesh, and stored in a dryer for later use, designated as BC. The preparation process for biochar-loaded NH+ 4-N is as follows: the loading solution is NH4Cl (1000 mg L−1), and the pH of the conditioning solution is 7.0. The biochar amount is 40 g L−1, shaken in a Constant Temperature Oscillation Chamber (25°C; 140 r min-1) for 48 h, centrifuged (4000 r min-1, 10 min), filtered and air-dried for 48 h. The NH+ 4-N loading of biochar is determined by calculating the concentration difference of NH+ 4-N in the solution before and after adsorption. The loading amount of biochar NH+ 4-N used in this experiment was 1.1975 mg g-1, and the biochar loaded with NH+ 4-N was labelled BC-N. The main physicochemical properties of DC and BC-N are summarized in Table S2.

### 2.2 Incubation experiment

Four different treatments were established for the incubation experiment: (1) blank control without fertilization (CK); (2) one-time application of synthetic nitrogen fertilizer (analysis of pure NH4Cl) (CF); (3) Biochar in conjunction with synthetic nitrogen fertilizer (BF); (4) biochar-loaded NH+ 4-N ( BN. The nitrogen content in each treatment was calculated to be consistent with the field nitrogen application rate (20.56 mg pure NH4Cl added for the BF treatment). The amount of biochar added in BF and BN treatment was 1.68 g.

The specific procedure of the test was as follows: 100 g of air-dried soil was placed into a 500 mL jar, and sterilized water was added to reach 30% of the maximum field moisture capacity. All soil incubations were initially cultured in a dark environment at 25°C for a period of 30 days, with the jar sealed using parafilm jelly and parafilm. After that, nitrogen fertilizer and/or biochar was thoroughly mixed with the soil, and the water was replenished to 60% of the maximum field moisture capacity. All soil samples were placed in jars containing 15 mL centrifuge tubes with 10 mL of 2 mol L-1 NaOH, as well as 10 mL centrifuge tubes with 5 mL of HCl. Three blank controls without soil samples were set up under the same conditions. At the beginning, incubation of 0–14 d, NaOH solution was replaced every 2 days, and then, NaOH solution was replaced every 7 days during 15–117 d. After that, NaOH solution was replaced every 14 days until day 181 d. Sterilized water was added during incubation to maintain a constant incubation weight. All soil samples were held at 25°C in a dark room for 181 days. After 7 days and again at 180 days of incubation, three samples from each treatment were randomly and destructively collected to measure CO2 emissions, carbon-degrading enzyme activity, and metagenomic sequencing. Soil collected from each jar was separated into three parts: one portion (40 g) was promptly utilized for the analysis of dissolved organic carbon (DOC) fractionation and microbial biomass carbon (MBC); another portion (20 g) was dried in the air for the fractionation and analysis of soil organic carbon (SOC) content, along with other chemical measurements including available phosphorus, available potassium, ammonium nitrogen, and nitrate nitrogen; the remaining portion (40 g) was kept at -80°C for the extraction of soil DNA and subsequent sequencing.

### 2.3 Measurements of soil respiration and biochemical properties

The soil cumulative carbon emission (soil respiration) was calculated (Xie et al. 2022) as described below: 5 mL of 1%NaOH was transferred to a 150 mL triangular flask, followed by the addition of 5 mL of 2 mol·L-1 BaCl2 and 1–2 drops of phenolphthalein . The solution was then titrated with 0.1 mol·L-1 HCl until the red color disappeared. The volume of HCl used was recorded, and the amount of soil CO2 emission was calculated. The calculation formula is given in Equation (1).

$$CO2\ emission\ (mg\ g\text{-}1) = (V0\text{-}V1) \times cHCl \times MCO2/m \quad \text{Equation (1)}$$

Where V0 represents the volume of HCl used to titrate the blank (mL), V denotes the volume of HCl utilized to titrate the sample (mL), cHCl indicates the concentration of hydrochloric acid (mol·L-1), M is 22 mg mmol-1, and SW refers to the dry weight of the soil (g).

The results of carbon mineralization in the soil were modelled using a first-order function, as well as first-order and zero-order functions, according to the following Equations (2) and (3).

$$Cm = C0 \times (1\text{-}\exp(\text{Equation (2)}$$

$$Cm = C0 \times (1\text{-}\text{Equation (3)}$$

Where Cm represents the mineralized C (g C kg−1 dry soil) after 180 days of incubation, and t denotes the incubation time (days). In the first-order function, C0 indicates potentially mineralizable C (g C kg−1 dry soil), and k is the rate constant (day−1). In the combined first- and zero-order function, CR refers to rapid potentially mineralizable C (g C kg−1 dry soil), and k is the rapid rate constant (day−1). Ac (g C kg−1 dry soil·day−1) signifies the rate of slowly mineralizable C equivalent to "CS ×kS," where CS represents slowly mineralizable C and kS is the slow rate constant).

Soil pH was assessed with a Sartorius PB-10 pH meter using a 1:2.5 ratio of soil to deionized water. Available phosphorus (AP) was measured by the molybdenum-antimony colorimetric method, while available potassium (AK) was quantified using the ammonium acetate leaching-flame photometric technique. Soil ammonia nitrogen (NH+ 4) and nitrate nitrogen (NO− 3) were extracted using 2 mol·L-1 KCl and determined using a flow injection autoanalyzer (SEAL-AA3, Germany). Soil organic carbon (SOC) was analyzed using an HT1100Exa Analyzer (Jena Analytik, Germany) analyzer. Total nitrogen (TN) was determined using the Semi-Micro-Kjeldahl method. Microbial biomass carbon (MBC) was determined utilizing chloroform extraction methods, while dissolved organic carbon (DOC) was extracted with 0.5 mol·L-1 K2SO4 and determined using IC5000+MultiC/N3100 (Jena Analytik, Germany) analyzer. β-glucosidase (S-β-GC), β-xylosidase (S-β-XYS), N-acetyl-β-glucosaminidase (S-NAG), and cellulase diisocharide hydrolase (S-CI) were determined using fluorescence analysis with 96-well enzyme-labelled plates.

### 2.4 SOC and DOC fractionation

The fractionation of soil organic carbon was analyzed employing solid-state 13C nuclear magnetic resonance (13C-NMR) combined with cross-polarization and magic-angle spinning (CPMAS). The procedure included weighing 7.5 g of soil into a centrifuge tube and then adding 50 mL of a 10% HF solution. The mixture was shaken at 25°C for 1 hour (300 r min−1), centrifuged at 3500 rpm for 10 minutes, and the supernatant was subsequently discarded. The procedure was repeated eight times, with the shaking durations of 1 hour (repeated four times), 12 hours (repeated three times), and 24 hours (once). Afterward, the sample was washed with deionized water and freeze-dried. A neutral pH, freeze-dried, and then ground sample (at 60 g) was packed into a 4-mm ZrO2 rotor at a 7 kHz rotation speed. The 13C resonance frequency was set at 100.625 MHz and chemical shifts were calibrated with the standard glycine. The measurement parameters consisted of a sampling time of 10 ms, a contact time of 10 ms, a spectral width of 100 kHz, a pulse width of 4 μs, a cycle delay of 1 s, and a total of 4096 scans. Functional group areas were calculated using MestReNova software. The spectra were integrated as follows: 0–45 ppm (Alkyl-C), 45–110 ppm (O-Alkyl-C), 110–165 ppm (Aromatic-C), 165–210 ppm (Carbonyl-C). Aliphaticity (Alkyl-C/O-Alkyl-C ratio), aromaticity (Aromatic-C/O-Alkyl-C ratio), and combined index (Alkyl-C × Aromatic-C/ O-Alkyl-C ratio) were calculated as indicators of soil organic carbon decomposition.

To analyze the structure of soil water-soluble soil organic carbon (DOC), dissolved organic matter was extracted with fourier-transform ion cyclotron resonance mass spectrometry (FTICR-MS) was employed. The DOC extracted from the soil involved the following steps: 2 kg of fresh soil was weighed, and 20 mL of ultrapure water was added. The mixture was shaken at a constant temperature of 25±1°C for 8 hours. Subsequently, the sample was centrifuged at 4200 rpm for 20 minutes, and the supernatant was filtered through a 0.22 μm filter membrane. The DOC concentration in the supernatant was measured after undergoing solid-phase extraction (SPE) purification using Agilent Bond Elut PPL. The SPE procedure included adjusting the sample pH to 2.0 with 1 mol·L -hydrochloric acid, followed by the addition of 12 mL of methanol and 12 mL of 0.01 mol·L -HCl to activate the SPE column. Next, the sample was gradually introduced into the column at a flow rate of about 2 mL min−1. After the sample had been processed, 18 mL of 0.01 mol·L -HCl was utilized to rinse the column and remove any salts. The column was then dried with a nitrogen stream, and the organic compounds were eluted using 12 mL of methanol. The collected eluate was evaporated to dryness under a nitrogen flow. Finally, the residue was reconstituted in 1 mL of a 1:1 aqueous-methanol solution prior to FT-ICR-MS analysis. The samples were analyzed using a SolariX FT-ICR-MS system from Bruker. Ionization was conducted in negative ion mode through electrospray ionization (ESI). Key instrument parameters included a continuous injection rate of 120 μL h−1, a capillary inlet voltage of −4.0 kV, an ion accumulation time of 0.06 seconds, and a mass range of 300 to 1000 Da. Data were recorded in a 64 32-bit format, incorporating 100 supercositions of time-domain signals to enhance the signal-to-noise ratio. The instrument was calibrated with 10 mmol·L -sodium formate before sample detection, and an internal standard was calibrated with soluble organic matter. After calibration, mass errors were maintained at less than 1 ppm.

The degree of unsaturation (DBE) and aromaticity (AI) of the DOC fractionation were calculated based on the molecular formula(ColthOrbeNpSq), using the formulas in Equations (4) and (5).

$$DBE = 1 + 2c - h - p + q/2 \quad \text{Equation (4)}$$

$$AI = (1 + c - 0.5o - s - 0.5h)/(c - 0.5o - s - n - p) \quad \text{Equation (5)}$$

Where c, h, o, n, and s are each represent the number of atoms of C, H, O, N, and S.

The Kow value of DOC was calculated by the weighted atom contributing according to Equation (6):

$$Mw = \sum (Mi * Ni) / \sum Ni \quad \text{Equation (6)}$$

Where Mi can represent O/C, H/C, DBE and AI, respectively, n represents the weighted average calculation, Ii and Mi are the relative content and the Mi value at i set, respectively, and the S relative content in the ratio of each peak intensity relative to the References peak.

### 2.5 Extraction of DNA, Construction of Libraries, and Metagenomic Sequencing

Genomic DNA was extracted from soil samples utilizing the Mag-Bind® Soil DNA Kit (Omega Bio-tek, Norcross, GA, U.S.) following the manufacturer's guidelines (Xu et al., 2021; Zhang et al., 2023). DNA concentrations were measured using a TBS-380 and a NanoDrop2000, respectively. The quality of the extracted DNA was assessed by electrophoresis on a 1% agarose gel. The DNA was then fragmented to an average size of approximately 400 bp using the Covaris M220 (Gene Company Limited, China) to prepare for paired-end library construction. The paired-end library was created using the NEXTFLEX Rapid DNA-Seq Kit (Bioo Scientific, Austin, TX, USA). Adapters with the complete set of sequencing primer hybridization sites were ligated to the blunt ends of the fragments. Paired-end sequencing was conducted using an Illumina NovaSeq (Illumina Inc., San Diego, CA, USA) at Majorbio Bio-Pharm Technology Co., Ltd. (Shanghai, China) using the NovaSeq 6000 S4 Reagent Kit v1.5 (300 cycles) according to the manufacturer's instructions (www.illumina.com). The data were annotated and analyzed using the non-redundant protein sequence set and the amino acid sequence databases of non-redundant proteins (NR) and carbohydrate-active enzymes (CAZy).

### 2.6 Statistical analysis

Genes responsible for expressing S-β-XYS, S-β-GC, S-NAG, and S-CI enzymes were identified based on the CAZy database. The following GH1–3, GH11, GH30 (GH30_1–GH30_9), GH39, GH43 (GH43_1– GH43_37), GH51, GH52, GH54, GH116 and GH120 enzymes S-β-XYS activity. GH3, GH5 (GH5_1, GH5_2, GH5_24– GH5_43, GH5_45–GH5_49 and GH5_51–GH5_56), GH9, GH30 (GH30_1–GH30_9) and GH116 enzymes S-β-GC activity. GH3, GH18, GH73, GH84, GH85, GH101, GH116 and GH163 enzymes S-NAG activity. GH5 (GH5_1, GH5_2, GH5_4–GH5_22, GH5_24–GH5_43, GH5_45–GH5_49 and GH5_51–GH5_56), GH8, GH9, GH30 (GH30_1–GH30_9) and GH116 enzymes S-β-GC activity. Microbiological-related analysis were performed using sequencing, and annotated by MajorBio Cloud (www.majorbio.com). A one-way analysis of variance (ANOVA) along with Welch-Duncan post hoc tests was employed to compare the soil and biochemical properties, soil carbon emissions, chemical composition of SOC and DOC, carbon degrading enzymes, the carbon degrading enzyme genes, microbial diversity, and community composition under different nitrogen inputs. Principal coordinate analysis (PCoA) based on Bray-Curtis dissimilarity was performed to explore the similarities in microbial community carrying the carbon-degrading enzyme genes S-β-XYS, S-β-GC, S-NAG, and S-CI. Permutational multivariate analysis of variance (PERMANOVA) was utilized to evaluate the impact of varying nitrogen inputs on microbial communities expressing these enzymes. The final equations were derived using SPSS 2021.

## 3 Results

### 3.1 Impacts of biochar-loaded NH+ 4-N on soil CO2 emissions

Different forms of N altered the cumulative soil carbon emissions (Fig. 1). As shown in Fig. 1a, daily CO2 emissions peaked around day 7 for all treatments, followed by a trough at day 30, after which the daily CO2 emissions gradually levelled off. On day 7, the daily CO2 emissions for the BF treatment were significantly greater than those observed in the other treatments. The cumulative CO2 emissions of the treatments after 180 days of incubation were ranked as follows: BF>CK>CF>BN. Compared to chemical fertilizer-only treatment, cumulative CO2 emissions in treatment of biochar mixed with chemical fertilizer BF increased by 50.16%, while those for biochar-loaded NH+ 4-N treatment decreased by 10.57%. These results suggest that biochar loaded with NH+ 4-N can effectively mitigate soil carbon emissions.

Soil C-mineralization was modelled with various forms of nitrogen input conformed to a combined first- and zero-order kinetic model (Fig. S1 and Table S3). The BF treatment increased C-mineralization (1.79±0.16g C kg-1 dry soil) in both the recalcitrant and labile C components compared to CF (2.53±0.04 g C kg-1 dry soil), whereas the BN treatment decreased C-mineralization (2.26±0.01 g C kg-1 dry soil) in both components. This indicates the C-mineralization in both recalcitrant and labile C pools varied with different forms of N input, where the recalcitrant C is more resistant to microbial decomposition than the labile C. Discrepancies rapidly by microbial metabolic activity during the initial stage.

### 3.2 Composition and structure of soil organic carbon

#### 3.2.1 SOC structure

Solid-state 13C-NMR showed shifts in the major carbon types among different N input treatments (Fig. S2). After 180 days of incubation, the organic carbon functional groups in the soil were primarily composed of O-alkyl-C, with alkyl-C and aromatic-C following in abundance, and the lowest proportion of carbonyl-C for all treatments (Fig. S2 and Table 1). Compared to chemical fertilizer (BF) and biochar-loaded NH+ 4-N (BN) significantly reduced alkyl-C, aliphaticity and the combined index by 16.27% and 22.16% (alkyl-C), 22.67% and 34.67% (aliphaticity), and 14.50% and 27.89% (combined index), respectively. Conversely, BN increased by 8.25% and 18.13% the relative both BF and BN treatments, respectively (Table 1). While the significant differences were found in the proportion of aromatic-C, carbonyl-C and aromaticity. In conclusion, both BF and BN increased labile organic carbon content while reducing recalcitrant organic carbon content. Additionally, biochar-loaded NH+ 4-N additives resulted in a great increase in labile organic carbon and a more significant decrease in aliphaticity and the combined index compared to biochar mixed with chemical fertilizer.

As shown in Fig. 2 and Table 2, the components of soil dissolved organic carbon (DOC) at day 180 were primarily composed of lignins, condensed aromatics, and tannins, which accounted for 39.58%-46.18%, 23.46%-30.28%, and 14.82%-18.77%, respectively. Compared to CF, BF and BN treatments increased condensed aromatics by 21.32% and 27.82%, respectively, while unsaturated hydrocarbons decreased by 21.82% and 44.26%, respectively. Additionally, the content of lignins, which are difficult to degrade, decreased by 11.05% and 13.16%, respectively (Fig. 2f and Table 2). The weighted mean (w) of DOC (Table 3) showed that the DBE-w values were similar between BF and BN treatments. While the Aln increased by 6.31% and 12.64% in BF and BN treatments, respectively, compared to CF treatment. The change may be attributed to the decrease in unsaturated hydrocarbons and the increase in condensed aromatics, which ultimately resulted in similar DBE-w values. Compared to BF, BN treatment increased the weighted mean value of soil condensed aromatics in DOC components, thereby enhancing the relative stability of DOC.

### 3.3 Impacts of biochar-loaded NH+ 4-N on soil carbon-degrading enzyme activity

With the extension of incubation time, the activity of S-β-XYS activity showed an increasing trend, while the activities of S-β-GC, S-NAG and S-CI decreased (Fig. S3). Specifically, compared to CF, S-β-XYS activities increased significantly by 12.88% under BF and BN treatments on day 7, respectively (Fig. S3a), while S-CI activity increased by 15.15% under BF treatment on day 7 (Fig. S3d). On day 180, S-β-GC activity was significantly higher by 15.21% and 16.19% for BF and BN treatments, respectively (Fig. S3b), and S-β-XYS activity increased by 11.66% under BN treatment compared to CF treatment (Fig. S3a). No significant differences were found in S-NAG activity between CF, BF and BN treatments after 180 days of incubation (Fig. 5c), though all treatments showed increased activity compared to CK. The total number of reads for genes expressing the four carbon degrading enzymes (S-β-XYS, S-β-GC, S-NAG and S-CI) across treatments were also detected (Fig. 3). On day 7 gene abundance for these enzymes were similar among treatments. However, by day 180, significant increase was found in the abundance of S-β-XYS gene in CF, BF and BN treatments compared to CK group, while significant decrease was found in the abundance of S-NAG gene in these treatments compared to CK group. however, no significant differences were found in the abundance of these four genes between CF, BF and BN treatment (Fig. 3). Overall, the abundance of expressed enzyme genes mirrored the enzyme activities (Fig. S3), suggesting that S-β-XYS and S-β-GC mediated carbon process play key roles in regulating soil organic carbon turnover under biochar-loaded ammonia nitrogen input.

### 3.4 The composition of microbial communities

Taxonomic annotation analysis showed the taxa composition at the phylum level involved S-β-XYS, S-β-GC, S-NAG and S-CI genes, respectively (Fig. S4a–d). On day 7, different forms of nitrogen input treatments had little effect on species composition, while by day 180, different forms of nitrogen input significantly impacted the microbial composition involved in S-β-XYS, S-β-GC, S-NAG and S-CI genes. The relative abundance of Actinobacteria encoding all four genes was significantly higher in CF treatment compared to the BF and BN treatments. In contrast, other microbial groups e.g. Acidobacteria, Proteobacteria, Gemmatimonadetes, Bacteroidetes, which also encode all these genes were more abundant in the BF and BN treatments than in CF. Taxonomic annotation of top ten microbes encoded S-β-XYS, S-β-GC, S-NAG and S-CI genes was also analyzed at the genus (Fig. S6–h). The microbial composition changed significantly during the incubation time, but the difference between each treatment was not obvious. The relative abundance of Sphingomonas encoding all these four genes on day 7 was lower than on day 180 in all treatments. And Caenorhabditis is unique taxa to encode S-CI genes (Fig. S4h).

The PCoA results indicated a significant difference in the microbial communities expressing S-β-XYS, S-β-GC, S-NAG and S-CI across various nitrogen input forms (Fig. 4). The community structures of microbes at the genus level harboring these genes varied significantly among the different nitrogen inputs (PERMANOVA test: p < 0.001; Fig. 4). Microbial communities from days 7 and 180 were distinctly separated based on nitrogen input form at day 180, but were not clearly separated at day 7 (Fig. 4).

### 3.5 The connection between microbial communities that participate in SOC degradation and soil properties, soil CO2 emissions, enzymes activity and soil organic carbon components

PERMANOVA analysis was conducted to evaluate the impact of soil properties, CO2 emissions, carbon-degrading enzyme activities, and the chemical composition of SOC and DOC on the S-β-XYS, S-β-GC, S-NAG and S-CI - expressing microbial communities (Table 4). Besides, the DOC, AP and MBC significantly (p < 0.01) influenced the S-β-GC, S-NAG and S-CI - expressing communities. Among the carbon-degrading enzymes, S-β-GC enzyme activity significantly (p < 0.01) correlated with the S-β-GC expressing microbial communities. Moreover, the composition of SOC, e.g. carbonyl-C and alkyl-C significantly (p < 0.01) influenced the S-β-XYS, S-β-GC and S-NAG encoding microbial communities. While most of the DOC chemical composition e.g. condensed aromatics, carbohydrates and lignin showed no obvious influence (p < 0.08) on all these carbon-degrading genes expressing microbial communities.

Structural equation modelling revealed how different forms of nitrogen inputs influenced the microbial community composition and soil carbon emission, and showing that 95.1% of soil carbon emissions could be explained by the selected variables (Fig. 5). The composition of DOC showed significant positive correlation with soil carbon emission, while the SOC composition negatively correlated with carbon emission. Additionally, different N input forms played critical role in the microbial community composition, soil nutrients, as well as the cumulative carbon emissions (Fig. 5).

## 4 Discussion

### 4.1 Biochar-loaded ammonia nitrogen decreases soil carbon emissions by soil organic carbon reserves

Soil carbon emissions are strongly influenced by exogenous C and N additions. In our study, biochar-loaded NH4+ −N significantly reduced soil carbon emissions (Fig. 1) and decreased C mineralization in both recalcitrant and labile C pools (Table S3). In contrast, biochar combined application of chemical nitrogen fertilizer promoted soil carbon emissions (Fig. 1) and increased C mineralization in the stabilized and degradable C pools (Table S3). Prior research indicates that applying biochar can result in nitrogen limitation for soil microbial communities during the decomposition of biochar (Schimel et al. 2022). This promotes microorganisms' use of nitrogen from organic matter, leading to a positive priming effect that elevates soil carbon emissions (Wu et al. 2021). Conversely, other research has shown that biochar lowers soil carbon emissions by reducing the degradability of organic carbon (Chen et al. 2022). The addition of biochar provided soil microorganisms with survival sites and nutrients, which significantly increases both biomass and activity of soil microorganisms (Su et al. 2017; Xiao et al. 2015; Zhang et al. (2018b) found that biochar adsorbed ammonium nitrogen mainly through complexation, cation exchange, and electrostatic interactions. In contrast to the application of biochar alongside chemical nitrogen fertilizers, biochar-loaded ammonia nitrogen attracted ammonium nitrogen into the abundant pores of biochar (both internal and externally) through physical forces. This adsorption reduced ammonium nitrogen volatilization (Zhang et al. 2020; Zheng et al. 2018c; Zheng et al. 2018b) and allowed microorganisms that colonize the pores to access N directly, thus alleviating the microbial N limitation caused by biochar input. This, in turn, enables microbes to preferentially utilize the labile C fraction of biochar over the recalcitrant C fraction (Chen et al. 2021a).

Most of the carbon structures in biochar prepared by high-temperature pyrolysis is in a stable form, with aromatic carbon being the major component (Cheng et al. 2006; Liao et al. 2022; Maljanen et al. 2010; Orsetualdi et al. 2018; Yang et al. 2022a). Analysis using 13C-NMR and FTIR revealed that both the combination of biochar with chemical nitrogen fertilizer and the application of biochar-loaded ammonia nitrogen improved the aromatic structure of the added biochar in our study (Figs. S2 and 2, Tables S1, S2, and 1). Among them, the aromatic carbon content of DOC was higher in biochar-loaded with ammonia nitrogen compared to biochar + chemical nitrogen fertilizer (Fig. 2, Tables S3 and 2). Nevertheless, dissolved organic carbon (DOC) is unstable and highly degradable, significantly impacting soil carbon emissions (Yibe-Costa et al. 2020). Yang et al. (2022a) and He found a positive correlation between soil carbon emissions and DOC content, which aligns with our findings (Fig. 5). In this study, the application of biochar enhanced the levels of soil organic carbon pools (SOC and DOC) (Table 1-3), yet soil carbon emissions decreased with the biochar-loaded ammonia nitrogen treatment (Fig. 1). Chen et al.(2021) showed that adding biochar enhanced the aromatic structure of soil SOC and DOC, thereby improving the stability of the soil carbon pool. Due to the higher content of aromatic structures in biochar, the soil carbon pool was more stable, and the carbon emissions were lower.

### 4.2 Biochar-loaded ammonia nitrogen affects carbon degradation enzymes and microbial composition, indirectly influencing soil carbon emissions

Differences in soil nutrient composition and nitrogen input form alter the activity of carbon-degrading enzymes and microbial composition, thereby affecting the composition of organic carbon and consequently influence the soil carbon emission (Figs. 1 and 5; Table S4). S-β-GC and S-β-XYS were used as enzymes for degrading unstable and stable carbon, respectively. Our study showed that biochar-loaded ammonia nitrogen input increased microbial secretion of extracellular enzymes S-β-GC and S-β-XYS, as evidenced by the detection of high enzyme activities and gene abundance (Figs. 3 and S3). However, the relative contribution of combined application of chemical nitrogen fertilizer and biochar to enzyme activity and gene abundance of S-β-GC (Fig. S3b; Fig. 3) The high adsorptive capacity, porous nature and carbon-rich properties of biochar contribute to significant biological, chemical, and physical impacts on the soil, stimulating or inhibiting microorganisms (Quilliam et al. 2013; Wang et al. 2017). When biochar adsorbs nitrogen fertilizer applied to the soil, it increases a chemophex (a soil microenvironment) (Yu et al. 2021), that provides microorganisms with sufficient C and N nutrients, promoting the secretion of extracellular enzymes like S-β-GC to degrade unstable carbon. In the early period (7 days), S-β-XYS enzyme activity increased rapidly in both biochar-applied treatment compared to fertilizer alone. In the later period (180 days), S-β-XYS enzyme activity was significantly higher in the biochar-loaded ammonia nitrogen treatment compared to the other treatments (Fig. S3a). In contrast to the joint application of biochar and chemical nitrogen fertilizer, the nitrogen in biochar-loaded ammonia nitrogen exhibited greater stability (Zheng et al. 2018a; Zheng et al. 2018b). The adsorbed reduced ammonium nitrogen loss through ammonia volatilization (Zheng et al. 2018c) and provides microorganisms with a continuous source through the slow release of ammonia nitrogen. This stability allows microorganisms to maintain steady metabolic activities while minimizing the stimulation of microbial activities caused by fertilizer inputs. Furthermore, this process alleviates the soil N limitation induced by biochar input and suppresses the positive initiation effect typically triggered by such inputs. This finding suggests that biochar-loaded ammonia nitrogen facilitates long-lasting and sustained decomposition of stabilized carbon, enhances soil carbon pool stability, and reduces soil carbon emissions.

Soil microbial communities are crucial in regulating soil carbon emissions and organic carbon performance (Wang et al. 2021). This study revealed subtle differences in the microbial community compositions of microorganisms that express the four carbon-degrading enzymes. At the phylum level for the top six microbial groups by relative abundances were identical (Fig. S4a, b, c, and d), while At the genus level, however, the relative abundances of microorganisms that express the four carbon-degrading enzymes differed significantly (Fig. S6a, c, g, and h). Biochar application reduced the relative abundance of Sphingomonas in the biochar-loaded ammonia nitrogen treatment (Fig. S6a, c, g, h) was likely attributed to the degradation of polycyclic aromatic hydrocarbons by Sphingomonas, which consequently enhanced the impact of biochar on aromatic carbon in the soil (Chen et al. 2016; Dai et al. 2015). Alterations in microbial community structure allow microorganisms to preferentially utilize specific carbon fractions, affecting the structure and functions of SOC and DOC (Sun et al. 2020). PERMANOVA analysis revealed that the dominant factor influencing the structure of microbial communities expressing the four degradative enzymes were generally similar, with soil pH, MBC−N and NO3−N being the most influential factor on microbial community structure (Table 4). Both biochar and chemical nitrogen fertilizer application significantly affected soil pH (Zhaxi et al. 2021), along with ammonia volatilization, nitrogen fixation, and nitrogen loading (Nguyen et al. 2017), which altered the soil C/N ratio and consequently the microbial community structure changes (Wang et al. 2018).

## 5 Conclusion

The structural equation analysis revealed that different forms of N inputs significantly affected soil carbon emissions. Nitrogen input affected carbon degrading enzymes by altering soil properties and microbial community composition, which in turn influenced the composition of SOC and DOC, ultimately leading to changes in soil carbon emissions. Ammonia nitrogen-loaded biochar substantially decreased soil carbon emissions, boosted carbon-degrading enzyme activity, improved the stability of the soil carbon pool, and enhanced microbial composition. Future studies should aim to investigate the long-term impacts of biochar loaded with ammonia nitrogen.

## ABSTRACT

Soil carbon (C) plays a central role in the global C cycle with the potential to mitigate the elevated atmospheric carbon dioxide ($CO_2$) concentration by sequestering C into soil organic matter (SOM). Phosphorus (P) fertilization influences SOM decomposition and microbial processes, including microbial C use efficiency (CUE), determined as the ratio of C allocated to biomass growth to C respired as $CO_2$. Non-allophanic Andosols are characterized by high organic C contents and strong P retention, but the effects of long-term P fertilization on C dynamics in these soils remain poorly understood. We conducted a 20-day incubation experiment to examine how soil P availability, driven by long-term fertilization practices, influenced microbial C dynamics in non-allophanic Andosols. We collected the soil samples from two contrasting P fertilization field (Truog-P: 157 mg $kg^{-1}$ or 12 mg $kg^{-1}$) in Tohoku University, Japan. Soil samples (100 g dry soil) were treated with water (control), $^{13}$C-glucose (450 mg C $kg^{-1}$), or glucose with ammonium sulfate (61 mg N $kg^{-1}$), and incubated at 25°C with 55% moisture content (w/w). Microbial CUE at the initial and latter stage of the incubation and SOM priming effects (PEs) during the incubation were measured.

Long-term P fertilization significantly influenced microbial respiration and CUE. In the high-P soils, glucose with N substrate addition resulted in negative PEs. In contrast, the low-P soils exhibited positive PEs under glucose addition, along with higher phosphatase activity and MBC:P ratios, suggesting that P limitation promoted microbial P-mining through SOM degradation. Furthermore, higher glucose-derived CUE was found in the high-P soils than in low-P soils at latter stage of the incubation. The low-P soils also maintained lower pH and higher exchangeable Al, conditions that, along with P limitation, likely constrained microbial respiration and CUE by increasing metabolic maintenance costs. Consequently, contrasting microbial C utilization between the soils were found, reflecting the combined effects of P deficiency and Al toxicity. This study demonstrated that CUE and substrate-induced SOM decomposition in non-allophanic Andosols is strongly influenced by the combined effects of long-term P fertilization.

**ABSTRACT**

Long-term fertilization is known to increase soil organic carbon (SOC) storage; however, the mechanisms linking SOC dynamics to biological nitrogen fixation (BNF) remain poorly understood. Here, using two long-term (>20 years) field experiments, we show that organic amendments significantly enhanced SOC storage by increasing reactive minerals in both corn-wheat rotation and paddy soils. Coincident with this C accumulation, long-term manure fertilization enriched microbial necromass and short-range ordered iron (oxyhydr)oxides. This enrichment elevated Molybdenum (Mo) storage and bioavailability, which in turn increased *nifH* gene abundance and nitrogenase activity. Metagenomic sequencing further revealed that micronutrient bioavailability was strongly correlated with the abundance of key N-fixing genera (e.g., *Azospirillum* and *Bradyrhizobium*). Crucially, structural equation modeling identified microbial necromass as the primary driver of N-fixing populations, highlighting an underappreciated role of necromass as a micronutrient reservoir. We conclude that micronutrient bioavailability is a critical factor regulating BNF in paddy soils, offering significant implications for sustainable nutrient management.

**ABSTRACT**

Tropical peatlands are major global carbon stores, yet their soil properties and $CO_2$ flux dynamics can shift over time through natural processes and land management. Detecting such long-term changes is essential for improving carbon assessments and ensuring that measurement approaches capture the unique behavior of peat soils. This study examines 25- year changes in peat soil properties and $CO_2$ flux in a planted tropical peat forest in Bukit Batu, Riau Province, Indonesia. Soil sampling at 0–30 cm depth evaluated physical, chemical, and biological indicators, encompassing moisture content, bulk density, ash content, and microbial biomass. Using a closed-chamber method, $CO_2$ fluxes were measured in blocks with excised and intact roots to obtain more accurate soil-derived fluxes. Measurements on the same undisturbed samples were also conducted in Bogor for comparison.

Over 25 years, surface peat conditions changed noticeably, with moisture declining, bulk density and ash content increasing, and microbial biomass decreasing. In contrast, the peat remained hemic but exhibited a finer material structure. Correspondingly, soil $CO_2$ flux in 2025 dropped by approximately 46–67% compared to 2010, reflecting not only reduced soil moisture and microbial activity but also decreased root-derived respiration. Microclimatic differences, including the absence of weeds in 2025, contributed to these changes. These findings highlight the importance of long-term, multi-parameter monitoring and show that peat-adapted flux measurement methods can enhance the accuracy of emissions estimates in peatland.

## ABSTRACT

Long-term intensive management, particularly continuous nitrogen fertilization, induces soil acidification, accelerating carbonate dissolution and leaching and thereby generating a trade-off between soil organic and inorganic carbon (SOC, SIC) that constrains agricultural sustainability. Based on a 20-year field experiment, this study quantifies the vertical distribution, transformation pathways, and net carbon balance of soil carbon components under contrasting nitrogen and organic inputs. Results showed that long-term N fertilization caused pronounced surface acidification (~0.4 pH-unit decline), inducing a strong SOC–SIC trade-off in the 0–20 cm layer that maintained surface total C stocks across most treatments. Profile-scale analysis revealed that surface-based assessments masked substantial carbon losses: N-only fertilization accelerated carbonate dissolution and downward leaching of dissolved inorganic carbon, resulting in a marked net carbon deficit across the profile (_1.2 Mg C ha_1 yr_1). Isotopic evidence showed that organic inputs promoted the conversion of biogenic carbon into pedogenic carbonates (PIC), with PIC increasing with organic input intensity, but sequestration efficiency differed among amendments. Straw return increased cation exchange capacity but failed to prevent base-cation depletion and SIC loss. In contrast, manure combined with N substantially enhanced SOC and nutrient status and, through shifts in δ13C signatures and PIC/LIC depth patterns, revealed a coupled pathway of organic C mineralization, carbonate dissolution–reprecipitation, and PIC formation. Notably, high-rate manure plus N (2CM+Nl) both supplied exogenous carbon and buffered acidification, achieving coordinated accumulation of SOC (+l.3 Mg C ha_1 yr_1) and PIC (+0.l3 Mg C ha_1 yr_1) across the profile and a net sequestration rate of 2.1 Mg C ha_1 yr_1. Overall, N-driven acidification vertically decouples SOC and SIC dynamics, indicating that carbon accounting in calcareous croplands must explicitly include SIC and optimize organic inputs and N management to sustain long-term multi-pool carbon sequestration.

# Effects of Eucalyptus robusta afforestation on soil carbon fractions and the underlying mechanisms

**Xin Zhou[1], Min Duan[2*]**

*[1] Key Laboratory of Ecology of Rare and Endangered Species and Environmental Protection (Ministry of Education) & Guangxi Key Laboratory of Landscape Resources Conservation and Sustainable Utilization in Lijiang River Basin, Guangxi Normal University, Guilin 541006, China*

**ABSTRACT**

Afforestation patterns are a critical factor influencing the stability and sequestration potential of soil carbon pools. However, the impact of Eucalyptus robusta afforestation on soil carbon stability and its key regulatory mechanisms remains unclear. This study focused on five plantation types with similar stand ages: Eucalyptus robusta monoculture, Pinus massoniana monoculture, Cunninghamia lanceolata monoculture, Eucalyptus robusta-Pinus massoniana mixed plantation, and Eucalyptus robusta-Cunninghamia lanceolata mixed plantation. Soil samples were collected from the 0-20 cm layer for systematic analysis of pH, moisture content, clay, silt, and sand content; total carbon (TC), total nitrogen (TN), total phosphorus (TP), ammonium nitrogen, and nitrate nitrogen; soil organic carbon (SOC), particulate organic carbon (POC), mineral-associated organic carbon (MAOC), and iron-bound organic carbon (FeOC); iron and aluminum oxides (in free, amorphous, and complexed forms); as well as amino sugars, lignin phenols, and phospholipid fatty acids (PLFA). The aim was to elucidate the effects of afforestation patterns on soil carbon stability and their underlying driving mechanisms.The results indicated that afforestation patterns significantly altered the distribution of soil carbon fractions, the iron/aluminum oxide-bound carbon pool, and the structure and activity of microbial communities. Compared to monocultures, mixed plantations (particularly the Eucalyptus robusta- Cunninghamia lanceolata mix) exhibited a higher proportion of MAOC and stronger protective effects of iron/aluminum oxides on organic carbon. Concurrent changes were observed in microbial community composition and indicators related to carbon transformation functions, suggesting an enhancement of carbon-mineral-microbial interactions. These differences collectively contributed to enhanced long-term soil carbon stability.This study demonstrates that rational mixed-species afforestation can improve soil carbon sequestration capacity by optimizing carbon fraction allocation, enhancing mineral protection, and regulating microbial processes, thereby providing a scientific basis for the sustainable management and carbon stewardship of plantation forests.

# Impact of burning cessation on soil carbon stocks and organic matter fractions in semi-natural grasslands

**Hajime Sakurada[1*], Kanta kuramochi[2], and Yo Toma**

[1] *Hokkaido University (Graduate school of agriculture, Hokkaido University, Sapporo, Japan)*

## ABSTRACT

Grasslands cover 40% of terrestrial land area and semi-natural grassland in Japan store large amounts of soil carbon. In Japan's Aso region, annual burning maintains semi-natural grasslands dominated by *Miscanthus sinensis* (C4 plant), whereas burning cessation leads to succession toward C3 broadleaf forests. Previous studies have shown that discontinuing burning and allowing vegetation succession leads to a reduction in soil carbon. This study examined how burning continuation and cessation affect soil organic carbon (SOC) and SOM fractions during succession.

The study was conducted in the Aso region, Kumamoto Prefecture. The grassland maintained by burning for over 20 years (Burning : BR) and the adjacent site where burning ceased 10 years ago (Unmanagement : UM) were selected. BR was dominated by *M. sinensis* with some C3 plants, while UM was dominated by mainly C3 vegetation. Soils (0-30 cm with 5 cm increments, 3 replicates) were fractioned using sodium polytungstate (1.8 g $cm^{-3}$) and ultrasonification (800 J $ml^{-1}$) into free particulate organic matter (fPOM), occluded particulate organic matter (oPOM), and mineral-associated organic matter (MAOM). Total carbon and nitrogen content, and $\delta^{13}C$ were measured for bulk soils and each SOM fraction. Carbon contents were expressed as SOC (bulk soil) and fPOC, oPOC, MAOC (SOM fractions). Depth-specific differences in $\delta^{13}C$ ($\Delta\delta^{13}C$) and C/N ($\Delta C/N$) between BR and UM were calculated as indicators of SOM turnover. Additionally, aluminum ($Al_p$) and iron ($Fe_p$) derived from humic complexes were measured.

SOC stock at 20-25 cm and fPOC stock at 10-15 cm exhibited significantly higher in BR than UM. However, no significant differences were observed at other depths or SOM fractions. Depth-specific comparisons revealed that the 0-5 cm layer exhibited both management relatively abundant fPOC and oPOC, while MAOC was scarce. In the range of 5-30 cm, both fPOC and oPOC declined, and MAOC comprised the predominant proportion (62-78%). This trend in both management suggests strong influence of surface litter and char in the top soil layer. $\delta^{13}C$ and C/N of bulk soils and SOM fractions were lower in UM, reflecting rich in C3-derived carbon inputs. Notably, $\Delta\delta^{13}C$ of all SOM fractions and $\Delta C/N$ of fPOM peaked at 5-10 cm depth, indicating carbon turnover was most active at 5-10 cm depth rather than the surface (Fig 1). This may be due to (1) dense *M. sinensis* rhizomes below 5 cm and higher surface C3 inputs at BR, and (2) decline of *M. sinensis* rhizomes and deeper C3 root inputs after burning cessation. In BR, mean $\delta^{13}C$ and C/N of fPOM at 5-30 cm depth were -17.0‰ and 22.2, while these were -20.5‰ and 18.5 at 0-5 cm. This indicated that C3-derived carbon in BR contributed in the surface. Positive correlations between $Al_p$ or $Fe_p$ and MAOM, with UM exhibiting higher values than BR, suggests that the cessation of burning may increase the acidic functional groups in MAOM.

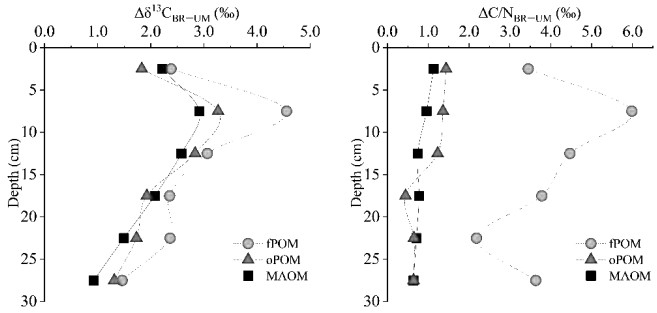

Fig. 1 Differences in $\delta^{13}C$ and C/N between continued burning and unmanagement at each depth (a) $\Delta\delta^{13}C$ (Burning - Unmanagement), (b) $\Delta C/N$ (Burning - Unmanagement)

**ABSTRACT**

Water is fundamental to microbial metabolism, and $H_2{}^{18}O$ is widely used in stable isotope probing (SIP) to quantify microbial growth and activity. However, it remains unknown whether different levels of $^{18}O$ enrichment perturb microbial communities and functions, and what enrichment levels are suitable for ecologically realistic experiments. We tested soil microbiome responses across an $H_2{}^{18}O$ gradient (0.2-80 atom%), integrating full-length 16S rRNA gene sequencing, functional gene profiling, and physiological assays. We found that overall diversity remained stable, but community composition shifted, with ~6% of indicator taxa exhibiting clear threshold responses, including both increasing and decreasing taxa. Functional genes showed pathway-specific thresholds, with change points for genes involved in carbon fixation as well as nitrogen, phosphorus, sulfur, and methane metabolism clustering at intermediate enrichment levels (~ 33-39 atom%$^{18}O$). Microbial physiological traits showed contrasting sensitivities to $^{18}O$ enrichment: respiration declined sharply with a change point at relatively low enrichment (~22 atom%$^{18}O$), whereas microbial growth, carbon use efficiency, and turnover varied continuously along the gradient and did not exhibit identifiable thresholds. Our results demonstrate that $H_2{}^{18}O$ enrichment is not biologically inert, but instead elicits hierarchical and nonlinear responses across microbial organizational levels. Integrating responses across community, functional, and physiological dimensions, enrichment levels of approximately 20-30 atom%$^{18}O$ can be considered a conservative threshold range at which isotopic stress begins to emerge. Accordingly, to minimize isotope-induced physiological artifacts and improve comparability across studies, future SIP experiments should avoid exceeding this enrichment range.

## ABSTRACT

Accurate knowledge of spatial variations in organic matter content of cultivated land topsoil (CTSOM) is crucial for the effective use and management of cultivated land. However, this knowledge remains largely uncertain owing to outdated and imprecise soil databases. Therefore, in 2020, this study meticulously collected 918 samples of cultivated land topsoil (0–30 cm) in Hebei Province of North China, and a Random Forest (RF) model was used to delineate the spatial variability of CTSOM. Results indicated the robust performance of the RF model containing 21 predictors, with an $R^2$ of 0.77, and soil properties emerging as the most important predictors. The current mean CTSOM level in the study area stood at 16.47 ± 3.94 g $kg^{-1}$, displaying a spatial pattern with higher CTSOM levels in the western and northern mountainous areas, and lower levels in the eastern plain areas. A comparison with the second national soil survey data revealed that the overall regional level of CTSOM has increased by 4.28 g $kg^{-1}$ over the last 40 years. However, a significant decline in CTSOM was observed in the northern part of the study area, where straw return and fertilization can be key contributing factors. This study provides updated knowledge on the spatial variations of CTSOM in North China, which is valuable for agricultural ecosystem management worldwide and for carbon accounting in terrestrial ecosystems.

## ABSTRACT

Accurate quantification of soil organic carbon (SOC) stocks is essential for evaluating land-use impacts, informing soil health assessments, and supporting carbon accounting frameworks. Comparisons between forest soils and adjacent cultivated lands provide valuable insight into the magnitude and depth distribution of SOC losses associated with agricultural conversion.

In this study, soil samples were collected to a depth of 1 m from a cultivated field and an adjacent forest at the Elora Research Station (Guelph, Ontario) to quantify SOC stocks and assess the relative contributions of topsoil and subsoil carbon. Soil organic carbon was determined using a muffle furnace method, and SOC stocks were calculated using an equivalent soil mass approach to account for differences in bulk density between land uses. The effects of land use and soil depth on SOC were evaluated statistically.

Soil organic carbon stocks were 180.6 Mg C $ha^{-1}$ in the cultivated site and 219.6 Mg C $ha^{-1}$ in the forest when expressed at an equivalent soil mass of 13,000 Mg $ha^{-1}$, representing an approximately 18% reduction following conversion from forest to agriculture. The majority of SOC loss (93%) occurred within the upper 30 cm, while subsoil layers accounted for a substantial proportion of total SOC stocks (52% in cultivated soils and 44% in forest soils). These results indicate that surface SOC is highly sensitive to land-use change, whereas subsoil SOC constitutes a significant and comparatively stable component of total SOC stocks.

Overall, this study highlights the importance of depth-resolved SOC assessment and standardized stock calculation methods for improving the precision of land-use comparisons and strengthening soil carbon accounting.

## ABSTRACT

Land-use transitions shift soil biogeochemical flux; however, adopting conservation agriculture, notably integrated systems, optimizes productivity, sequesters carbon, bolsters biodiversity, enhances nutrient cycling, water infiltration and storage, and gaseous exchange. Consequently, integrated crop-livestock-forest systems (ICLFs) are a flagship of Brazil's "Low-Carbon Agriculture" program for greenhouse gas offset or mitigation through increased harvest efficiency. ICLFs support sustainable intensification by synergizing annual crop, forestry, and livestock activities within synchronized spatio-temporal frameworks in the same area and season. This system leverages crop rotation and no-tillage to optimize the volume and biochemical quality of surface residues, fundamentally enhancing soil organic carbon sequestration, edaphic quality, and functional health. ICLFs use crop rotation and no-tillage to optimize the volume and quality of above- and below-ground residues, enhancing soil organic carbon sequestration, edaphic quality, and functional health. A long-term ICLFS in São Carlos, SP, Brazil (21°57'S, 47°50'W, 860m), evaluated soil carbon sequestration and edaphic health across integrated management systems within the Atlantic Forest biome. Physical, chemical, and biological properties were quantified to a depth of 1.0 m across a 30-ha typic Haplorthox under Cwa climatic conditions. The experimental design comprised: i) intensive (INT) grazing in Palisade grass (*Urochloa brizantha*) pasture; ii) crop-livestock (ICLS) featuring interannual rotation of maize intercropped with Palisade grass; iii) crop-livestock-forest (ICLFS) integrating *Eucalyptus urograndis* (83 trees $ha^{-1}$) with ICLS; iv) livestock-forest (ILFS) combining Palisade grass and Eucalyptus; v) extensive (EXT) grazing of *Urochloa decumbens* pasture; and vi) a native Atlantic Forest fragment as a control. Results indicate that land-use transitions toward ICLFs, driven by adequate farm and soil management strategies such as balanced nutrient management, optimized grazing, no-till farming, and crop rotation and diversification, fundamentally bolstered the edaphic health. These systems optimized nutrient cycling and soil fertility. ICLFs also enhanced carbon sequestration throughout the soil profile and modulated organic matter stability compared with traditional pastures. Integrated systems exhibited substantial soil carbon accretion rates, exceeding 1.5 t C $ha^{-1}$ $year^{-1}$. Physical indicators, specifically saturated hydraulic conductivity, showed greater improvement in ICLFs than in extensive pastures, supported by the development of biogenic macroporosity. Furthermore, increased biological diversification stimulated macrofauna abundance, with earthworm populations emerging as highly sensitive bioindicators for tracking these management-induced transitions.

# Vulnerable Zone of Soil Inorganic Carbon Loss in Intensive Agricultural Regions

**Jianbin Zhou*, Jingjing Tao, Mengzhen Zhao, and Zhujun Chen**

*College of Natural Resources and Environment, Northwest A&F University, Yangling, Shaanxi 712100, China*

**ABSTRACT**

Soil carbon (C) comprises organic carbon (SOC) and inorganic carbon (SIC). The role of SOC in soil heath and climate change is well known and has received widespread attention. Although globally, SIC stocks in the upper 1 m soil profile are equal to nearly half of SOC in the same layer, our understanding of SIC dynamics and its contribution towards soil heath and climate change is still rudimentary, due to it is usually considered that SIC is very stable, and has a limited role in the global C cycle. In recent years, more evidences have indicated that the turnover rate of SIC is much faster than was thought. As a result, increasing researches have studied the SIC changes. More studies focus on SIC roles in sequestrating carbon and buffering soil pH, and relationship between SIC and risk of heavy metals pollution. The mechanism controlling SIC changes in intensive agricultural region, and the hotspot regions of SIC loss remain unclear.

We have built the database both by collecting the data from literatures and determining soil samples taken from the different provinces to study the driving forces of SIC content change in the top soil layer of farmland in China from the 1980s to the 2010s. It found that the changes of SIC density (SICD) in the 0-40 cm soil layer of farmland in China from the 1980s to the 2010s were significantly correlated with the ratio of rainfall (P)/potential evapotranspiration (PET) (drought index). The decaling rate of SICD in humid and semi-arid regions was increased with the P/PET ratio, and their relative changes were enhanced by high N fertilizer input. In contrast, the SICD was increased in arid regions. It conforms that the drought index and N fertilization are major drivers that lead to dramatic losses of SICD in croplands. In regions where carbonate content is low, and N application rate and P/PET are high, the SIC pool is vulnerable to lose. For example, soils in the transition zones between the North and the South China (Qinling Huaihe River), brown soil and alluvial soil in the Shandong Peninsula, black soil and chernozem in Northeast China. These regions are designated as vulnerable zone SIC loss. If SIC pool is consumed up, soil pH will drop dramatically. Several case studies in China will be introduced. For a sustainable reduction of SIC loss induced by soil acidification, the different measures are suggested, including adequate application of N fertilizers, combining the application of N fertilizers with organic fertilizer and nitrification inhibitors and replacing the ammonium bearing fertilizers with nitrate fertilizer.

## ABSTRACT

Mollisols (black soils) are the most fertile and productive soils in the world, and their fertility are often associated with their high organic matter content. Their long-term cultivation has caused severe degradation including decline in soil organic carbon (SOC) content; however, the fundamental processes governing changes in carbon inputs, fractions transformation and turnover dynamics due to cultivation are still poorly understood. Here, we used stable carbon isotope ($\delta^{13}C$) and C/N ratios of bulk SOC and mineral-associated organic carbon (MAOC) analysis of five Phaeozems soil profiles and 30 pairs of cropland and natural topsoil samples along a latitude transect from Northeast China to document the organic matter source during soil formation, to understand the dynamics and transformation of SOC induced by cultivation, and to provide insights into soil conservation practices. Two profiles from the southwest steppe region show an upward increase of ca. 5‰ in $\delta^{13}C_{soc}$ from -26.3‰ to -21.4‰, suggesting progressive increases in C contributions from C4 plants expansion caused by increasing aridity and weakened summer monsoon during the late Holocene. In contrast, three profiles from the northeast forest region show a decrease of ca. 2‰ from -23.6‰ to -25.5‰ in $\delta^{13}C_{soc}$ and an increase in C/N ratios from 6 to 12 upward, a pattern consistent with greater microbial C inputs at depths. The enrichment of 1.8‰ in $\delta^{13}C_{soc}$ values on average in the plough horizon of all five profiles indicated impact of corn (C4 plant) cultivation. Also, similar enrichment was observed in 30-paired topsoil samples (0-30 cm), showing that the $\delta^{13}C$ values in cropland soils were higher (from -18.8‰ to -25.5‰, with a mean of -22.9‰) than natural soils (from -21.9‰ to -27.7‰, mean value is -25.2‰). The 2.3±0.5‰ enrichment of $\delta^{13}C$ in cropland topsoil indicated that corn cultivation contributed 12.3±6% to SOC. Furthermore, the $\delta^{13}C_{MAOC}$ were lower than $\delta^{13}C_{SOC}$ by 0.63‰ at 0-5 cm and 0.02‰ at 25-30 cm, suggesting progressive incorporation of C4 corn signature into MAOC at depths even in the plough horizon. The C/N ratios in MAOC was higher than C/N ratios in bulk SOC, also suggesting that MAOC was mostly plant-derived C. In summary, the degrees of deviations in plough horizon from long-term trend of soil $\delta^{13}C$ profiles suggest the various intensity of impacts of corn cultivation on SOC, both temporally along the soil profiles and geographically across black soils region in Northeast China. Natural $\delta^{13}C$ analysis is a powerful tool to quantify the contribution of crop residues into different carbon fractions and potentially provides important insights into the preservation of SOC and conservation of black soils.

**ABSTRACT**

Regenerative agriculture (RA) practices are increasingly promoted to enhance soil health and carbon (C) sequestration in agricultural systems, yet their effectiveness is often evaluated using surface soil measurements that overlook processes occurring at depth. In perennial cropping systems such as vineyards, deep soil layers represent a substantial but poorly characterized component of soil organic carbon (SOC) storage, where interactions among soil physicochemical properties, microbial communities, and management practices may govern long-term C stabilization. This study investigates soil C dynamics and microbial associations across the soil profile in Northern California vineyards to establish a baseline framework for evaluating management impacts on SOC. We sampled soils to 1-m depth in three cover-cropped vineyards, collecting samples at 0-15, 15-30, 30-60, and 60-100 cm. Baseline measurements included particulate organic carbon (POC), mineral-associated organic carbon (MAOC), dissolved organic carbon (DOC), and microbial biomass carbon (MBC), alongside soil physicochemical properties. Bacterial community composition was characterized using 16S rRNA gene amplicon sequencing to examine associations between SOC pools and microbial structure along soil depth gradients. Baseline results show strong vertical stratification of SOC pools, with increasing dominance of MAOC in subsoil layers, highlighting the importance of subsurface processes for long-term C storage. Bacterial community composition varied systematically with soil depth and was closely associated with changes in soil properties and SOC pool distribution, indicating that microbial organization is an important component of depth-dependent C dynamics. In parallel, a short-term RA assessment incorporating no-till and sheep-grazing practices was established in one vineyard. Ongoing analyses are evaluating how two years of RA management influence soil physicochemical properties, SOC pool distribution, and bacterial and fungal community structure across soil depth. By integrating completed baseline observations with emerging management-focused assessments, this work aims to improve our understanding of how land use and regenerative practices shape soil C dynamics across entire soil profiles in vineyard systems. These insights will contribute to more comprehensive evaluations of SOC sequestration potential and inform management strategies aimed at improving soil function and resilience under Mediterranean-climate conditions.

**ABSTRACT**

Globally, farmland abandonment is increasing, with the cessation of rice cultivation being particularly pronounced in East Asia. Previous studies have shown that soil organic carbon (SOC) in abandoned paddy fields declines during the early stages of abandonment but tends to reaccumulate over the long term. This initial SOC loss is attributed to enhanced microbial decomposition following the shift from flooded to aerobic conditions, leading to depletion of both free particulate organic carbon (fPOC) and occluded particulate organic carbon (oPOC), as well as mineral-associated organic carbon (MAOC), traditionally regarded as a stable carbon pool. However, how SOC fraction dynamics are linked to soil microbial characteristics in abandoned paddies remains poorly understood. This study aimed to elucidate the temporal dynamics of SOC fractions along a chronosequence of abandoned paddy fields and their relationships with microbial activity and abundance. We investigated 13 abandoned paddy fields in central Korea (2–39 years since abandonment), along with seven cultivated paddies and ten adjacent forest sites as controls (30 sites total). Soil samples were fractionated into fPOC, oPOC, and MAOC, and their relative distributions and stocks were quantified. Microbial characteristics were assessed through measurements of enzyme activities related to carbon (C) and nitrogen (N) cycling and by quantifying bacterial and fungal abundance. SOC stocks initially declined following abandonment but gradually recovered over time, reaching levels comparable to cultivated paddies after approximately 12 years using the equivalent soil mass (ESM) approach and 17 years using the fixed-depth method. Among SOC fractions, oPOC showed a sharp initial decline followed by a slower-than-expected recovery, indicating high sensitivity to microbial decomposition. In contrast, MAOC exhibited notable temporal variability despite its presumed stability. Changes in the oPOC/MAOC ratio closely tracked oPOC dynamics, highlighting significant shifts in SOC composition during abandonment. Future work will expand the chronosequence by incorporating additional abandoned paddy fields from other regions, particularly targeting underrepresented abandonment periods, to further clarify microbial-mediated SOC stabilization processes during long-term paddy abandonment.

**ABSTRACT**

Understanding carbon cycling in urbanization-induced fragmented ecosystems requires a dynamic approach that captures carbon fluxes rather than static storage indicators. According to previous studies, microbial biomass carbon (MBC) serves as an active carbon pool that drives organic matter decomposition and nutrient transformation. Particularly, the ratio of MBC to soil organic carbon (MBC/SOC) represents carbon bioavailability and has been proposed as a key indicator that responds sensitively to environmental disturbances and provides early signals of ecosystem functional changes. Nevertheless, existing research on urban fragmented ecosystems has primarily focused on quantitative changes in SOC, insufficiently addressing how fragmentation-induced landscape characteristics such as physical boundaries and adjacent land uses influence MBC/SOC dynamics. Therefore, this study aimed to examine the effects of physical boundaries and adjacent land use types on SOC content and MBC/SOC in forests and grasslands fragmented by urbanization. We analyzed SOC and MBC/SOC in topsoil (0-15 cm), comparing edge (≤30 m) and interior (>30 m) zones of urbanization-fragmented forests and grasslands. The results revealed distinct carbon storage and utilization strategies between the two ecosystems. Forests exhibited high SOC content but low MBC/SOC, suggesting that carbon is stored in a physicochemically stabilized state with limited microbial accessibility. In contrast, grasslands showed low SOC content but high MBC/SOC, indicating a carbon system with a high proportion of active carbon pool and elevated biological turnover rates. Notably in forests, edge effects did not significantly alter total SOC, but MBC/SOC was significantly reduced at road-adjacent edges, suggesting that road proximity impairs active carbon pool formation. This study demonstrates that assessing carbon cycling in urbanization-fragmented ecosystems requires integrated consideration of not only SOC storage but also microbial-mediated carbon cycling indicators that reflect urbanization-induced fragmentation characteristics. Future studies will integrate soil respiration data to verify if the observed alterations in MBC/SOC at urban edges result in actual carbon losses.

**ABSTRACT**

Lime addition, widely advocated to alleviate soil acidity and promote plant growth in acidic soils, can influence soil organic carbon (OC) turnover by multiple mechanisms, including fostering soil aggregation, disrupting OC-mineral association, and indirectly increasing C inputs. Due to the interplay of competing processes, the net impact of liming on soil OC remains debated. To clarify the generalizable impact of lime application on soil OC across the soil profile and to decipher the underlying mechanisms, we combined a global meta-analysis of field observations with microcosm experiments across two soil types. Our results show that, overall, lime application increased soil OC by 5.7%, primarily through enhanced plant C inputs and associated increases in particulate organic carbon ($r = 0.77$). This effect, however, depended on both initial OC content and soil depth. Specifically, in OC-poor topsoil (OC<20 g/kg), liming enhanced the destabilization of particulate organic carbon and increased dissolved OC content. This process stimulated both OC decomposition and microbial necromass formation, yet the subsequent interaction between microbial-derived OC and mineral was inhibited, as elevated $OH^-$ competed with organic ligands for reactive mineral binding sites. Nevertheless, this negative effect was offset by increased C inputs due to enhanced plant growth, resulting in a net increase in topsoil OC (7.7 %). Within OC-rich subsoils (OC≥20 g/kg), lime application also destabilized OC and accelerated its decomposition. However, due to the inherently low microbial carbon use efficiency in the subsoil, microbial necromass production did not increase proportionally. Given the declining plant C inputs with depth, the enhanced C outputs — primarily as $CO_2$ — dominated the C turnover, leading to a net OC loss of approximately 5%. Our findings underscore that the loss of persistent subsoil OC should be carefully considered in the development of land management strategies aimed at maintaining or increasing soil OC, particularly while promoting the use of alkaline amendments for atmospheric $CO_2$ removal.

## ABSTRACT

The role of phosphorus (P)-fertilization in soil organic carbon (SOC) sequestration is critical yet paradoxical, as its impact on both carbon input and loss remains inadequately quantified. Through a 30-year paddy field experiment, we demonstrated that long-term high-level P-fertilization creates a significant trade-off between SOC accumulation and mineralization. While P-fertilization increased total SOC by up to 24.3%, this gain was driven exclusively by the accumulation of particulate organic carbon (POC) from enhanced plant-derived inputs. Conversely, the mineral-associated organic carbon (MAOC) pool, crucial for long-term stability, decreased by 6.5%. Phosphate anions competitively occupied binding sites on iron (Fe) oxides, as evidenced by a significant decrease in active Fe and a spatial decoupling of C and P at the microscale. This competition directly constrained MAOC formation. Furthermore, high-level P-fertilization accelerated SOC mineralization, increasing $CO_2$ emissions by up to 46.7%. This was mechanistically explained by a broad stimulation of microbial extracellular enzymes (both hydrolytic and oxidative) and a reduction in microbial carbon use efficiency. Consequently, the net ecosystem carbon balance peaked at an optimal P-fertilization level, beyond which the carbon costs from increased emissions and fertilizer production outweighed the gains. Our findings reveal that high-level P-fertilization directs carbon into a vulnerable, rapidly-cycling POC pool at the expense of a stable MAOC pool, challenging its efficacy for sustainable carbon sequestration. Based on these findings, precision P management was advocated to optimize the trade-off between productivity and stable SOC storage in agroecosystems.

**ABSTRACT**

Conservation practices in agriculture can aid in carbon sequestration and contribute to the 4 per mille initiative. No-tillage is a promising practice to enhance carbon storage in soil compared to conventional tillage. It has shown its effectiveness in field experiments, but there is limited data supporting the justification of no-tillage on a farms scale due to the complex assessment of interacting factors in space and time. The research aims to evaluate the rate of carbon stock accumulation and forecast its dynamics using no-tillage (NT) versus conventional tillage (CT) in farms in three regions of European Russia. The farms were selected in Samara (Haplic Chernozems) and Rostov (Calcic Chernozems) regions, which have non-waterlogged landscapes, as well as in the Krasnodar region (Stagnic Chernozem), which has a periodic waterlogged landscape. In 2022-2023, we selected three adjacent fields at each site: one with CT, and two with NT for 5–14 years. At each field 30 sampling points were selected using a conditioned Latin hypercube design, taking into account variations in both spectral and terrain characteristics of the landscape. The soil samples were selected from the top (0-10 cm) and subsoil (10-30 cm) layers at each point (a total of 270 soil samples). Soil bulk density was determined at each point. The total carbon (TC) and inorganic carbon (IC) contents were analyzed to calculate soil organic carbon (SOC) content. Finally, the soil SOC stocks were calculated. In 83% of cases, it was observed that SOC stocks increased under NT compared to CT in the topsoil. This effect was observed due to an increase in both SOC content and bulk density. The accumulation rate of SOC stocks for NT was evaluated from 0.15 to 1.12 Mg $ha^{-1}$ $yr^{-1}$. In the subsoil, the SOC under NT decreased in 50% of cases, while in other cases it remained basically unchanged compared to CT. Using DNDC model, the long-term dynamics of SOC stocks were forecasted from 2023 to 2100 years, considering the SSP2-4.5 and SSP5-8.5 climate change scenarios in the Samara and Krasnodar regions. In the first 30 years of using the NT, the rate of SOC accumulation in topsoil (from 0.19 to 0.26 Mg $ha^{-1}$ $yr^{-1}$) will exceed its losses in the subsoils (from 0.06 to 0.12 Mg $ha^{-1}$ $yr^{-1}$) for the farm fields in two regions. However, in the following 50 years (2051–2100), the trend will reverse: SOC losses from the subsoil will exceed its accumulation in the topsoil by 1.1–2.6 times. Therefore, the development of technologies is necessary to enhance and preserve soil carbon in subsoils under NT practices. Here, it could be considered incorporating perennial cover grasses into crop rotations to enhance rhizodeposition.

# Effects of Historical Land Use Changes on Deep Soil Carbon, Nitrogen and Microbial Communities in Alpine Sandy Region

**Jinlu Guo[1], Yuan Wang[1], Lei Deng[2], Wenjing Li[1], Xiaogang Li[3], Wenying Wang[1], Huichun Xie[1], Jinhong Guan[1*]**

## ABSTRACT

Land use change is a key driver of soil carbon and nitrogen dynamics, significantly influencing soil fertility. However, the effects of historical land use changes on deep soil carbon and nitrogen dynamics, as well as microbial community composition in alpine sandy regions, remain poorly understood. This study examined a 23-year-old *Caragana microphylla* shrub forest in the Gonghe Basin, comparing carbon and nitrogen dynamics, as well as microbial community characteristics, across the 0-500 cm soil depth in historically afforested farmland forest (FF), planted forest (PF), and mobile dunes (CK). The study area is located at an elevation of 2,871 to 3,870 meters above sea level, with an annual mean temperature of 3.9°C and average annual precipitation of 246.3 mm, primarily occurring between May and September. The annual mean potential evaporation is 1,716.7 mm, resulting in an exceptionally arid climate. This region is classified as an alpine arid zone, with predominantly sandy soils. The results demonstrated that historical land use changes significantly influence the content and storage of soil organic carbon (SOC), inorganic carbon (SIC), and total nitrogen (STN). Across the 0-500 cm soil depth, average SOC, SIC, and STN concentrations were as follows: FF (2.40, 10.37, 0.28 g·kg$^{-1}$) > PF (1.46, 9.53, 0.17 g·kg$^{-1}$) > CK (0.89, 8.31, 0.11 g·kg$^{-1}$). Soil organic carbon, inorganic carbon (SIC), and total nitrogen storage at each 100 cm subsoil depth were as follows: FF (28.99-39.16, 132.92-149.48, 3.44-4.76 t·hm$^{-2}$) > PF (18.08-23.08, 128.27-139.39, 1.71-3.02 t·hm$^{-2}$) > CK (12.97-14.39, 123.82-130.29, 1.69-1.76 t·hm$^{-2}$). Soil water content is a critical environmental factor influencing deep soil carbon and nitrogen cycling in alpine sandy regions. Soil microbial community diversity was highest in the 0-40 cm surface layer under FF, whereas PF exhibited greater diversity in the 100-500 cm deeper layer. Soil bacterial communities were more sensitive to historical land use changes than fungal communities. In CK, soil microbial communities were primarily influenced by nitrogen and physical factors, while in PF, soil organic carbon and total nitrogen were the principal influencing factors. In FF, soil bulk density and water content were the key determinants. In summary, the FF model in alpine sandy regions outperforms the PF model in enhancing soil SOC, SIC, and STN content across the 0-500 cm layer and promoting surface microbial diversity. Conversely, the PF model plays a unique ecological role in maintaining deep soil microbial diversity. Therefore, attention to the long-term effects of historical land use transitions is crucial for advancing the sustainable development of desertification prevention and control efforts.

**ABSTRACT**

Soil is a potential sink for greenhouse gases. The possibility of accumulation of soil organic carbon (SOC) in arable soils requires accurate consideration of interactions between climate, soil, and farming systems. This task can be solved by modeling the dynamics of SOC stocks based on data from long-term field experiments.

SOC dynamics in a long-term field experiment with mineral and organic fertilization on sandy loam Retisol in Tver Region, Russia, was traced with the dynamic SOC model RothC from the launching the experiment (1956) until the present. The initial SOC content in the studied soils was about 30 t/ha. During the observation period, C stocks decreased by 10-34% compared to the initial level, depending on the fertilization system and quantity of fertilizers applied. The model was also used to forecast SOC changes up to 2090 and to assess the prospects for different agricultural techniques in increasing SOC stocks for the two contrasting climatic scenarios (RCP4.5 and RCP8.5) and the two economic scenarios (implying changes in crop rotations and fertilizer rates). Up to 2090, steady growth of SOC stocks is expected in all the compared treatments for both scenarios.

The possibility of application various organic fertilizers and alternative methods of soil cultivation as additional approaches to the accumulation of SOC has been studied. It is shown that if existing technologies are maintained in the conditions of the future climate, the increase in SOC stocks in the arable layer (0-20 cm) of the studied soils by 2090 can amount from 19% (RCP8.5) up to 34% (RCP4.5) of the initial content, and the implementation of carbon-saving technologies can provide an additional increase of more than 19%. Among the alternative sources of organic fertilizers, the best result can be expected with compost and peat mixtures application. Both fertilizers can provide additional accumulation of SOC up to 8 t/ha by 2090 (over 70 years) compared with the use of FYM, while the use of green-manure fallow and minimal tillage cannot be considered as optimal strategies, since these techniques lead to a slower SOC accumulation compared to FYM.

It is shown that the studied soils have a significant potential for carbon sequestration, since its consistent accumulation can occur even for business as usual scenario with maintaining the field practices of the initial treatments. However, proper SOC management makes it possible to achieve a significantly greater increase in carbon stocks.

## ABSTRACT

Carbon (C) and nitrogen (N) are essential soil components that drive fertility, regulate nutrient cycling, and influence the stability and productivity of agricultural ecosystems. Land use and management change (LUMC) influence the distribution and stability of C and N pools in the soils. Shifts from rice paddies to aerobic conditions alter organic matter inputs, decomposition rate, and isotopic composition, such as the soil stable isotope ratio ($\delta^{13}C$ and $\delta^{15}N$), reflecting transformations in C and N sources and cycling processes. The more labile or easily decomposable, fractions such as hot water or water-extractable organic C (HWEOC or WEOC) and N (HWEON or WEON) are critical for rapid nutrient turnover and microbial activity and are sensitive to changes in land use and management practices; because water-extractable fractions represent the more bioavailable forms of C and N, their concentrations tend to respond quickly to environmental changes. This study examined the effects of long-term land-use and management change from rice paddy to orchard (apple and chestnut), upland (soybean, wheat, etc.), and pasture (reed canary grass) on soil organic C (SOC) and total N (TN) contents, including their $\delta^{13}C$ and $\delta^{15}N$, and the concentrations of HWEOC/N or WEOC/N. Soil samples were collected in November 2024 from the surface (0–15 cm) and sub-surface (15–30 cm) layers across four distinct land types at the Yamagata University Farm, Northeast Japan, where the LUMC occurred 50 years ago from 1974. Samples were air-dried, homogenized by grinding, and passed through a sieve prior to analysis. Air-dried soils were used to measure SOC and TN contents and calculated for SOC and TN stocks, and stable isotope ratios for C and N were determined. To extract labile form of organic C and N, soils were mixed with water at a 1:5 ratio. HWEOC/HWEON were obtained by extraction at 80°C for 16 hours, whereas WEOC/WEON were extracted at room temperature. Following filtration, the extracts were divided into two portions: one for the analysis of C and N concentrations, and the other was freeze-dried for subsequent stable carbon isotope ratio analysis. The results demonstrate that LUMC significantly affects SOC and TN contents. Conversion from the original paddy rice (used as a control) to aerobic land uses significantly reduced SOC content at the 0-30 cm soil depth by 33.3%, 45.8%, and 47.9% in pasture, orchard, and upland soils, respectively. Similarly, TN content was highest in the paddy rice soil at 4.0 g $kg^{-1}$. It decreased to 3.2 g $kg^{-1}$ in pasture soil ($P$ <0.05), and to 1.6 g $kg^{-1}$ and 1.3 g $kg^{-1}$ in orchard and upland soils, respectively ($P$<0.05). SOC stock at 0-30 cm depth was highest in rice paddy soils (6.74 Mg C $ha^{-1}$), followed by pasture (5.93 Mg C $ha^{-1}$) and upland (5 Mg C $ha^{-1}$) soils, and lowest in orchard soils (4.86 Mg C $ha^{-1}$). TN stocks were greatest in pasture soils (0.59 Mg N $ha^{-1}$), but did not differ significantly from rice paddy soils (0.57 Mg N $ha^{-1}$), whereas upland and orchard soils had significantly lower values (0.47 and 0.45 Mg N $ha^{-1}$, respectively). Statistically significant differences among land-use types indicate substantial reductions in both SOC and TN in orchard and upland soils compared with rice paddy and pasture soils, suggesting depletion of C and N stocks following conversion of paddy rice to aerobic land uses, particularly to orchards. The lowest soil $\delta^{13}C$ (-27.60‰) and $\delta^{15}N$ (0.93‰) values in paddy rice soils, relative to aerobic land uses, reflect the impacts of anaerobic conditions on C and N cycling processes such as suppressed nitrification and enhanced denitrification. Soil C and N contents showed strong correlations with the water-extractable fractions, regardless of extraction temperature. We conclude that the conversion of rice paddies to aerobic land uses significantly decreased the soil C and N stocks within the 0-30 cm layer and affected soil fertility and climate change.

# Chemical carbon sequestration dominates leguminous green manure return, whereas physical carbon sequestration prevails in non-leguminous systems

**Huitong Li[l*], Shanshan Wang[l], and Wentao Dong[l]**

[1] *College ofLife Sciences, Yan'an University, Yan'an, China*

*E-mail: huitongli1314@yau.edu.cn

## ABSTRACT

Soil organic carbon (SOC) is fundamental to agricultural sustainability, yet intensive practices have depleted global SOC stocks by 25-75%. Leguminous green manure (LCS) enhances carbon input via biological N2 fixation, while non-leguminous green manure (NLCS) primarily improves physical protection through soil aggregation. The distinct carbon sequestration pathways of these two green manure types require systematic evaluation for optimized soil carbon management. A global meta-analysis of l586 paired observations from 2l0 studies (l990-2022) quantified LCS/NLCS impacts on SOC fractions. Data from Web of Science and CNKI were analyzed using random-effects models. Key variables included POC (particulate organic carbon), MAOC (mineral-associated organic carbon), and total SOC, with moderators encompassing climate (MAT-mean annual temperature/MAP-mean annual precipitation), soil properties (pH/texture), and agronomic practices (N fertilizer rate/tillage) et al. LCS increased POC (+27.95%), MAOC (+7.2%), and total SOC (+9.4l%) through chemical pathways (N-enhanced organic matter input). NLCS predominantly enhanced MAOC (+l2.3%) via physical mechanisms (improved soil aggregation). Climate effects revealed MAT >l5°C and MAP >l000mm amplified POC sequestration, while MAOC responses were soil-specific. Acidic soils (pH<6) and fine textures (clay>40%) favored MAOC increases. Optimal N rates (0-l20 kg ha_1) and reduced tillage maximized carbon benefits, with LCS showing stronger labile carbon accumulation than NLCS. LCS exhibits chemical-dominated carbon sequestration, while NLCS demonstrates physical-dominated mechanisms. This pathway divergence necessitates site-specific green manure selection. Climate-soil-management interactions must be considered to optimize carbon sequestration. The findings provide actionable strategies for enhancing agricultural carbon sinks and advancing sustainable farming practices under climate change scenarios, with implications for global carbon neutrality targets.

# Beyond Methane: Reassessing the Role of Rice Paddies in Global Warming

**Pil Joo Kim*, and Hyeon Ji Song**

*Division of Applied Life Science (BK 21 Plus), Gyeongsang National University, Jinju, South Korea*

*pjkim@gnu.ac.kr

**ABSTRACT**

As a major cereal crop, the global demand for rice continues to increase. However, the expansion of rice cultivation is constrained by substantial methane ($CH_4$) emissions during flooded rice cultivation. Since various soil management practices have been developed to mitigate $CH_4$ emissions, and rice paddies have high potential for soil carbon (C) sequestration, the impact of rice cropping systems on global warming requires re-evaluation. To compare the effects of cropping on global warming between rice paddy and maize upland systems, the net global warming potential (GWP) was evaluated by integrating $CH_4$ and nitrous oxide ($N_2O$) fluxes and changes in soil organic C (SOC) stocks under identical fertilization regimes. During crop cultivation, net GWP in rice paddies was predominantly driven by $CH_4$ flux, whereas in upland fields it was strongly influenced by SOC stock depletion. Under conventional fertilization (NPK and green manure), net GWP was substantially higher in rice paddies than in upland systems; however, under biochar application, the climatic impact was markedly lower. Moreover, the combined application of $CH_4$ mitigation practices, including mid-season drainage, reduced the net GWP of paddy fields to levels considerably lower than those observed in upland fields. A similar trend was observed for greenhouse gas intensity (GHGI), which indicates the net GWP per grain productivity. Consequently, if $CH_4$ mitigation practices for rice paddies are effectively implemented, rice could be produced in a more climate-friendly manner than in upland systems.

## ABSTRACT

Tree-based farming systems are widely promoted to enhance soil fertility and sequester carbon, yet fine-scale empirical evidence from semi-arid agroecosystems remains limited. Here we quantify how individual trees modify soil physical, chemical and hydrological properties in a Mediterranean dryland landscape. Soils were sampled around 14 individual trees representing four contrasting lineages (Cupressaceae, Pinaceae, Myrtaceae and mallee species; scenarios S1–S4) using a nested depth–distance design (0–5, 5–10, 10–20 and 20–30 cm at 1, 2, 4 and 8 m from trunks). We measured bulk density, gravimetric moisture, soil organic carbon (SOC), total nitrogen (TN), mineral nitrogen ($NH_4^+$-N, $NO_3^-$-N) and Colwell P. Effects of depth and distance were tested using linear mixed-effects models. Across scenarios, SOC and nutrient pools were consistently elevated beneath canopies, with the strongest enrichment typically within 1–2 m of trunks and in surface mineral soil (0–10 cm; 0–5 + 5–10 cm combined), forming spatially confined fertility islands. Bulk density increased with depth and distance from trees; for example, in the 10–20 cm layer, average bulk density was ~1.07 g $cm^{-3}$ at 1–2 m versus ~1.25 g $cm^{-3}$ at 8 m. Importantly, soil moisture did not decline near trees: in the upper 0–20 cm, gravimetric moisture averaged ~10–12% at 1 m compared with ~8–10% at 8 m, while differences largely disappeared at 20–30 cm where soils were near field capacity (~15%). Partial redundancy analysis showed that soil depth was the dominant structuring factor (explaining 85–95% of variance), with distance from trees representing a weaker but consistent secondary gradient aligned with SOC and nutrient enrichment. Together, these results demonstrate that scattered trees can enhance near-surface carbon storage, nutrient availability and soil structure without an apparent moisture penalty in this dryland system, supporting strategic tree integration as a pathway for climate mitigation and soil restoration.

# Land use effects on soil carbon retention through glomalin-mediated aggregation

**Ying Zhao[1*] and Wenxiu Zou[1]**

*[1] State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin, China*

*E-mail Address of Presenting Author: zhaoy@iga.ac.cn

**ABSTRACT**

The glomalin-related soil protein (GRSP), produced by arbuscular mycorrhizal fungi, plays a critical role in soil organic carbon (SOC) storage and stabilization across terrestrial ecosystems. We examined the effects of four contrasting land-use types (bare land, cropland, grassland, and woodland) originating from the same soil matrix on GRSP dynamics, soil aggregation, and SOC accumulation. We found that grassland and woodland ecosystems exhibited significantly higher contents of macroaggregates (>0.25 mm), SOC, total nitrogen (TN), total GRSP (TG), easily extractable GRSP (EEG) and aggregate stability compared with cropland and bare land. Across all land uses, the EEG/SOC and TG/SOC ratios in Mi and SC were higher than other aggregates sizes. Correlation analyses showed that TG was significantly and positively correlated with SOC in bulk soil and macroaggregates (>2 mm), while EEG exhibited significant positive correlations with SOC in smaller macroaggregates and microaggregates. Furthermore, GRSP was strongly and positively correlated with aggregate stability, and the content of TG and the TG/SOC ratio were mainly influenced by microbial biomass carbon (MBC) and SOC. Our findings highlight the contrasting correlations of TG and EEG to SOC storage across aggregate size classes, with TG playing a more prominent role in bulk soil and large macroaggregates, and EEG more significantly associated with SOC accumulation in small macroaggregates and microaggregates. This study advances our understanding of the mechanisms by which GRSP facilitates SOC sequestration and soil aggregate formation under different land-use regimes, informing sustainable land management strategies for climate change mitigation.

# Demonstration and application of zero-carbon Taoyuan biochar carbon sequestration technology

**Zhenya Wang,**

*Agriculture and Rural Committee of the Fujian Provincial Committee of the Democratic Construction of China,Fuzhou,China*

455587341@qq.com,

**ABSTRACT**

The Zero-Carbon Peach Orchard Demonstration Project in Fu'an applies biochar-based carbon sequestration technology to establish a low-carbon, high-efficiency agricultural model. Agriculture contributes 10–12% of global anthropogenic greenhouse gas emissions—mainly methane ($CH_4$), nitrous oxide ($N_2O$), and $CO_2$—yet it remains one of the few sectors capable of transforming from a net carbon source into a net carbon sink. Biochar, a negative-emission technology produced via pyrolysis of agricultural and forestry biomass under oxygen-limited conditions, contains highly stable carbon structures with residence times ranging from centuries to millennia. When introduced into soils, biochar enhances long-term carbon storage while improving soil fertility, water retention capacity, pH balance, nutrient availability, and microbial activity.

Fu'an City possesses abundant biomass resources and soils with strong carbon sequestration potential. The project implements biochar soil amendment in a peach orchard located in Hutu Village, the core production area of Muyang honey peaches. A one-year field experiment includes three treatments: an unfertilized control, a conventional fertilization plot, and a biochar-amended plot with equivalent fertilizer inputs. Soil samples collected at multiple depths and seasonal stages—following national sampling standards—are analyzed for pH, organic matter, nutrients, total carbon, bulk density, moisture, salinity, heavy metals, and GHG-related parameters. Peach tree growth, yield, and fruit quality indicators (size, sugar content, acidity, firmness, vitamin C, and heavy metals) are also monitored.

The project also establishes a green technology evaluation framework and conducts a full lifecycle carbon footprint assessment of peach production. Using ISO 14040/14044 and ISO 14067 standards, carbon emissions from resource inputs, cultivation, and harvesting are quantified based on localized data and IPCC emission factors. Outputs include a Green Technology Evaluation Certificate, a Product Carbon Footprint Report, and carbon-neutrality verification for the orchard. The project ultimately provides a replicable methodology for low-/zero-carbon orchard development, offering data-driven guidance for resource efficiency, emission reduction, enhanced carbon sinks, and sustainable agricultural modernization in Fu'an.

**ABSTRACT**

Soil organic carbon (SOC) is central to soil health and the global carbon cycle, as it represents the largest terrestrial carbon pool. SOC stocks are strongly affected by agricultural management. Unsuitable management often leads to SOC loss and soil degradation, while adapted management sustains or enhances SOC content in agricultural soils. Understanding and quantifying the impact of management on SOC dynamics is therefore critical for agricultural sustainability and climate mitigation. Here, we present results of a biogeochemical model-based tool to estimate the effects of farm management on long-term SOC stock dynamics in Swiss croplands under varying management actions and climate scenarios. The tool integrates well-established models, such as RothC, DayCent and AMG, and was calibrated using long-term management and SOC measurement data from the Swiss Soil Monitoring Network (NABO) and field trials. By combining multiple national datasets, including information on soil properties, weather conditions, land use types, and manure management, the tool reduces the data input requirements for users. The resulting platform will be designed to enable field-scale simulations of SOC stock dynamics, offering farmers, advisors, and policymakers a science-based tool to evaluate the influence of management options on soil health. The overarching goal is to promote sustainable soil management and support national agricultural objectives.

# Effects of tillage practices on environment, energy, and economy of maize production in Northeast China

**Yang Zhang[1*] and Aizhen Liang[1]**

*[1] State Key Laboratory of Black Soils Conservation and Utilization, Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, China*

Email:zhangyang@iga.ac.cn

**ABSTRACT**

Conservation tillage plays a positive role in restoring degraded cropland in terms of increasing carbon sequestration, improving soil aggregation, and maintaining crop productivity. Assessing the key indicators of environment, energy, and economy under different tillage practices could provide a comprehensive scientific basis to implement low-carbon emission, clean and sustainable agricultural management, especially in the long-term experiment field. Our objectives were: 1) to compare crop production under different long-term tillage practices, 2) to evaluate the carbon footprint (CF), energy budget, and net ecosystem economic benefit (NEEB) of spring maize production under different long-term tillage practices. Three tillage practices consisting of conventional tillage with complete removal of residue (CT), moldboard plowing with residue return (MP) and no-tillage with residue return (NT), had been conducted for eight years. Greenhouse gas (GHG) emissions from the soil were measured, and the inputs of raw materials and outputs of crop production were also recorded. CF, energy budget, and NEEB were evaluated for two consecutive growing seasons based on the life cycle assessment (LCA) approach. Compared with CT, NT could reduce $N_2O$ emissions and absorb more $CH_4$, whereas MP significantly increased $CO_2$ emissions from soil. However, there was no significant difference in maize yield among all treatments. Moreover, NT led to both the lowest GHG emissions from soil (GWPGHG) and agricultural inputs (AIGHG), thus NT decreased CF by approximately 40% compared to CT for maize production. Furthermore, MP and NT decreased 8.4% and 35.7% of the energy inputs owing to lower diesel fuel consumption in comparison with CT, yet there was no significant difference in energy output among different tillage practices. The same was true in NEEB, although MP and NT showed lower investments during maize production. These results indicated NT required the lowest energy and financial investment for the same maize yield. In conclusion, NT could minimize CF and energy inputs while insuring maize production from a long-term perspective. Long-term NT can be implemented in Northeast China and similar agro-eco-regions around the world. The findings of our study provide scientific data on the performance of different long-term tillage practices in the environment, energy budget and economic benefits.

# Exogenous organic carbon-induced stoichiometric balance stimulates microbial high growth potential yield strategies to promote necromass accumulation in soil carbon pools

**Jiaqi Hao[1], Xing Wang[2*], and Xiaohong Tian[1]**

[1] *College of Natural Resources and Environment, Northwest A&F University, Yangling, China*

[2] *College of Agronomy, Northwest A&F University, Yangling, China*

*E-mail:wangxing0103@nwafu.edu.cn

**ABSTRACT**

Understanding the microbial transformation of exogenous organic carbon (EOC) into persistent soil organic carbon is paramount for mitigating climate change. While microbial necromass carbon (MNC) is a key stable carbon pool, the mechanisms governing its accumulation under EOC inputs remain elusive. To address this, we integrated a global meta-analysis of 400 paired observations with an eight-year field experiment and metagenomic sequencing. Our meta-analysis revealed that EOC inputs significantly enhanced soil MNC by 38.13% and increased its contribution to the total soil organic carbon pool by 5.24%. Amendment type was a critical regulator, with low C/N manure inducing a greater MNC increase (up to 75.17%) than high C/N plant residues. Field data robustly validated these global trends: compared to the control, composted sheep manure (C/N=14.1) and wheat straw (C/N=64.6) elevated total MNC by 39.6% and 26.4%, respectively. We identified that EOC-induced alleviation of soil stoichiometric imbalance (C/N-imbalance index shifting towards 1) was the universal driver, promoting a community-wide shift towards a high growth potential yield (Y) strategy. Metagenomic dissection uncovered two quality-dependent metabolic gateways: 1) High C/N straw sustained a mild C/N imbalance, forcing a costly "Y+A" trade-off. This involved significant upregulation of flagellar assembly (A-strategy) for motility and nitrogen mining, coupled with cell division pathways (Y-strategy), ultimately favoring fungal necromass accumulation. 2) In contrast, low C/N manure achieved stoichiometric equilibrium, minimizing investment in resource acquisition. This facilitated a pure Y-strategy, channeling energy into biofilm formation and amino acid biosynthesis, which concurrently boosted both bacterial and fungal necromass. Importantly, the Y-strategy encompassed the highest number of unique genera (387), indicating evolutionary selection for growth-oriented taxa. Our study establishes a mechanistic paradigm where EOC quality, mediated by soil stoichiometric balance, steers microbial life-history trade-offs to dictate the pathway and efficiency of necromass carbon sequestration. We propose that tailoring organic amendments to foster Y-strategies offers a targeted, microbiology-based approach to optimize the 'microbial carbon pump' and enhance carbon sequestration in agricultural soils.

# Management practices to mitigate long-term soil organic carbon losses in temperate arable soils

**ABSTRACT**

Over the past decades, soil organic carbon (SOC) in agricultural soils has shown a decreasing trend across Europe, reflecting the combined effects of management practices and climate change. Long-term field experiments offer a unique opportunity to study these effects and identify management strategies that can mitigate SOC losses under changing climatic conditions.

This contribution combines results from two long-term experiments located at the same site in Puch/Fürstenfeldbruck, Southern Germany: a compost amendment experiment (1994–2023) and a management comparison experiment (IOSDV, 1983–2021) with varying organic matter inputs and mineral nitrogen fertilization rates. Both experiments revealed a distinct SOC content decline, coinciding with a marked regional temperature rise and increased frequency of drought–rewetting cycles. Despite continuous or even increasing organic inputs, SOC contents declined in most cases, indicating climate-driven acceleration of SOC mineralization. Across treatments, only management strategies combining multiple organic amendments (e.g., slurry, straw incorporation, and cover crops) or the application of compost can mitigate SOC loss to a certain extent. The results emphasize that improved management can buffer SOC losses and compensate enhanced decomposition processes under a warming climate.

The analysis of both long-term experiments highlights the necessity for improved agricultural management to mitigate SOC losses and maintain soil functionality in a rapidly changing climate.

**ABSTRACT**

Carbon and nitrogen are fundamental elements in global biogeochemical cycles, exerting critical influences on air and water quality, biodiversity, and human health. Over the past four decades, China has released substantial amounts of carbon and nitrogen into the environment, leading to significant regional and global consequences. To support effective monitoring and regulation, we developed a coupled human and natural systems (CHANS) model that quantifies national carbon-nitrogen budget and evaluates their ecosystem-level interactions from 1980 to 2020. During this period, carbon emissions increased by a factor of 6.5 and nitrogen emissions by a factor of 2.3. Our results show that integrated carbon and nitrogen management could reduce nitrogen pollution to air and water by up to 75% and lower carbon emissions by 91% by 2060. Relative to managing carbon or nitrogen in isolation, the integrated approach enables additional reductions of 1.8 million tonnes of nitrogen and 26.6 million tonnes of carbon by 2060. It also decreases the unit abatement cost by 37% and yields total societal benefits of US$1,384 billion. These findings underscore the necessity of coordinated carbon-nitrogen governance and offer a robust scientific basis for nature-based solutions, aligning with China's pursuit of net-zero carbon emissions and synergistic air and water quality improvements.

**ABSTRACT**

Mangroves are notable for providing diverse ecological functions and ecosystem services, including carbon (C) sequestration and climate change mitigation. In fact, these ecosystems, recognized as Blue Carbon Ecosystems, can store large amounts of C within living and dead biomass, but mostly on its soils due to the predominant anoxic/sub-oxic conditions and organo-mineral interactions that hampers organic matter decomposition. In this sense, Brazil holds the world's second largest area, covering approximately 8% of the total global mangrove area. However, since Brazil present a unique coastal zone conformation, spanning from northern hemisphere to subtropical latitudes, there is a wide variation in litho-climate conditions which controls C dynamics along Brazilian coast. Thus, the main goal of this work is to integrate C stock data across Brazilian mangroves, assessing variability of coastal compartments. Total Ecosystem C Stocks (TECS) were quantified, considering soil, above- and belowground stocks from mangrove areas in the Southeastern, Northeastern, and Amazon regions of Brazil. The aboveground biomass of evaluated Brazilian mangroves accumulated 5.82-254.95 Mg C per hectare (mean±SD = 73.3±68.07 Mg C per hectare), while the carbon stored in the soils, at depths up to 100 cm, was found to be between 13.2 and 405.5 Mg C per hectare (156.95±123.47 Mg C per hectare). The largest amounts of soil C stock were found along the Southeastern (332.16±74.79 Mg C per hectare) and Amazon (327.75±17.32 Mg C per hectare) coasts. Amazon region also showed the highest aboveground stock amount (170.50±16.26 Mg C per hectare). In contrast, the Northeastern coast presented mean soil C stock of 95±67.23 Mg C per hectare and an aboveground stock of 64.54±67.34 Mg C per hectare. These findings support prevailing research, showing that mangrove soils can store considerably more carbon than aboveground biomass, highlighting the role of the soil as an important blue carbon sink. The highest carbon stock rates were also observed in mature mangroves, recovered and under revegetation processes. Thus, conservation and regeneration efforts must prioritize the protection of mangrove soils to effectively mitigate the emission of greenhouse gases, such as carbon dioxide and methane, into the atmosphere.

## ABSTRACT

Mangrove forests are key Blue Carbon ecosystems due to their high primary productivity and exceptional capacity to store carbon in soils. However, extreme weather events threaten this ecosystem, particularly in previously impacted or degraded areas. This study examines the relationship between Gross Primary Productivity (GPP) and soil carbon content in pristine and degraded mangroves within the Cananéia-Iguape Coastal System (São Paulo, Brazil). Soil samples were collected at multiple depths and analyzed for pH and redox potential (Eh), and organic carbon content. In parallel, GPP was estimated using MODIS products (MOD17A2H and MOD13Q1), enabling a temporal assessment of vegetation dynamics from 2012 to 2023. Results show that the degraded mangrove exhibits markedly lower soil carbon content and lower Eh values (6.4 ± 0.4 mV) compared to the pristine mangrove. These conditions reflect intensified organic matter decomposition due to loss of vegetation and carbon inputs. In contrast, the pristine site maintains higher soil carbon content and Eh values (30.6 ± 21.8 mV), indicating a geochemically functional and expected geochemical environment. Remote sensing analysis further revealed persistently low vegetation vigor in the degraded area expressed by low EVI/NDVI and reduced GPP while the pristine mangrove sustained consistently higher productivity throughout the temporal record. Together, these results highlight how vegetation decline and soil carbon losses reinforce redox deterioration in degraded mangroves and underscore the value of integrating field and satellite indicators for effective conservation and management of these ecosystems. Ultimately, strengthening the monitoring and preservation of mangrove ecosystems is essential not only for maintaining local ecological functions, but also for safeguarding global climate stability and the well-being of human populations that depend on these critical Blue Carbon reserves.

**ABSTRACT**

Urban green areas provide major ecosystem services which are essential for the well-being of the most populated areas of the world. We hypothesized that the healthier the city, the better ecosystem services it provides. In this context, carbon dynamics could be used as indicators of soil health. Under a Mediterranean-type climate, carbon fluxes follow a pattern modulated by climate and vegetation type, and are influenced by a set of environmental and management factors. A set of plots (n=3) was selected across four types of vegetation (perennial and annual grassland, open-sized herbs of *Diplotaxis* sp., and meadow grassland of *Malva silvestris*) in four different urban green areas of Madrid. In each of the plots, an intensive monitoring programme of the soil carbon cycle was performed during 2023-2024, including: soil respiration, enzyme activities of the carbon cycle (α, β-Glucosidase, β-Galactosidase, Cellobiose, Phenoloxidase); Total Organic Carbon (TOC), hot and cold water soluble carbon fractions, microbial biomass, among other biological properties. Results show that climate (temperature and humidity) has a predominant effect on respiration rates, whereas vegetation type drives enzymatic activities. Moreover, perennial grasslands tend to accumulate more carbon than the rest of the vegetation communities, while the grassland of *Malva silvestris* shows a high rate of mineralisation.

## ABSTRACT

Soil organic carbon (SOC) accumulation is a key strategy for mitigating global warming. However, in Korean greenhouse horticulture, the combined effects of cropping system and organic amendment type on soil properties and SOC dynamics are poorly quantified. This study compared crop productivity, soil chemistry, and SOC stocks and fractions under fertilization regimes (chemical fertilizer, animal manure compost, and commercial organic fertilizer) combined with cropping systems (repeated cropping vs. crop rotation). The experiment was conducted from March 2023 to October 2025 in Anseong, Gyeonggi, Korea. Treatments comprised a chemical fertilizer control (CF), animal manure compost (AC), and a commercial organic fertilizer (OrF). The AC and OrF treatments were each managed either as a repeated-cropping system (RC) with continuous mustard greens or as a crop rotation system (CR) with mustard greens, spinach, and hairy vetch. RC involved two cropping cycles per year, and CR three cycles including hairy vetch as green manure/cover crop. Key soil chemical properties (pH, available P, exchangeable cations, total N, and SOM) differed markedly among treatments. Soil pH was particularly sensitive to amendment type, being lowest in OrF plots and suggesting acidification-related growth constraints. In 2025, mustard green yields were higher in CF and compost treatments (1,608.3–1,850.4 kg 10a$^{-1}$) than in OrF treatments (1,236.7–1,287.7 kg 10a$^{-1}$), with CF and AC forming a significantly higher-yielding group. Within each organic amendment type, rotation tended to outyield repeated cropping, indicating that hairy vetch–based rotation improved nutrient supply and organic matter inputs, although these differences were not statistically significant. SOC stocks increased in all treatments between 2023 and 2025. SOC stock in CF rose from 19.48 to 37.72 Mg C ha$^{-1}$ (+18.24 Mg C ha$^{-1}$). In organic-amended plots, SOC increased by 21.25 and 21.12 Mg C ha$^{-1}$ in RC-AC and RC-OrF, and by 34.02 and 36.76 Mg C ha$^{-1}$ in CR-AC and CR-OrF, respectively, giving organic-amended soils 6.8–16.1 Mg C ha$^{-1}$ more SOC than CF in 2025. The mineral-associated organic matter (MAOM) fraction, representing a relatively stable SOC pool, was similar in CF and OrF treatments (38.33–39.04 g kg$^{-1}$) but higher in compost treatments (47.36–51.23 g kg$^{-1}$), indicating that compost particularly promoted SOC stabilization in mineral-associated forms. Overall, combining animal manure compost with a crop rotation system including hairy vetch in protected horticultural soils maintained or exceeded conventional yield levels, mitigated soil acidification relative to sole application of commercial organic fertilizer, and enhanced SOC stocks and MAOM fractions over the medium term. These results show that integrated organic matter management via compost and diversified crop rotation can increase SOC storage and sustain soil functions, offering a practical strategy for carbon-neutral protected horticulture.

# Permafrost ecosystems of Pur-Taz interfluve (Western Siberia) as a source of methane in the context of climate change

**Arina V. Larina[1], Nikita B. Ustinov[1], Georgy O. Gavrilov[1] and Vladimir S. Kazantsev[1]**

[1] *Laboratory of Greenhouse Gases, A.M. Obukhov Institute of Atmospheric Physics, RAS, Moscow, Russia*

*larin.arina2003@gmail.com

**ABSTRACT**

Among greenhouse gases (GHG) whose concentrations in the atmosphere have been rising throughout industrial era, methane ($CH_4$) is the second most potent one for its contribution to global warming. Being low in absolute terms, $CH_4$ atmospheric content has increased by 260% since 1750. About a third of total $CH_4$ emissions comes from freshwater ecosystems where it is produced anaerobically by methanogens decomposing organic matter (Saunois et al., 2024).

Among the most waterlogged regions of the world, West Siberian Lowland (WSL) is characterized by vast reserves of frozen organic carbon in permafrost-affected tundra wetlands. As permafrost thaws due to accelerated (+0.5 ºC decade$^{-1}$ over 1965–2015 period) Arctic warming (NOAA), this carbon becomes entrained in the active layer (AL) and available for conversion to $CH_4$. Within WSL, low-Arctic tundra wetlands are the most vulnerable to climate change due to near-zero permafrost temperatures. As for Pur-Taz interfluve, where our study area was located, their vulnerability has been assessed through the prism of ecosystem changes. The key changes are the following:

1. lengthening of the growing season by 4.8 days$_{t>10°C}$ decade$^{-1}$;
2. deepening of the AL at a rate of 15–20 cm decade$^{-1}$ (CALM) accompanied by mobilization of previously frozen organic carbon;
3. formation of thermokarst lakes and sub-lake taliks as a result of permafrost-thaw induced ground subsidence and surface inundation;
4. subsurface drainage of lakes through their taliks (according to Landsat-7 satellite data, the regional lake area decreased by 10.4% over 2000–2015 period) followed by waterlogging of drained lake basins.

To reveal how these changes affect $CH_4$ emissions from low-Arctic tundra wetlands of WSL, we carried out $CH_4$ flux measurements in different permafrost ecosystems of Pur-Taz interfluve in the summer seasons of 2023–2025. According to our results, measured $CH_4$ fluxes from dry polygonal tundra did not exceed 0.35 mg$CH_4$ m$^2$·h$^{-1}$ (median −0.01). Upon waterlogging, much higher flux values (up to 11.0 mg$CH_4$ m$^2$·h$^{-1}$) were observed (median 1.7). Thermokarst lakes emitted $CH_4$ at a rate of 0.1−9.0 mg$CH_4$ m$^2$·h$^{-1}$ (median 0.4), whereas $CH_4$ fluxes from their young and old drained basins were up to 21.6 (median 5.6) and 9.0 mg$CH_4$ m$^2$·h$^{-1}$ (median 4.6), respectively.

Among the above-mentioned ecosystem changes, lengthening of the growing season, deepening of the AL as well as waterlogging are the key ones that enhance $CH_4$ emissions from permafrost ecosystems of WSL low-Arctic tundra.

## ABSTRACT

Wetlands are the largest natural source of methane ($CH_4$) – the second most potent greenhouse gas (GHG) in terms of contribution to global warming. Among them, Arctic permafrost-affected wetlands are extremely vulnerable to GHG-induced warming. As permafrost degrades, organic carbon becomes entrained in the active layer (AL) and converted to $CH_4$ by methanogens using mainly acetate or carbon dioxide as substrate (acetoclastic and hydrogenotrophic pathway, respectively). As a result, $CH_4$ emissions from Arctic wetlands increase in a positive feedback manner.

In the summer seasons of 2023 and 2024, we studied temperature controls on $CH_4$ fluxes and its production at polygonal tundra wetland of Samoylov Island in the Lena River Delta. The study area represents a mosaic of ice-wedge polygons with wet low centers and elevated drained rims. The increasing trend of summer $CH_4$ emissions from Samoylov polygonal tundra (Rößger et al., 2022) is determined by: a) water regime changes due to the degradation of intact low-center polygons (LCP); b) deepening and warming of AL. LCP degradation affect $CH_4$ emissions depending on local relief features whereas AL depths and temperatures are expected to increase further.

We monitored $CH_4$ fluxes at the wet (5 LCP) and drained (two intact rims and a high-center polygon with degraded rim) microsites at the peak of growing season by static chamber method. Measured fluxes from wet LCP (0.8–4.5 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$) were by two orders of magnitude higher than those from drained microsites and were poorly correlated with air and soil temperatures (Fig. 1), while their correlations with dissolved $CH_4$ concentrations in pore water were significant ($r_s$ = 0.64 and 0.55 at the depth of 10 and 15 cm, respectively). This was indicative that anaerobic $CH_4$ production and its release from AL occur on different timescales.

To study temperature sensitivity of $CH_4$ production, peat was sampled below the water table and incubated anaerobically. Based on $CH_4$ accumulation rates (Fig. 2), $Q_{10}$ coefficient between 5 ºC (mean value at the sampling depth) and 10 ºC was estimated to be 22. Parallel incubations with inhibitors of methanogenesis revealed that such a high value was due to an overwhelming contribution of acetoclastic pathway to overall $CH_4$ production. As its contribution was found to rise from 65% at 5 ºC to ~90% at 10 ºC, expected increase in AL temperatures may enhance $CH_4$ emissions from Arctic polygonal wetlands by an order of magnitude over centennial timescale.

## ABSTRACT

Understanding effects of future climate change requires accurate estimates of the impacts of atmospheric nitrogen (N) deposition on ecosystem carbon (C) cycling. Most previous studies have focused on inorganic rather than organic N deposition in influencing C fluxes. However, organic N is a substantial component of N deposition. Here we report the response of grassland soil respiration to 10 years of experimental addition of organic N (ON) and inorganic N (IN) separately and in mixture. Soil respiration increased greatly with N addition, regardless of N form, in the first five years. However, after six years of experimental additions, these effects of IN were reversed, and by 10 years, respiration from IN plots decreased by 24% and 69% relative to control and ON treatments, respectively. The divergent temporal responses of soil respiration to different N forms resulted from differences in the relative contributions of autotrophic respiration (RA) and heterotrophic respiration (RH), which mediated by the cumulative effects of N-induced soil acidification (pH decrease). The sharp decline of RH in response to IN addition corresponded to greater acidification in the IN treatment. Collectively, our findings indicate that the response of soil respiration to decade-long N deposition was modulated by soil pH and highlight that organic N in atmospheric deposition should be considered to improve understanding of how grassland ecosystems respond to long-term N deposition.

**Key-words:** inorganic N deposition, organic N deposition, grassland soil respiration, soil acidification.

**ABSTRACT**

This study focuses on the response mechanisms of soil organic carbon (SOC) sequestration and greenhouse gas emissions in paddy fields under climate change, aiming to elucidate the effects of elevated $CO_2$ concentration ($eCO_2$) and warming on carbon cycling processes in paddy ecosystems, and to evaluate the potential of biochar as a measure for carbon sequestration and emission reduction. Through in situ Warming-Free Air $CO_2$ Enrichment (T-FACE) platforms, long-term open-top chamber (OTC) experiments, and data analysis of global biochar trials, the impacts of $eCO_2$, warming, and their interactions on SOC dynamics, $CH_4$ and $N_2O$ emissions, as well as the underlying microbial and biogeochemical driving mechanisms, were systematically investigated. The results indicate that $eCO_2$ significantly increased subsoil SOC content by enhancing plant- and microbe-derived carbon inputs without stimulating the decomposition of native soil carbon. Elevated $CO_2$ also raised soil dissolved organic carbon (DOC) and acetate levels, thereby enhancing methanogenic potential and significantly increasing $CH_4$ emissions, whereas warming and its interaction with $eCO_2$ had no significant effect on $CH_4$ emissions. The interaction between $eCO_2$ and warming exhibited nonlinear characteristics in SOC and $CH_4$ responses, the mechanisms of which require further clarification. Biochar demonstrated sustained effects on carbon sequestration, emission reduction, and yield improvement. Long-term biochar application significantly reduced $CH_4$ and $N_2O$ emissions, enhanced SOC sequestration, and increased crop yield by approximately 10.8%, with almost no negative impacts on soil health. This study clarifies the mechanism by which $eCO_2$ influences SOC accumulation in paddy soils through regulating carbon input and decomposition processes, and reveals that biochar retains significant potential for carbon sequestration and emission reduction under climate change. Future research should further quantify the types of interactions among climatic factors to support adaptive management strategies for paddy systems in response to climate change.

## ABSTRACT

Since the onset of industrialization, atmospheric carbon dioxide ($CO_2$) concentrations have increased rapidly and have reached their highest levels in at least two million years. The IPCC has clearly stated that the accumulation of atmospheric $CO_2$ driven by human activities has significantly altered the Earth's energy balance by enhancing the greenhouse effect, constituting the dominant driver of current global warming, and exerting profound impacts on global and regional climate systems through perturbations of terrestrial carbon cycling, hydrological processes, and ecosystem feedback mechanisms.

Terrestrial ecosystems are a critical component of the global carbon cycle, characterized by pronounced diversity and hierarchical organization among carbon pools, including both active carbon pools such as vegetation biomass carbon and soil organic carbon (SOC), as well as more stable pools such as inorganic carbon. For decades, research has primarily focused on net primary productivity and the formation and turnover of SOC; however, these carbon pools are relatively dynamic across temporal scales and highly sensitive to climatic fluctuations and land-use change. In contrast, carbon pools with longer residence times and higher stability play an irreplaceable role in regulating atmospheric $CO_2$ concentrations under global change scenarios, and their identification and quantitative assessment are essential for accurately estimating the long-term carbon sink potential of terrestrial ecosystems. Nevertheless, such stable carbon pools remain substantially underestimated within existing carbon cycle frameworks, and their formation mechanisms, sources of stability, and spatial distribution patterns have yet to be systematically elucidated.

Phytoliths are amorphous silica ($SiO_2$) particles formed in plants through the uptake of soluble silicon from soils—primarily in the form of monosilicic acid—via the root system, followed by precipitation within cell walls, cell lumens, or intercellular spaces. During phytolith formation, a fraction of photosynthetically fixed organic carbon becomes encapsulated and occluded within the silica matrix, forming phytolith-occluded carbon (PhytOC). The organic carbon occluded within phytoliths can be preserved for extended periods in soil environments, thereby constituting a long-term stable carbon pool with considerable potential in terrestrial ecosystems. This long-term stability primarily arises from the intrinsic dissolution kinetics of phytoliths and multiple protective mechanisms operating within soil environments.

From a micro-process perspective, phytolith dissolution behavior is jointly regulated by morphological characteristics, chemical composition, and environmental conditions. Studies have shown that phytolith dissolution rates are significantly negatively correlated with ambient initial silicon concentrations (Nakamura et al., 2020), and that their spatial distribution within plant tissues exerts a strong influence on stability: compared with structurally fragmented phytoliths with larger specific surface areas (phytolith fragments), phytoliths deposited within cell lumens and cell walls generally exhibit greater structural integrity and lower dissolution rates (Nakamura et al., 2020). In soil environments, phytoliths can further be differentiated into fast-cycling and stable pools, reflecting the coexistence of young, rapidly recycled biogenic silica reservoirs and old, slowly dissolving stable reservoirs; the latter are typically dominated by dense morphotypes such as spherical phytoliths and exhibit markedly reduced dissolution rates. Although phytoliths, as amorphous silica minerals, are overall more soluble than crystalline silicate minerals, their dissolution is strongly constrained by soil pH, hydration state, and adsorption of metal elements, particularly through complexation with aluminum on phytolith surfaces, which effectively suppresses silica framework dissolution and prolongs phytolith residence time in soils (Cornelis et al., 2016).

Meanwhile, phytoliths in soils can acquire additional physical protection by associating with organic matter and clay minerals to form micro-aggregate structures. The formation of micro-aggregates substantially reduces direct contact between phytoliths and soil solutions, thereby further slowing dissolution processes. Higher contents of organic matter and clay in forest soils favor the stabilization of micro-aggregates, resulting in greater phytolith preservation compared with grassland or sparsely vegetated soils. In addition, under acidic conditions, phytolith surfaces readily develop coatings of hydroxyaluminosilicate precipitates, which not only inhibit silica dissolution but also significantly enhance the physical and chemical stability of phytoliths in soils.

Compared with SOC, PhytOC exhibits substantially higher stability due to encapsulation within a siliceous shell that provides enhanced structural protection, allowing residence times in soils to extend to several millennia (Liu et al., 2025). In contrast, SOC is prone to rapid losses following land-use changes such as grassland cultivation, with declines reaching up to 50% (Song et al., 2024). Fertilization experiments further demonstrate that PhytOC predominantly exists in stable forms within phytoliths and is resistant to microbial decomposition (Rutkowska et al., 2024). Principal component analyses indicate that PhytOC content is significantly correlated with soil pH and mineral elements such as Al and Fe, which enhance stability by suppressing phytolith dissolution (Wang et al., 2023). Even in karst bamboo forest soils characterized by low bulk density and unfavorable conditions for carbon preservation, PhytOC stability remains markedly higher than that of bulk SOC (Song et al., 2024). In oat and barley cropping systems, although PhytOC contents are significantly lower than SOC, their longer residence times still confer a pronounced stability advantage (Rutkowska et al., 2024).

The stability of PhytOC has not only been validated mechanistically but its sequestration potential has also been quantified using multiple metrics. At the global scale, the annual sequestration potential of PhytOC in bamboo forests has been estimated at $2.05 \pm 0.17$ Tg $CO_2$, accounting for approximately 11% of the contemporaneous annual atmospheric $CO_2$ increase (Liu et al., 2025). Field fertilization experiments show that PhytOC accumulation in oat fields ranges from 14.94 to 41.73 kg e- $CO_2 \cdot ha^{-1}$, with silicon fertilization increasing PhytOC contents by approximately 2.5-fold (Rutkowska et al., 2024). Statistical analyses further indicate that PhytOC stocks in moso bamboo and Neosinocalamus affinis forests range from 0.49 to 2.07 $t \cdot hm^{-2}$, and that mature stands store 1.5–2 times more PhytOC than young stands, reflecting a pronounced age-related accumulation effect (Wang et al., 2023). In karst soils, PhytOC can even account for up to 82% of SOC, highlighting its exceptionally high long-term sequestration potential (Liu et al., 2025).

Because phytolith formation and dissolution stability are jointly regulated by multiple factors, phytolith contents and their associated carbon vary substantially among plant taxa, plant organs, and ecological environments. Gramineous species possess highly efficient silicon uptake, transport, and accumulation mechanisms, enabling large quantities of soluble soil silicon to be translocated to aboveground tissues, thereby significantly promoting phytolith formation and enhancing carbon sequestration potential (de Tombeur et al., 2024). At the organ scale, phytolith carbon exhibits pronounced organ-level heterogeneity, with leaves, stems, straw, and roots contributing differently to total phytolith carbon stocks across plant types (Zhang et al., 2019) (Parr et al., 2010).

In addition to vegetation traits, environmental conditions also play a critical role. Soil-available silicon is widely regarded as a key material constraint on phytolith formation, with its supply directly controlling phytolith content and accumulation rates (Wang et al., 2022). The amount of silicon absorbed by plants determines the material basis for phytolith formation and thus directly influences phytolith production (Nakamura et al., 2020). In highly weathered soils, this phytolith-driven biological silicon cycle can even dominate silicon fluxes, as plants convert soil LSi and PSi into PhSi, enhancing silicon bioavailability within the soil–plant system and continuously influencing the coupled cycling of silicon and carbon (Cornelis et al., 2016).

Meanwhile, climatic factors such as temperature and precipitation indirectly affect phytolith formation intensity by regulating plant productivity, growth cycles, and silicon uptake, whereas soil physicochemical properties—including pH, organic matter content, and nutrient status—further control phytolith accumulation and preservation by influencing silicon dissolution, transport, and phytolith stability in soils (de Tombeur et al., 2024). (Deng et al., 2025)Deng employed a meta-analytical approach to comprehensively evaluate the effects of environmental factors on soil phytolith contents within a unified statistical framework. The results indicate that climatic conditions, soil physicochemical properties, and vegetation types all exert significant influences on soil phytolith contents; however, the direction and magnitude of these effects exhibit high heterogeneity among studies and ecosystems, reflecting the strong multi-factor control over phytolith formation and accumulation processes.

However, as soil phytoliths originate from plant-internal formation, are subsequently transferred via litter inputs, and gradually accumulate in soils, their contents are not only controlled by soil environmental conditions but are also highly dependent on plant silicon uptake capacity, organ allocation patterns, and litter deposition and decomposition processes. Existing meta-analyses that focus solely on soils provide valuable insights into environmental controls at the soil scale, but they are unable to disentangle the relative contributions of different factors during plant formation, litter transformation, and soil preservation stages, nor can they fully elucidate the integrated contributions of these processes to final soil phytolith contents.

Despite substantial advances in understanding phytoliths and their carbon sequestration functions, notable knowledge gaps remain. Most existing studies are based on local-scale observations, with limited geographic coverage and ecosystem representation; data are fragmented and indicators are inconsistent across studies, constraining large-scale synthesis. Moreover, many studies emphasize the independent effects of single or a few environmental factors, while systematic assessments of multi-factor interactions among vegetation, soil, and climate remain scarce. Methodologically, conventional statistical models have limited capacity to capture complex nonlinear relationships, thereby restricting accurate prediction of phytolith spatial patterns and their driving mechanisms.

Against this background, this study uses measured phytolith data from terrestrial ecosystems to systematically analyze the formation mechanisms and spatial distribution patterns of phytoliths and their associated carbon. Specifically, it aims to elucidate how climatic factors, soil properties, and vegetation types jointly regulate the spatial differentiation of phytolith and phytolith carbon contents, and to develop predictive models based on published empirical datasets to enable quantitative estimation of phytolith contents at broader spatial scales. By integrating global phytolith measurements with multi-factor statistical analyses, meta-analysis, and machine-learning approaches, this study seeks to overcome current limitations in spatial scale, analytical methods, and predictive capacity, and to develop predictive models based on published empirical datasets, enabling quantitative estimation of phytolith contents at broader spatial scales.

## ABSTRACT

Soil organic carbon (SOC) and inorganic carbon (SIC) jointly determine terrestrial carbon (C) storage and its climate feedbacks, yet their coupled responses to warming and drought remain poorly quantified. We synthesize two global analyses to resolve how climate warming and aridity regulate SOC–SIC dynamics across ecosystems and soil depths. First, using a global soil-profile dataset (25,492 observations) and integrating historical baseline comparisons, synthetic control analysis, and meta-analysis, we quantified warming effects in cropland, grassland, and forestland. Relative to the pre-industrial period, mean annual temperature has increased by 1.90 ± 0.67 °C, corresponding to a net loss of 126.8 Pg C in soil total carbon (STC). Responses varied significantly across C pools, ecosystem types, soil depths, and warming levels. Initial soil C content emerged as the strongest predictor of the direction and magnitude of warming-induced change, while cropland the most variable response. Second, focusing on cropland, we assessed drought effects using global soil-profile C data (11,585 observations). Average STC stocks in the 0–30 cm, 30–100 cm, and 100–200 cm layers were 8.0, 16.7, and 21.6 kg C $m^{-2}$, respectively. STC in deep soils (100–200 cm) declined linearly along the drought gradient, whereas surface STC exhibited a nonlinear response, reflecting distinct moisture sensitivities of SOC and SIC. Notably, the ratio of SIC to STC increased with increasing aridity, indicating a proportionally larger contribution of SIC under drier conditions. Irrigation, a major drought adaptation strategy, increased SIC contributions in dry sub-humid regions but tended to reduce it elsewhere. Together, our integrated results demonstrate that SOC and SIC respond divergently yet interactively to climate drivers. Accurate soil C budgets and climate mitigation assessments therefore require explicit inclusion of SIC alongside SOC, particularly in dryland and agricultural systems facing progressive warming and intensifying drought.

# $CO_2$ emission following total vegetation removal: a pilot study

**Sigurlaug B. Gudmundsdottir[1*], Solveig Sanchez[1], Elva B. Benediktsdottir[1], Hrafnhildur V. Fridriksdottir[1] and Johann Thorsson [1]**

[1] *Land and Forest, Iceland (Gunnarsholt, Iceland)*

*sigurlaug.birna.gudmundsdottir@landogskogur.is

**ABSTRACT**

Icelandic heathlands, currently categorized as grasslands under the LULUCF framework, are widespread ecosystems with complex carbon dynamics that are still not fully captured by existing accounting methods. Current estimates in the national greenhouse gas inventory rely on IPCC default Tier 1 emission factors and therefore involve considerable uncertainty. Ongoing research aims to improve the understanding of carbon processes in heathland systems and to advance greenhouse gas accounting for grasslands to higher methodological tiers. In this context, land-use options are evaluated as part of broader climate mitigation and land management strategies. Forestry is one such land-use option that is often considered for its potential contribution to carbon sequestration. Current approaches in afforestation include using TTS Hydraulic Power Disc Trenchers to tear up the vegetation and remove the topsoil before planting. This causes considerable disturbances and increases the probability of carbon losses which are not accounted for when the total carbon budget is calculated. Here we test the hypothesis that disturbances following such approaches will cause increased $CO_2$ emissions. Twelve 1 $m^2$ plots were selected in fall of 2024 and baseline $CO_2$ emission established with regular measurements until July 2025 when the vegetation was totally removed from six randomly selected treatment plots. The measurements have since been continued in all plots to explore the long-term effect of the treatments. The experiment is located in a low-production artificial heathland site (managed experimental area) and was chosen for accessibility. Preliminary results show that there was no active carbon sequestration before vegetation removal. However, we found a significant increase in $CO_2$ emissions after the vegetation was removed, while the $CO_2$ flux in the control plots remained stable. This suggests that the management approach used here will increase $CO_2$ emissions compared to intact land, even though this pilot study was not conducted under optimal conditions. We plan to repeat this experiment under more realistic conditions in the future to get more representative results that can be related to current afforestation management practices.

# Greenhouse Gas Fluxes and Their Environmental Drivers in a Coastal Peatland of the Kamchatka Peninsula

**Liudmila A. Krivenok[1*], Vladimir S. Kazantsev[1], Nikita I. Tananaev[2,3,4], Rodoslav I. Izrapil[3], Mikhail A. Semenov[3], and Sergey A. Tikhonov[2,3]**

## ABSTRACT

This study presents the first comprehensive measurement of greenhouse gas emissions from a coastal peatland in Kamchatka, a region with a significant gap in terms of field data on methane and carbon dioxide fluxes. Research was conducted in September 2025, on a peatland 19 km east of Petropavlovsk-Kamchatsky. High-frequency monitoring (every two hours) was conducted over three full days at two adjacent sites (Ecosystem I and II) within the peatland. The water table was at or above the soil surface at both sites, with marginally higher levels recorded in Ecosystem II. Methane fluxes and ecosystem respiration were measured using the static dark chamber method with a portable LI-COR 7810 gas analyzer, alongside key environmental parameters.

Median $CH_4$ fluxes were similar: 1.11 and 1.31 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$ for Ecosystems I and II, respectively, and median $CO_2$ fluxes were 317.9 and 356.6 $mgCO_2 \cdot m^{-2} \cdot h^{-1}$. The key difference was the flux dynamics: Ecosystem I showed stable emissions with a gradual decline, while Ecosystem II was characterized by sharp peak events of both gases (up to 7.52 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$ and 644.5 $mgCO_2 \cdot m^{-2} \cdot h^{-1}$), several of which were synchronous in time.

Spearman correlation analysis identified the main environmental drivers of flux variability. In Ecosystem I, fluxes of both gases positively correlated with soil surface temperature ($r_s$=0.47 for $CH_4$, and 0.60 for $CO_2$) and negatively with wind speed ($r_s$=-0.48 and -0.54, respectively). In Ecosystem II, the key factor for $CH_4$ was air temperature ($r_s$=0.51) and atmospheric pressure ($r_s$=-0.48), indicating a possible contribution of ebullition.

Analysis of diurnal dynamics showed that restricting measurements to daytime (11:00–16:00) leads to a systematic overestimation. For Ecosystem II, the average daytime $CH_4$ flux (3.54 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$) was 74% higher than the 24-hour average (2.04 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$). For Ecosystem I, the overestimation was 10% (1.30 vs. 1.18 $mgCH_4 \cdot m^{-2} \cdot h^{-1}$).

This work fills a data gap and highlights the importance of accounting for diurnal cycles and spatial heterogeneity for accurate emission assessment for Kamchatka peatlands.

# Decoupling the "Pump" and the "Tomb": Depth-Dependent Soil Organic Carbon Stabilization Mechanisms under Long-Term Conservation Tillage

**Hongxuan Duan[1*], Xin Zhao[2], and Hai-lin Zhang[3]**

*[1] College of Agronomy and Biotechnology, China Agricultural University; Key Laboratory of Farming System, Ministry of Agriculture and Rural Affairs of China, Beijing 100193, PR China.*

*duanhx@cau.edu.cn

**ABSTRACT**

Conservation tillage (CT), particularly no-till with straw mulching, is a critical strategy for enhancing soil organic carbon (SOC) sequestration. However, current understanding is largely confined to the surface layer, leaving the depth-dependent stabilization mechanisms—specifically the interplay between plant-derived carbon (PC), microbial-derived carbon (MC), and mineral associations—poorly resolved.

To address this gap, we synthesized data from two long-term field experiments (8 and 14 years) located in distinct temperate agroecosystems in Northeast and North China. We integrated molecular biomarkers (amino sugars and lignin phenols), enzyme stoichiometry, and physical fractionation (POC vs. MAOC) with structural equation modeling to deconstruct the vertical stratification of SOC stabilization.

Our results reveal that CT does not merely increase SOC inventory but fundamentally re-engineers the soil profile into two functional niches with divergent stabilization pathways:

The Topsoil Synergistic Niche (0–20 cm): Functioning as the "Microbial Carbon Pump," this layer is resource-rich. CT significantly enhanced C- and N-acquiring enzyme activities, accelerating the turnover of plant residues. Here, SOC accumulation is driven by a synergistic pathway: fresh residues primarily form Particulate Organic Carbon (POC), while simultaneous high microbial activity transforms labile inputs into microbial necromass, which then stabilizes as Mineral-Associated Organic Carbon (MAOC).

The Subsoil Preservation Niche (20–30 cm): Functioning as a "Carbon Tomb," this layer is resource-limited. We found a decoupling of stabilization pathways. The persistence of microbial necromass (the dominant component of subsoil SOC) became independent of contemporary microbial activity, relying instead on direct physicochemical protection (mineral entombment). Paradoxically, the stabilization of recalcitrant plant lignin at this depth required a "microbial gatekeeper" step—transformation by specialized communities was a prerequisite for subsequent mineral association.

**ABSTRACT**

Reliable quantification of soil carbon fluxes is fundamental for climate mitigation and soil health, yet major uncertainties persist when scaling management effects from field experiments to regions. Straw return is widely promoted to increase soil organic carbon (SOC) and improve fertility, but its net climate benefit depends on coupled responses of SOC turnover and greenhouse-gas fluxes ($CO_2$, $CH_4$, $N_2O$) under diverse soils, climates, and management regimes.

We present a conference-ready framework that integrates process-based modeling, knowledge-guided machine learning, and satellite remote sensing to assess and optimize straw-return strategies across major cereal systems. A calibrated process model is used to represent soil C–N cycling and carbon–GHG flux pathways under varying residue inputs and agronomic practices. Machine-learning modules are then applied for residual correction and ensemble fusion to reduce structural bias and improve transferability while maintaining mechanistic consistency. Sentinel-2 time series are used to retrieve residue cover and crop status, and are assimilated to constrain key model states/parameters and enable consistent plot-to-regional upscaling. Finally, multi-objective optimization (e.g., NSGA-II) is employed to identify region-specific straw management solutions that jointly target SOC accrual, net $CO_2$-equivalent mitigation, and yield stability.

The framework is designed to deliver spatially explicit estimates of soil carbon fluxes and management-sensitive uncertainty bounds, providing actionable evidence for carbon farming and climate-smart soil management.

## ABSTRACT

Soils represent the largest terrestrial reservoir of carbon, and their good management has been widely discussed as a means of partially compensating for global greenhouse gas emissions from anthropogenic sources and as a means to make soils more resilient to climate change. Yet, substantial uncertainties remain regarding the realistic, durable, and scalable contribution of soil organic carbon (SOC) sequestration to climate change mitigation and adaptation. In this assessment, we provide a global expert assessment of the potential role of SOC sequestration and avoided SOC loss in contributing to climate targets. We conduct an international survey designed to gather expert judgements on three key dimensions: (a) the magnitude of $CO_2$-equivalent emission reductions achievable through SOC sequestration by 2050 under realistic, sustainable land-management practices; (b) SOC losses resulting from the conversion of natural or semi-natural ecosystems to cropland, and the proportion of these losses that could feasibly be recovered by 2050 through improved cropland management; and (c) the plausible time horizon over which SOC sequestration can deliver measurable and lasting climate-mitigation and adaptation benefits.

To strengthen the scientific and policy relevance of this assessment, we explicitly distinguish between the mitigation potential of SOC sequestration (new carbon inputs) and SOC protection (avoided losses), as these mechanisms differ in magnitude, reversibility, and timescales. This expert-based approach complements empirical measurements and modelling studies, helping clarify persistent uncertainties across ecosystems and management contexts. It also contributes to ongoing discussions on the realistic contribution of soils to achieving the Paris Agreement targets for 2050.

Here, we present the preliminary results, motivation, and objectives of this ongoing assessment. We also extend an open invitation to soil scientists, biogeochemists, agronomists, modellers, and related experts worldwide to participate in and strengthen the evidence base needed to evaluate the global mitigation and adaptation potential of SOC.

# Integrating Soil Properties and Management into Data-Driven Modeling of Soil $CO_2$Efflux in Urban Green Roofs

**Cho Junyoung[1*], Kim Hyomin[1]**

[1] *Korea Institute of Civil Engineering and Building Technology, Gyeonggi-do, 10233, Korea*

*junyoungcho@kict.re.kr

**ABSTRACT**

Soil $CO_2$ efflux (respiration), driven by microbial activity, root respiration, and physical diffusion processes, is a key component of the carbon balance in urban greening systems. Although green roofs are recognized for their potential to sequester atmospheric carbon and mitigate urban heat, accurate evaluation of their carbon reduction performance requires comprehensive consideration of $CO_2$ emissions from soil under varying environmental, soil, and management conditions.

In this study, soil $CO_2$ efflux was monitored at four urban green roof sites in Seoul and Goyang, South Korea, from March to October 2025, encompassing extensive, semi-intensive, and intensive systems with diverse vegetation types, soil depths, and substrate compositions. Soil $CO_2$ efflux was measured using a portable gas analyzer (EGM-5), accompanied by concurrent observations of air temperature and humidity, soil temperature, and soil moisture to capture atmospheric and belowground microclimatic controls. In addition, soil physicochemical properties, including soil pH, bulk density, total porosity, and soil carbon stocks, as well as site-specific management variables such as irrigation frequency and maintenance intensity, were incorporated into the analysis.

We applied a data-driven modeling framework that accounts for nonlinear interactions, temporal variability, and site heterogeneity among multiple environmental drivers. Principal component analysis (PCA) and cluster classification revealed distinct groupings of sites based on combined atmospheric conditions, soil microclimate, soil properties, carbon stocks, and management regimes. Furthermore, cluster-specific mixed-effects models demonstrated that the sensitivity of soil $CO_2$ efflux to air and soil temperature, moisture, and soil physicochemical properties varies substantially across green roof types and management intensities.

These results indicate that integrating atmospheric variables, soil microclimatic conditions, soil physicochemical characteristics, and management-related factors significantly improves the interpretability and predictive performance of soil $CO_2$ efflux models. This study underscores the importance of holistic, data-driven approaches for accurately characterizing soil respiration dynamics and carbon balance in urban green roof systems.

# Monitoring Soil Carbon Storage and Soil Respiration in Street-Level Green Infrastructure

**Kim Hyomin[1*], Cho Junyoung[1]**

[1] *Korea Institute of Civil Engineering and Building Technology, Gyeonggi-do, 10233, Korea*

*hyominkim@kict.re.kr

**ABSTRACT**

Urban green infrastructure is widely recognized as a multifunctional system that provides climate regulation, ecosystem services, and social benefits. However, existing studies on carbon fluxes in urban green spaces have primarily focused on natural soils such as forests and parks, while measurement-based investigations of carbon fluxes in artificial green infrastructure, including green roofs and street-level greenery, remain limited.

The objective of this study is to quantitatively assess soil carbon storage and soil respiration in street-level green infrastructure through field-based monitoring and to characterize carbon dynamics during the operational phase. Study sites were selected to represent typical street-level green infrastructure types—flowerbeds and planters—which differ in soil depth, substrate composition, planting structure, and management practices.

Soil carbon storage was estimated by analyzing total carbon content in soil samples and measuring bulk density to calculate areal carbon stocks. In addition, thermogravimetric analysis (TGA) was conducted to examine the compositional characteristics of soil carbon. Soil respiration was measured in situ using a portable closed-chamber $CO_2$ measurement system (EGM-5). Monitoring was conducted across multiple periods to capture seasonal variations associated with changes in air temperature and soil moisture conditions.

The results showed substantial variability in soil carbon storage across street-level green infrastructure systems, depending on system type, soil properties, and vegetation characteristics. Soil respiration rates increased significantly with rising seasonal temperatures and higher soil organic matter content, and during certain periods, soil $CO_2$ efflux exceeded plant carbon uptake.

This study provides empirical, measurement-based evidence of both soil carbon storage and emissions in artificial ground-based green infrastructure, thereby extending the scope of urban soil carbon research that has traditionally focused on natural soils. The findings suggest that the effective use of artificial green infrastructure as a climate change mitigation strategy requires integrated consideration of soil composition and operational carbon dynamics during both the design and maintenance stages. The results also provide a foundational dataset for the development of urban-scale carbon accounting frameworks.

## ABSTRACT

Climate change, caused by increasing greenhouse gases (GHG) concentrations in the atmosphere, is one of the most serious threats to the sustainability of the Earth's ecosystems and food security. Soils play a key role in the global carbon cycle, acting as both sources and sinks of GHGs. One way to prevent further climate change is to increase the carbon sequestration in agricultural soils. We can use carbon-saving farming technologies for this purpose, particularly the seeding of perennial grasses and green manure. The positive effects of grass seeding on soil carbon accumulation and soil health are widely known, but the high variability of carbon dioxide ($CO_2$) and methane ($CH_4$) fluxes requires representative data for soils in different regions. Obtaining such data for one region of Russia was the aim of this study.

We investigated agroecosystems of Chashnikovo carbon testing site, which is located in about 40 km northwest of Moscow, in June–August 2024 and 2025. The climate is moderate continental; soils are Albic Retisols (Aric, Loamic, Cutanic). Five monitoring plots (25–30 $m^2$) were located in three adjacent fields. Two plots were with annual green manure grasses (white mustard and vetch-oat mixture) and another two plots were with perennial grasses (legume-cereal grasses and hybrid giant miscanthus). One plot was fallow, without plants. GHG fluxes measured using a portable chamber and a Li-7810 gas analyzer (Li-Cor, the USA) after the preliminary removal of the aboveground part of the plants. The soil temperature and moisture, soil density, particle size distribution, pH, aboveground and underground phytomass, and carbon content in soils and plants were measured, and the potential microbial production of $CO_2$ by soils was calculated based on the their basal respiration.

The investigated soils acted as a weak sink for atmospheric $CH_4$ and emitted $CO_2$ in amount less than or comparable to that which could be assimilated in the phytomass of green manure and perennial grasses.

The rate of $CH_4$ consumption by soils depended on the crop grown and varied from 0,05 to 0,75 $mgC \cdot m^{-2} \cdot day^{-1}$. In soils under fallow, mustard, and perennial grasses, it was highest in July, while under the vetch-oat mixture and miscanthus, it gradually increased throughout the summer. Total summer $CH_4$ uptake by soils was highest under miscanthus, decreased statistically significantly under the vetch-oat mixture, perennial grasses and mustard.

Soil $CO_2$ emission was determined by changes in soil moisture and plant growth stages and varied from 2 to 12 $gC \cdot m^{-2} \cdot day^{-1}$. Total summer fluxes were highest in soils under perennial grasses, decreased under miscanthus, vetch-oat mixture and mustard. Increased $CO_2$ emission from soils under perennial crops was due to higher microbial $CO_2$ production and active root respiration, resulting in the formation of statistically significantly greater belowground phytomass than under green manure.

**ABSTRACT**

Integrated agricultural systems (IAS) are nature-based solution that can support the recovery of degraded areas. Given the central role of soil as both a carbon source and reservoir, the inclusion of trees in pasture systems can significantly influence nutrient cycling and carbon dynamics. Soil $CO_2$ efflux, a key component of the carbon cycle, is strongly affected by biotic and abiotic factors, including temperature, soil moisture, root biomass, and land management practices. In IAS, microclimate alterations and increased organic inputs near tree rows can modulate $CO_2$ emissions and impact soil carbon dynamics. This study evaluated the effects of eucalyptus trees in an agrosilvopastoral system on $CO_2$ efflux, comparing it with nominal pasture and native vegetation. This study evaluated the effects of *Eucalyptus* trees in an agrosilvopastoral system on soil $CO_2$ efflux, comparing it with nominal pasture and native vegetation. Soil $CO_2$ efflux exhibited pronounced seasonal patterns across all systems, with higher emissions during the rainy season, highlighting the dominant role of soil moisture in regulating soil respiration. In the agrosilvopastoral system, elevated $CO_2$ efflux near tree rows was associated with greater shading, litter accumulation, and root biomass, which together created a more stable microclimate conducive to microbial activity. In contrast, areas farther from the trees and the nominal pasture exhibited lower moisture retention and higher thermal variability, resulting in reduced $CO_2$ emissions. In native vegetation, dense ground cover and extensive root systems maintained stable microclimatic conditions, supporting higher $CO_2$ efflux compared to nominal pasture despite lower light availability. These results confirm that soil respiration is strongly governed by the interaction of moisture, temperature, root activity, and surface residue, and emphasize the critical role of vegetation structure in modulating soil carbon fluxes in both managed and natural systems.

## ABSTRACT

Carbon sequestration in agricultural soils is a promising strategy for mitigating carbon dioxide ($CO_2$) emissions while simultaneously enhancing soil health. However, the permanence of sequestered carbon, defined as the duration over which carbon remains stored without re-emission to the atmosphere, in agricultural soil can be affected by soil management and land use changes. This makes the climate mitigation potential of agricultural soils uncertain. The stability of soil organic carbon depends on a complex interplay of intrinsic soil characteristics and (historical) land use and soil management. There are still quite some knowledge gaps on this interplay. In particular, it is still unknown which factors influence the permanence and to what extent. To obtain more insight, data on the $CO_2$ release rate after stopping the application of a carbon mitigation measure is essential. Long-term experiments (LTEs) (>30 years) provide valuable insight in the effect of carbon mitigation measures on soil organic carbon content, but only a few LTE studies also analysed the $CO_2$ release after stopping. These few LTE studies showed that sequestered carbon is released again, but the new equilibrium is in all LTEs higher compared to the baseline (i.e., fields without carbon sequestration measures). This suggests that carbon mitigation measures are always beneficial for $CO_2$ mitigation. We also learned from this analysis that soil management and historical land use seem to play an important role in permanence of carbon sequestration, and therefore the analysis was extended by a space-for-time analysis on data of the Dutch soil sampling campaign. These data were combined with soil management information and historical land use maps that go back until 1900. This analysis confirmed that land use change (cropland to grassland and grassland to cropland) plays a significant role in the carbon sequestration and release rate. It is recommended that both, the duration of applying a carbon mitigation measure and historical land use, are taken into account when assessing the long-term contribution of agricultural soils to climate change mitigation.

**ABSTRACT**

Soil organic carbon (SOC) constitutes a fundamental component of terrestrial ecosystems, playing an indispensable and multifaceted role in maintaining ecological functions, productivity, and global biogeochemical balances. This review synthesizes current knowledge to elucidate the multifaceted mechanisms through which SOC underpins ecosystem functionality and sustainability. The review first establishes the foundational role of SOC in soil health, detailing its contribution to soil structure formation, nutrient retention and supply, and water dynamics. These physicochemical improvements are directly linked to enhanced primary productivity and agricultural resilience. Subsequently, it examines the biological mechanisms, highlighting how SOC fuels microbial metabolism and drives the decomposition-mineralization nexus, thereby regulating nutrient cycling and energy flow. A significant portion of this review is dedicated to the climate-regulating function of soil. It analyzes the mechanisms of carbon sequestration and stabilization, discussing the factors influencing the turnover between labile and recalcitrant carbon pools, and its critical feedback to global carbon cycling and climate change mitigation. Furthermore, the review explores the cascading effects of SOC on broader environmental services, including its role in water purification, erosion control, and biodiversity conservation. By integrating findings from biogeochemistry, ecology, and land management science, this review presents a cohesive framework that links molecular-scale interactions of SOC to landscape-level ecosystem outcomes. The review concludes by identifying key knowledge gaps, particularly concerning the responses of different SOC fractions to global change drivers and land-use practices, and emphasizes that the intentional management of soil carbon represents a vital strategy for achieving climate, food, and water security goals in the 21st century.

## ABSTRACT

Arid and semi-arid ecosystems are often overlooked, yet they play a key role in regulating the variability of the terrestrial carbon (C) sink. These ecosystems are strongly constrained by water availability and are therefore highly sensitive to land-use change. In Mexico, more than 45% of the territory shows signs of human-induced soil degradation, with drylands being among the most affected. This study explores how land use and seasonal rainfall patterns shape soil respiration (Rs) and biological soil degradation in the southeastern Chihuahuan Desert, Coahuila, Mexico.

We evaluated 45 field sites representing five contrasting land uses: conserved shrubland, agricultural crops, livestock grazing areas, walnut orchards, and industrially influenced zones. Thirty-five biotic and abiotic variables were measured, including Rs, soil water content (SWC), microbial biomass carbon (MBC), total carbon, pH, soil texture, and microclimatic conditions. Measurements were carried out during both dry and wet seasons. Rs was quantified using an infrared gas analyzer as an integrative measure of soil biological activity. Structural Equation Modeling and multivariate regression trees were applied to disentangle direct and indirect controls on Rs and to identify sensitive indicators of degradation.

Rs responded to both land use and seasonality. Managed systems showed Rs rates 250–372% higher than conserved shrublands and industrial sites, while wet-season fluxes increased by 145–191% compared to the dry season. Across all land uses, SWC consistently emerged as the dominant control of Rs, highlighting the central role of water in regulating carbon exchange in this dryland system. In contrast, soil temperature exerted a weak and seasonally variable influence. Irrigation and grazing increased water availability and reduced soil pH in managed lands, stimulating MB and accelerating C losses.

By integrating Rs, pH, MBC, and total carbon, we developed a Biological Degradation Index that explained 84% of the variation in soil biological condition, with Rs as the most sensitive indicator. Overall, our results show that land-use change accelerates soil carbon losses in the Chihuahuan Desert and emphasize the need for management practices that conserve soil moisture and organic matter to sustain soil functioning in water-limited environments.

**ABSTRACT**

The adoption of integrated agricultural systems (IAS) in Brazil has become established as a strategy for the restoration of degraded pastures, combining sustainable production with increased local biodiversity through synergistic interactions among production components. However, it is crucial to advance studies that determine the complexity of factors influencing greenhouse gas emissions, considering the diversity of climatic conditions and soil types. This study evaluated soil $CO_2$ efflux and microclimatic conditions across different land-use systems in the Brazilian Cerrado. Seven land use systems were assessed: low-productivity pasture (LPP); well-managed pasture (WMP); consortium of sorghum + marandu grass (CSM); consortium of cratylia + marandu grass (CCM); integrated crop–livestock–forestry system with marandu grass + sorghum + eucalyptus (ICLF1); ICLF with marandu grass + sorghum + eucalyptus + cratylia (ICLF2); and native vegetation of Cerrado (NVC). The variables assessed—soil $CO_2$ efflux, Wflux, soil moisture, and soil temperature—were monitored monthly over a one-year period. Soil temperature, moisture, and Wflux exhibited pronounced seasonal variability, with higher values during the rainy season, which directly influenced soil $CO_2$ efflux, as this period is characterized by enhanced soil microbial activity. Soil $CO_2$ efflux decreased from December to September, with the highest values observed in January (~ 12 µmol $m^{-2}$ $s^{-1}$.), a period characterized by higher soil moisture and temperature, which favored microbial respiration and soil organic matter decomposition. The comparative analysis of the treatments throughout the year showed that NVC exhibited the highest $CO_2$ effluxes (~ 6 µmol $m^{-2}$ $s^{-1}$), whereas the IAS (ICLF1, ICLF2, CSM, and CCM) showed intermediate values (~ 4 µmol $m^{-2}$ $s^{-1}$), suggesting that conservation-oriented management practices using integrated agricultural systems enhance soil quality and improve carbon-use efficiency in the Cerrado biome.

**ABSTRACT**

Microbial products and residues are essential for the formation of soil organic carbon (SOC), supporting ecosystem health and contributing to global climate regulation. A key concept in understanding this process is the soil Microbial Carbon Pump (MCP), which emphasizes the role of microbial-derived carbon in the transformation and storage of SOC. Although research on the significance of the MCP in SOC storage has grown rapidly, direct assessments based on this concept remain limited. To address this, we refine key aspects of the MCP by reviewing relevant literature, presenting model scenarios, and offering perspectives on sustainable soil carbon management. We introduce a new metric, △MCP efficacy, which represents the change in the ratio of microbial necromass to SOC. This metric captures the differing responses (asynchronous or synchronous) of microbial necromass and SOC, allowing for the assessment of *in-situ* SOC storage driven by the soil MCP. In this regard, we propose a conceptual, integrated framework that outlines predictable scenarios involving microbial necromass and SOC, illustrating how the soil MCP operates and influences within SOC dynamics. We encourage future research to move beyond quantifying microbial necromass contributions to SOC, and instead focus on evaluating their dynamic, asynchronous changes in magnitude and direction.

## ABSTRACT

Soil viral communities play a pivotal role in terrestrial carbon cycling through their regulation of host metabolism. Despite this, the long-term coevolutionary dynamics between viruses and their hosts in response to climatic variations and its implications on carbon sequestration remain poorly understood. Here, we uncover a novel carbon compensation mechanism facilitated by viral auxiliary metabolic genes (AMGs). Employing a cross-climatic zone black soil chronosequence experiment spanning from cold temperate to subtropical zones over 16 years (2005–2021), integrated with the global virus database IMG/VR and multi-omics analyses, we observed a marked enrichment of carbon sequestration-associated AMGs (specifically GT2 and GT4) in viruses under high-temperature conditions. The abundance of these AMGs correlated positively with annual mean temperature and precipitation, exhibiting a 37.8% increase in gene expression post long-term evolution. Protein structure predictions and promoter annotation suggested efficient expression potential of AMGs within host bacteria. Host prediction modeling further indicated that the functional efficiency of AMGs for viral carbon sequestration surpassed 85%, corroborated by transcriptomic evidence. Viral transplantation experiments demonstrated a 26.7% enhancement in carbon sequestration by soil viruses. $^{13}C$ isotope labeling illuminated the role of viral AMGs in facilitating microbial conversion of carbon from both microbial and plant sources into recalcitrant organic matter. Our findings demonstrate that viral activities can counteract climate-driven carbon loss by modulating carbon cycling pathways, providing new insights into phage-host interactions and offering critical implications for predicting terrestrial carbon sequestration under global change.

## ABSTRACT

Microbial involvement in carbon fixation processes can enhance the carbon sink capacity of forest ecosystems, playing a positive role in mitigating global warming. However, there is a lack of large-scale, systematic data necessary to investigate changes in microbial carbon fixation potential and fixation rates during forest succession. We hypothesized that both microbial carbon fixation potential and actual fixation rates would be higher in the early stages of succession compared to later stages, potentially due to greater organic carbon input in younger forest ecosystems. To test these hypotheses, we collected extensive global metagenomic data and conducted a long-term field experiment coupled with $^{13}CO_2$ labelling.

Our results find the following highlights:

(1) Microbial communities—including bacteria, fungi and protists—underwent synchronous succession with vegetation, but microbial carbon fixation potential declined significantly. Vegetation richess, soil organic carbon (SOC), and litter quality were key factors influencing this functional potential.

(2) From global metagenomic datasets, we recovered 253 high-quality MAGs, primarily classified as Pseudomonadota and Actinomycota, which harbored abundant carbon fixation genes. We also found that planted forests had significantly higher carbon fixation gene abundance than natural forests.

(3) The $^{13}CO_2$ labelling experiment confirmed that both microbial carbon fixation potential and actual $CO_2$ fixation rates declined markedly with successional progression.

These findings underscore the ecological importance of microbial carbon fixation in early forest succession, emphasizing its foundational role in initiating soil carbon accumulation and shaping long-term carbon cycling trajectories.

# Synergistic regulation of dissolved organic matter and microbial communities on microbial necromass accumulation under long-term organic material application

**Yuanchen Zhu[1*], Xiaozeng Han[1], Wenxiu Zou[1]**

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Harbin , China*

*E-mail zhuyuanchen@iga.ac.cn

**ABSTRACT**

Microorganisms drive soil organic carbon formation primarily through microbial necromass carbon (MNC). This process is regulated by heterogeneous dissolved organic matter (DOM), which induces functional differentiation of microbial communities by serving as energy substrates. However, how the molecular composition and characteristics of DOM regulate microbial community succession and thereby control MNC accumulation remain unexplored, especially under long-term application of organic materials. This study identified the key driving pathways of MNC accumulation using a long-term field experiment initiated in 1990, including chemical fertilizer (CF), CF combined with straw (SCF) or manure (MCF), and an unfertilized control (CK). Results showed that, compared to CK, SCF and MCF significantly increased MNC content by 9.2–38.2%. The application of organic materials (SCF and MCF) transformed labile into refractory DOM through thermodynamically limited process. Moreover, organic materials resulted in fewer labile DOM-bacteria positive networks but more refractory DOM- fungi negative networks, thereby promoting a shift in DOM degradation from rapid bacterial consumption to slower fungal transformation. Further analysis revealed that the SCF treatment promoted fungal network modularity and necromass accumulation by altering the molecular weight of DOM. Whereas MCF treatment enhanced bacterial necromass accumulation by enriching specialized bacterial taxa through DOM with higher aromaticity. Interestingly, the drivers of MNC accumulation shifted from a multi-factor synergy in the 0–20 cm layer to a DOM-dominated (explaining 66.6% of the variation) pathway in the 20–40 cm layer. Overall, our findings highlight the central role of DOM in microbially mediated MNC accumulation and provide mechanistic insights linking DOM characteristics to agricultural management strategies.

# Patterns and drivers of soil microbial residue carbon responses to precipitation changes in grassland ecosystems

**Yingchao Yu**[1,2*], **Xinyu Zhang** [1,2]

[1] *Key Laboratory of Ecosystem Network Observation and Modeling, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China*

[2] *College of Resources and Environment, University of Chinese Academy of Sciences, Beijing, China*

*E-mail Address of Presenting Author: yuyc.19s@igsnrr.ac.cn

**ABSTRACT**

Microbial residue carbon (MRC) the response of SOC is a vital component of the soil organic carbon (SOC) pool in grassland ecosystems, regulating the response of SOC to precipitation changes. However, existing studies have largely been confined to individual ecosystems or meta-analyses, yielding no consistent conclusions. There is an urgent need to elucidate the response patterns of soil MRC to precipitation changes and to clarify the underlying driving mechanisms in grassland ecosystems.

We addressed the scientific question based on the China Global Change Network. The experimental network was established in 2017 across alpine and temperate grassland ecosystems, primarily covering alpine meadow, alpine steppe, temperate meadow steppe, temperate typical steppe, and temperate desert steppe. There are three precipitation treatments (decreased 50% precipitation, Control, and increased 50% precipitation), two soil depths (0-10 cm topsoil and 20-40 cm subsoil), and two precipitation duration (short-term three-year precipitation and long-term six-year precipitation).

Our results showed that: 1) Topsoil MRC content ranged from 0.9 to 8.6 g $kg^{-1}$, highest in meadow steppe and lowest in desert steppe. Subsoil MRC content ranged from 0.8 to 4.4 g $kg^{-1}$, higher in meadow and typical steppe, lowest in desert steppe. 2) Short-term decreased precipitation decreased topsoil MRC content by 8%, while short-term increased precipitation reduced soil MRC content by 24%. Under decreased precipitation, diminished plant biomass inhibited soil MRC formation. Increased precipitation induced soil microbial nitrogen limitation, which enhanced soil microbial nitrogen enzyme activity, thereby accelerating soil MRC decomposition and utilization. Compared to drier ecosystems, decreased precipitation resulted in greater soil MRC loss in wetter ecosystems. 3)

Long-term precipitation treatments had no significant effect on topsoil MRC content, indicating that prolonged precipitation changes attenuated the response of topsoil MRC compared to short-term treatments. These results suggest that soil microorganisms exhibit some acclimation to sustained precipitation changes. 4) Under long-term decreased and increased precipitation treatments, subsoil MRC exhibited an asymmetric response pattern and demonstrated greater sensitivity to precipitation changes than the topsoil. Long-term decreased precipitation significantly reduced available nitrogen content, leading to a marked 27.7% decline in MRC, whereas long-term increased precipitation resulted in a slight 10.9% increase in MRC in the subsoil.

Our study reveals that soil microbial residue carbon responses to precipitation changes are shaped by precipitation duration and soil depth, then systematically elucidates the underlying mechanisms, providing a scientific basis for predicting the grassland soil organic carbon pool under future climate change scenarios.

## ABSTRACT

Soil aggregates, key soil structural units, act as soil organic carbon (SOC) reservoirs and key microbial colonization sites, but systematic research on their aggregate-scale coupling is limited. This study investigated how long-term nitrogen (N) and phosphorus (P) fertilization regulated SOC and aggregate stability via microorganisms in a meadow steppe. Soil samples under Control, N, P, and NP treatments were collected in withered-yellow (October), green-up (May), and growth (August) period, to analyze SOC, MWD, and microbial communities in bulk soil and aggregates of mega-aggregates, macro-aggregates and micro-aggregates. Results showed that SOC exhibited no significant seasonal variation, with only significant increases observed in May for the bulk soil (NP treatment) and micro-aggregates (P treatment). Micro-aggregate SOC was lower than that of the bulk soil for all sampling times. MWD significantly increased in all months for N and NP treatments (by 16.19%-42.45% for the N treatment, and by 10.00%-19.05% for the NP treatment). Soil microbial biomass exhibits a “peak in May, bottom in October” pattern, and both N and NP treatments generally inhibit microbial activity, with macro-aggregates serving as the core microbial colonization zone. The regulation of SOC by microorganisms was limited to the bulk soil, and there was a overall-scale regulation of MWD. MWD was mainly regulated by arbuscular mycorrhizal fungi (AMF) in the bulk soil, mega- and macro-aggregates, while the role of bacteria in micro-aggregates was enhanced. Microbial contribution to MWD variation peaked in August. In summary, under long-term N and P application, AMF and bacteria respectively dominated the maintenance of stability in different sizes of aggregate. Microbial regulation of aggregate stability exhibited scale dependence and temporal dynamics.

**ABSTRACT**

Soil pH is a key factor determining microbial community structure and carbon (C) dynamics. However, the responses of different microbes to soil pH remain poorly understood, as soil pH covaries with nutrient availability and metal toxicity. Therefore, it is difficult to isolate the direct effects of pH. This study aimed to evaluate the effects of altering soil pH as a single parameter on individual microbial species by measuring microbial respiration rates in artificial soil.

Artificial soils were prepared based on previous reports by Ellis (2004) with minor modification. The artificial soils consisted of quartz sand (sand fraction) kaolinite, and bentonite (clay fraction) at a (7:2:1). Humic acid (0.5%) was also used as the pH buffering. The soil pH was adjusted to values ranging from 4 to 9 using 1 M HCl. Eight heterotrophic microbial species were selected from the NBRC culture collection based on their phylum-based life strategies. Each species was inoculated individually into the artificial soil with glucose (C substrate). The inoculated soils were incubated for 10 days at 30 °C, maintaining soil moisture at 20% (w/w). During the incubation, microbial respiration was measured using the MicroResp system (Campbell et al. 2003).

The respiration was suppressed in all species as pH decreased. Based on their response to the pH gradient, species were broadly categorized into three patterns: (i) species whose respiration was sharply inhibited below a specific pH threshold, (ii) species whose respiration was decreased with decreasing with pH, and (iii) species whose respiration was low at all pH ranges. Notably, at pH 7, we observed the strongest negative correlation between cumulative respiration and the genomic traits of GC content and genome size.

This study highlights the diverse and species-specific responses to soil pH. The observed correlations between respiration and genomic traits at neutral pH suggest a link with metabolic potential. This work demonstrates that simplified artificial soil systems are effective tools for isolating and directly evaluating the physiological responses of soil microbes to environmental factors.

**ABSTRACT**

Changes in turnover of dissolved organic matter (DOM) influence the stability and storage of soil carbon under global warming (Tao et al., 2024). The understanding of its responses to the climate extremes like drought has advanced in recent years (Shi et al., 2024). Nevertheless, how global warming-induced moisture fluctuation affects the ecological process of DOM, and the underlying mechanisms of this microbe-driven C-cycling remain less known. Our study established a microcosm system to experimentally test the differential impacts of moisture fluctuation under different water availability conditions by regulating the precipitation intensity, precipitation frequency, and evaporation intensity. The results from the 16-week incubation showed that intense moisture fluctuation promoted DOM accumulation with distinct mechanisms. The increased DOM content at drought was likely due to the abiotic processes associated with the weakening in bacterial activity and network complexity, while it was mainly contributed by the enhancement of the activity and metabolism of bacteria at wet condition. Although highly fluctuated moisture substantially inhibited microbial respiration and simplified the network topological structure, such detrimental influence could be compensated when water availability condition was favorable for the bacterial growth. Collectively, these findings demonstrated that the ecological process of DOM was regulated by the interactive effects of average and fluctuation of soil moisture condition, highlighting the importance of considering fluctuation pattern in understanding the microbe-driven DOM turnover in the context of climate change.

# Changing from divergence to convergence between soil microbial communities derived from intracellular and extracellular DNAs along a hydrothermal gradient on the Tibetan Plateau

**Ting Li[1], Zejin Zhang[1], Fang Wang[1], Zheng Wang[1], Xiaoyong Cui[1]***

[1]College of Life Sciences, University of Chinese Academy of Sciences, Beijing, China

**ABSTRACT**

Distinguishing intracellular DNA (iDNA) from extracellular DNA (eDNA) is essential for accurately interpreting soil microbial patterns and understanding the dynamics of microbial living and dying, especially in ecosystems where relic DNA accumulates. In this study, we characterized iDNA and eDNA derived soil microbial communities to assess the pattern and driving factors of living and relic components along a pronounced hydrothermal gradient across the Tibetan Plateau.

The cold–dry regions showed exceptionally high eDNA proportions, often exceeding 50% of total soil DNA, indicating strong historical accumulation under extreme water limitation. In parallel, the two DNA pools displayed divergent ecological drivers: iDNA diversity was mainly governed by temperature, nutrient availability, and ecosystem productivity, whereas eDNA richness was more strongly associated with aridity and soil texture. NMDS analysis further revealed clear separation between iDNA and eDNA communities, with the divergence intensifying in cold–dry sites, where eDNA contained numerous ASVs absent from the active community. In contrast, warm–humid sites exhibited greater convergence between iDNA and eDNA, suggesting that extracellular DNA in these regions reflects more recent biological inputs due to faster turnover. Distance–decay analysis showed steeper spatial structuring in eDNA, highlighting preserved historical biogeographic signatures, while iDNA captured contemporary environmental filtering.

Together, these results demonstrate that iDNA and eDNA encode distinct temporal and ecological information, corresponding to active and historical microbial states. Separating the two pools is therefore critical for resolving microbial biogeographical patterns, interpreting environmental responses, and identifying ecological interactions. This distinction provides a mechanistic foundation for understanding how microbial living and dying shape soil carbon processes across heterogeneous and climate-sensitive alpine landscapes.

# Soil microbial community structure and soil carbon dynamics in fields and hedgerows of Northern Irish Grasslands

**Selva Dhandapani[1*], Chris Chagumaira[1], Colin McRoberts[1], Ruth Loy[1] and Alex Higgins[1]**

[1] *Soil Biogeochemistry and Terrestrial Ecology Research Programme, Agri Food and Biosciences Institute, Belfast, UK.*

**ABSTRACT**

It is estimated that global grasslands store 236 giga tons of carbon (C) in soil belowground, playing an important role in global climate change mitigation. This is particularly important for Northern Ireland (NI) where grasslands cover ~95% of farmland. As part of Soil Nutrient Health Scheme (SNHS) project we selected 257 grasslands across NI, representing wider active grassland management practices across NI, and are measuring soil C stocks, nutrients, carbon lability, age of carbon via radio carbon dating and microbial community structure (MCS) via phospholipid fatty acid analyses up to 30 cm depth, extending to 1 m depth which is currently ongoing, sampling both within the farm and nearby hedgerows. Our results show that grassland MCS is dominated by Gram-negative bacteria, and it significantly varies with depth, and between fields and hedgerows. Actinobacteria ($P<0.001$), Gram-positive ($P<0.001$) and fungi ($P<0.001$) showed greater relative abundance in fields soils, while other bacterial ($P<0.001$) and unclassified ($P<0.001$) fatty acids showed greater relative abundance in hedgerow soils. Fungi:bacteria and Gram-positive:Gram-negative ratios were greater in field soils, whilst other fatty acid ratios that were used as stress indicators were greater in hedgerow soils. Soil MCS is also significantly affected field/hedgerow topography and showed no seasonal effects. Microbial biomass was greater in the field than hedgerow soils. C and nitrogen (N) content in hedgerow soils were greater than nearby farm soils, showing significant interactions with topography and soil microbial community structure. Our preliminary results show significant increase in C and N stocks from the year 2004 to 2024, indicating C sequestration in NI farms over the last two decades. Currently, we are analysing the samples for MCS to full soil depth (up to 1m) and exploring the relationship between soil microbial community structure and carbon dynamics in these grasslands. Findings from our research will provide important insights into grassland carbon sequestration and sustainable land management for NI.

## ABSTRACT

Soil microorganisms regulate terrestrial carbon (C) cycling by partitioning assimilated C between respiration (R), growth (G), and carbon use efficiency (CUE). Yet how microbial C allocation responds to warming across distinct temporal scales remains unclear. We combined a long-term elevation gradient (3200–4000 m), a decade open-top chamber (OTC) warming experiment, and a short-term +10 °C incubation to quantify how different time-scale warming shape R, G, CUE, and their temperature sensitivities (Q10) on the Qinghai–Tibetan Plateau.

Warming effects were strongly time-scale dependent. Along the elevation gradient, moderate thermal and nutrient conditions enhanced G more than R, producing the highest CUE at mid-elevation, whereas both warm and cold sites exhibited reduced CUE due to nutrient depletion or physiological constraints (Broderick et al., 2025). Medium-term OTC warming increased CUE at the cold site but suppressed it at warmer sites, indicating that historical climate and resource availability modulate microbial adaptability (Ren et al., 2024). Short-term warming consistently stimulated R while failing to proportionally enhance G, leading to universal CUE declines (Bian et al., 2022).

Mass-specific responses showed that warming shifted the balance between catabolism and anabolism. Short-term warming increased maintenance respiration and shortened microbial turnover, while phosphorus availability and soil physical structure moderated anabolic capacity and microbial persistence (Spohn et al., 2016). Q10 values varied widely: Q10_G showed the strongest variability and was the principal driver of Q10_CUE. CUE increased when G was more temperature-responsive than R and declined when respiration dominated, reflecting inherent trade-offs between metabolic pathways (Tao et al., 2023). Our findings demonstrate that microbial CUE is not a fixed parameter but a dynamic, trait-like property shaped by multi-temporal warming, nutrient stoichiometry, and soil structure.

**ABSTRACT**

Chitin is one of the most abundant nitrogen containing polymers in forest soils. Previous work showed that the ectomycorrhizal (ECM) fungus including *Suillus luteus* can efficiently liberate nitrogen from exogenous chitin (Maillard et al., 2023). However, the data did not support the actions of classical chitin-degradation pathways involving hydrolytic and oxidative enzymes. Using tightly controlled spectroscopic, isotopic, transcriptomic and chemical experiments, we here demonstrate that *S. luteus* degrade chitin using an oxidative mechanism including the action of hydroxyl radicals ($HO^{\bullet}$) generated by Fenton chemistry ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\bullet} + OH^-$). Collectively, our experiments suggest that Fenton chemistry is driven by extracellular fungal metabolites that reduce $Fe^{3+}$ bound to glucosamine residues in the chitin substrate. The $H_2O_2$ generated by fungal activity initiates a localized Fenton reaction. The resulting $HO^{\bullet}$ radicals target the amino groups of glucosamine, leading to the release of ammonium, which is taken up by the fungus. $HO^{\bullet}$ oxidation also destroys the crystalline structure and polymeric chains of the chitin substrate. Concomitant with oxidation, the fungus secretes chitinases and β-N-acetylglucosaminidases, suggesting that Fenton oxidation works in concert with hydrolytic enzymes. Taken together, we propose a novel fungal pathway for chitin degradation that is similar to the Fenton-based mechanism used by saprotrophic brown-rot fungi to degrade cellulose.

## ABSTRACT

Aridity thresholds shape ecosystem functions worldwide. Despite the importance of soil microbiomes in engineering ecosystem processes, the specific strategies employed by soil microbiomes to support ecosystem multifunctionality (EMF) across aridity gradients remain virtually unknown. Here, we investigated 474 soil samples across a continental-scale aridity gradient and identified an aridity threshold beyond which plot-level EMF declines sharply. Microbial habitat and decomposition functions were among the last to respond to aridity, with thresholds occurring under more arid conditions compared to plant productivity and soil fertility. Combining metagenomic sequencing with physiological assays to characterize microbial life-history strategies of high yield (Y), resource acquisition (A), and stress tolerance (S), we introduce a microbial trait-based framework to mechanistically link community-level microbial life-history strategies to ecosystem multifunctionality. Our results reveal that microbial Y-strategy is positively correlated with EMF across aridity gradients, A-strategy exhibits a negative association with EMF across aridity gradients, and S-strategy is negatively correlated with EMF in arid ecosystems. Collectively, this study offers empirical evidence and novel insights into how aridification interacts with soil microbiomes in shaping EMF, highlighting the pivotal role of microbial life-history strategies in understanding the mechanisms behind EMF variation in an increasingly arid world.

## ABSTRACT

Microbial necromass is thought to form a key component of the persistent soil carbon stock, and production and consumption rates should equate with stocks estimated with amino sugars. We tested this in soils from grasslands, croplands, and forests from Luxembourg and Sweden. In soil incubations, we quantified production as growth rate of, consumption as mining rate on, $^{13}$C-necromass substrate generated from bacteria (*Bacillus licheniformis*) and fungal (*Trichoderma harzianum*), and compared the differences in these rates to necromass stocks as estimated from amino sugars. On average, the growth rate of microbial biomass after adding fungal necromass was 9.3 times that of adding bacterial necromass. The carbon utilization efficiency of fungal necromass is also higher than that of bacterial necromass. Although there was also high fungal mining, rates were much lower than growth rates. The decay rates of fungal and bacterial necromass were 0.44 and 0.40 ng $g^{-1}$ $h^{-1}$. Bacterial necromass was more susceptible to variations in soil conditions compared to fungal necromass. Amino sugars were also dominated by fungal necromass (>90%) and as a result, the relationship between net necromass (production-consumption, growth rate-decay rate) correlates positively with necromass stocks as calculated from amino sugars. Our hypothesis that the difference between rates of production and consumption would predict necromass stocks was supported, largely determined by the faster growth on fungal necromass. This insight could inform broader ecological models, even climate change mitigation strategies by highlighting the importance of microbial necromass in nutrient cycling and C dynamics.

# Microbial sequestration pathways of soil organic carbon in meadow steppes under long-term nitrogen and phosphorus application: Analysis based on aggregate scale residual carbon

**ABSTRACT**

The regulation of microbial residue carbon (MRC) in soil aggregates, a key component of stable soil organic carbon (SOC), remains poorly understood under nitrogen (N) and phosphorus (P) deposition. Based on a 14-year nitrogen and phosphorus addition field experiment on meadow grassland, we systematically analyzed the seasonal dynamics of MRC, microbial biomass, and SOC across aggregate size classes (LMA: >2 mm, SMA: 0.25-2 mm, MI: <0.25 mm) to elucidate how long-term N and P application alter the contribution of aggregate-scale microbially mediated MRC to SOC. The results indicate that SOC content did not exhibit significant seasonal variation, with significant increases observed only in May for bulk soil under NP treatment and MI under N treatment. MRC responses to nitrogen and phosphorus varied by season and particle size. in October LMA, MRC increased significantly by 17.80% under N treatment, whereas NP treatment reduced MRC content across multiple particle-size fractions in May and August (decreases of 11.41%–15.59%). Fungal residue carbon consistently contributed more to SOC than bacterial residue carbon across all treatments, seasons, and particle sizes, driving MRC dynamics. N and NP treatments consistently suppressed microbial biomass across aggregate sizes. The SMA emerged as a critical niche for microbial activity and MRC accumulation, attributed to its structure and carbon availability. Notably, MRC accumulation and its contribution to SOC peaked in August but were lowest in May, contrasting with microbial biomass, which peaked in May and troughed in October. This asynchrony indicates that MRC buildup reflects seasonal coordination between microbial turnover and soil protection mechanisms rather than biomass alone. Specifically, in October, N and NP treatments increased MRC in SOC by inhibiting microbial growth and residue decomposition, leading to a rise in MRC as microbial biomass decreased. In May and August, MRC's contribution to SOC was linked to microbial biomass, showing dependence on residue production rates. These findings highlight that long-term N and P application differentially regulate the contribution of MRC to SOC across aggregate size classes and seasons, offering insights for precise grassland carbon sequestration management.

**ABSTRACT**

Soil organic matter (SOM) persistence depends on how plant inputs are transformed by microbial growth and mortality, yet depth patterns in SOM composition are rarely connected to viral control of microbial turnover. We integrate 0–100 cm paddy soil profiles quantifying plant- vs microbial-derived C with 1824 soil metagenomes from eight biomes to test whether viral regule SOM allocation. In paddy soils, topsoil (0–40 cm) was enriched in carbohydrate- and lignin-like fractions (38–50%), whereas subsoil (40–100 cm) contained more protein- and lipid-like fractions (26–60%). With increasing SOM, plant-derived C rose while microbially derived C declined; the microbial-to-plant C ratio decreased 23–30% faster in topsoil than subsoil. Plant C input and temperature best explained topsoil variation, whereas the fungi:bacteria ratio and clay content dominated subsoil controls. Globally, soil viromes were dominated by lytic strategies (88%; Siphoviridae 35.34%) and were associated with lower microbial carbon use efficiency (CUE) and higher necromass, consistent with viral-mediated mortality redirecting C from growth to necromass pathways. CUE emerged as the strongest predictor of microbially derived C, with lytic viruses exerting a larger direct contribution (3%) than lysogenic viruses (1%). Overall, our results identify viral-driven microbial death as a key mechanism connecting depth-specific drivers to SOM allocation and long-term carbon preservation

# Protist predation shifts bacterial life strategies and increases carbon use efficiency across contrasting soils

**ABSTRACT**

Microbial carbon use efficiency (CUE) helps determine whether organic carbon is retained in soil as microbial biomass or returned to the atmosphere as $CO_2$. Protists are common bacterial grazers in soils, but their effects on carbon use efficiency, and the mechanisms involved remain poorly understood. We examined the effects of protist predation in two typical agricultural soils with different nutrient levels (Mollisol and Ultisol) using metagenomics, carbon catabolic fingerprints, and physiological measurements. Protist predation altered bacterial community composition differently in the two soils, yet it drove similar shifts in carbon catabolic fingerprints across soils. Metagenomic analyses indicated that predation was associated with reduced resource-acquisition functions (A-strategy) and enhanced biosynthesis and yield-oriented functions (Y-strategy). In line with this pattern, functions involved in biosynthesis and core metabolism increased, whereas traits linked to resource acquisition, including motility and siderophore production, decreased. CUE increased under predation, especially in Ultisol, and this was accompanied by higher microbial biomass carbon and lower respiration-related indicators. Predation also reduced activities of key carbon-degrading enzymes and decreased the inferred potential for organic carbon decomposition based on CAZyme functions, with distinct responses between the two soils. Together, our results highlight protists as important regulators of bacterial physiology and suggest that predator-driven shifts in bacterial functional traits can influence soil carbon cycling.

**ABSTRACT**

Microbial necromass is increasingly recognized as a major source of stable soil organic matter (SOM), and its persistence is often attributed to interactions with clay-sized minerals. However, the mechanisms by which these mineral associations stabilize necromass remain poorly understood. Here, we conducted an in situ dual-labelled ($^{13}C$ and $^{15}N$) microbial necromass experiment across a clay gradient to quantify how clay content and necromass type (bacterial vs. fungal) regulate its persistence. We found that higher clay content markedly enhances necromass retention by increasing mineral protection, suppressing microbial activity and diversity, and limiting leaching loss. The NanoSIMS imaging showed that newly added necromass preferentially associates with organic matter coating the rough mineral surfaces, highlighting organo-organic interfaces as dominant stabilization pathways. Necromass origin has little effect on retention, even though bacterial and fungal necromass differed in their C:N ratios and bulk chemical composition. This further suggests that finer-scale molecular features, rather than these broad compositional differences, may govern necromass stabilization in soil. Together, these findings reveal how clay-sized minerals modulate multiple protection and loss pathways to determine necromass persistence, providing mechanistic insight essential for improving predictions of SOM dynamics.

**ABSTRACT**

Soil organic matter (SOM) constitutes the largest terrestrial carbon pool, yet its dynamics remain poorly predicted by current Earth system models that partition SOM into mineral- and aggregate-mediated pathways based on litter chemistry, largely overlooking microbial contributions to long-term persistence. We show that while fine litter contributes to both pathways, SOM persistence emerges from a recursive microbial necromass–mineral cycle. Litter-derived microbial necromass initiates organo-mineral aggregation, shifting microbial metabolism from substrate-selective bacterial assimilation to fungal-mediated, non-selective SOM catabolism. This reprogramming sustains the cycle, generating recursive microbial–structural–stoichiometric feedbacks that progressively convert particulate organic matter into a stable yet dynamically recycling mineral-associated pool. When disrupted—often due to stoichiometric imbalance—these feedbacks intensify microbial competition and accelerate carbon loss, particularly in long-cultivated soils with degraded resilience. Our framework establishes iterative microbial life–death cycles within plant-derived microsites as the central engine of SOM dynamics, resolving long-standing SOM paradoxes and providing a mechanistic, process-explicit foundation for understanding the soil–microbe ecosystem as self-organizing, thereby improving carbon–climate projections and guiding resilience-focused soil stewardship.

## ABSTRACT

Urban areas cover less than 0.6% of the Earth's land surface yet account for over 70% of global energy-related $CO_2$ emissions. Soil viruses, with populations up to $10^{10}$ per gram of soil, play a vital role in regulating microbial communities and the carbon biogeochemical cycle. Although the global patterns of soil viruses have been well established in natural ecosystems, few studies have explored urban soil viruses and their roles in carbon cycling. Here, we used a global database of paired urban greenspaces and natural ecosystems in 27 cities from 17 countries across six continents encompassing broad variation in SOC stocks and quality. We analyzed the distribution of soil viruses and their contributions to soil organic carbon pools in urban and natural ecosystems. Urban greenspaces exhibited reduced soil viral diversity and significant community homogenization, forming a subset of the viral pool found in natural ecosystems. Virus-host interaction analysis revealed that only 4.5% of vOTUs could be linked to microbial hosts (MAGs), with natural ecosystems harboring more virus-host pairs than urban greenspaces. In addition, there are obvious differences in the pattern of virus-mediated organic carbon regulation between urban green spaces and natural ecosystems. Viral abundance showed stronger negative correlations with bacterial genes involved in chitin, cellulose, pectin, and hemicellulose degradation in urban soils, suggesting urban conditions may favor viral proliferation over these specific decomposer communities. While natural ecosystems maintained higher AMG diversity, urban greenspaces exhibited significant enrichment of viral glycosyltransferase genes (particularly GT2 and GT4), indicating enhanced viral contributions to carbon sequestration. Our results reinforce the importance of soil viruses in supporting urban soil carbon sequestration, offering potential microbial-oriented strategies for the conservation of urban soil carbon pools and the capacity of improve global C cycle models.

**ABSTRACT**

As the largest terrestrial carbon reservoir, soil plays a critical role in the global climate system. Soil inorganic carbon (SIC) has traditionally been regarded as more stable than soil organic carbon (SOC). However, growing evidence challenges this perspective, indicating a widespread decline in SIC stocks. Current approaches to enhance SIC primarily include silicate weathering enhancement and biochar application. Beyond these, specific microorganisms can induce carbonate precipitation through metabolic processes such as photosynthesis, urea hydrolysis, and sulfate reduction. To investigate SIC enhancement and its interaction with SOC, a microcosm experiment was conducted using carbonate-precipitating microorganisms. This study integrated analyses of soil carbon fractions, stable isotope measurements, and microbiome profiling. Inoculation with microorganisms increased soil inorganic carbon content by 2.41 mg/g and 1.85 mg/g in alkaline and acidic soils, respectively. Furthermore, treatments with higher SIC content exhibited increased mineral-associated organic carbon (MAOC). These findings advance the understanding of soil carbon sequestration mechanisms and support the development of sustainable soil management strategies for climate change mitigation.

**ABSTRACT**

Thermal responses of microbial carbon use efficiency (CUE) to warming remain a major uncertainty in predicting soil-climate feedbacks. Long-term studies have reported variable outcomes, including decreases, increases or no detectable change, reflecting the interacting influences of microbial physiological adaptation and resource availability. Here, in a five-year in situ warming experiment, we resolved these inconsistencies by statistically isolating the direct physiological responses from co-varying environmental factors. We found that microbial CUE follows a non-monotonic adaptive trajectory, shifting from an initial suppression to a subsequent enhancement. Importantly, the direct warming effect on CUE strengthens over time, indicating that microbial growth adaptation outpaces compensatory adaptation in respiration. This community-level adaptation is associated with an ecological selection for higher metabolic efficiency, with functional gene composition emerging as a stronger predictor of the CUE thermal response rather than microbial taxonomic composition. Integrating observed CUE dynamics into a biogeochemical model improved prediction of the labile organic carbon pool, confirming the importance of the thermal adaptive process. Our findings clarify the long-term thermal response of microbial CUE and show that the initial physiological decline can be offset by growth adaptation. This highlights the need for Earth system models to incorporate the thermal adaptation of microbial physiological traits to accurately predict future soil carbon dynamics.

**ABSTRACT**

Soil microbial communities play a crucial role in nutrient cycling and ecosystem functioning, with their activity being heavily influenced by environmental factors such as cover cropping and nitrogen fertilization. This study investigates the interactive effects of cover crop types and nitrogen fertilization on the soil microbial dormant fraction, focusing on the changes in microbial activity during different nitrogen levels and cover crop systems. Through a two-year field experiment, we assessed the impact of various cover crop treatments (no-cover, soybean monoculture, Sudan grass monoculture, and mixed cover crop) under different nitrogen fertilization levels (0, 60, and 120 kg/ha) on microbial dormancy. Our results demonstrate that the mixed cover crop treatment significantly reduced the microbial dormant fraction compared to monoculture systems, highlighting its potential for enhancing microbial activity. Additionally, nitrogen fertilization, especially at higher levels (N120), further suppressed microbial dormancy, indicating that nitrogen availability is a key driver in the activation of dormant microbial populations. Variance partitioning analysis revealed that the regulatory mechanisms differed across cover crop systems, with nutrient availability playing a dominant role in mixed cover crops. These findings suggest that combining appropriate cover crop management with optimized nitrogen fertilization strategies can effectively stimulate soil microbial activity, promoting healthier soils and improving nutrient cycling efficiency. This research provides insights into how agricultural practices can be tailored to activate soil microbial communities, potentially boosting crop productivity and advancing sustainable farming practices.

**ABSTRACT**

Increasing frequency of extreme climate events is posing a significant threat to soil ecosystems, including microbial life and functions. Because soil microorganisms are sensitive to environmental perturbations, leading to shifts in the composition and stability of microbial-derived carbon pools. Microbial necromass, commonly identified by amino sugars, is accumulated through microbial growth and turnover and thereby contributing to stable soil organic carbon. While extracellular polymeric substances (EPS) are actively secreted, this requires high-cost investment by microorganisms. Whether such intracellular and extracellular microbial strategies in carbon allocation can be regulated over time, to meet their survival or resource needs under environmental stress, is largely unknown.

Here, we studied the interannual variability in the dynamic changes of soil microbial-derived carbon under two long-term experiments that manipulated extreme drought and sustained warming in a subtropical forest. We quantified soil amino sugars and EPS, characterized their major compositional components, and linked their dynamics to changes in soil organic carbon and microbial communities. Our results reveal distinct responses of EPS and microbial necromass to different global change scenarios across years. Under extreme drought, compared to the weak response of microbial necromass, EPS exhibited strong interannual dynamics, suggesting that microorganisms primarily adjust extracellular carbon allocation to cope with extreme water shortage. In contrast, sustained warming markedly shaped microbial necromass over time, but hardly influenced EPS, indicating that warming predominantly regulates microbial growth–death turnover processes and the subsequent accumulation of microbial residues.

Overall, our results demonstrate different microbial mechanisms resulting in contrasting dynamic changes in intracellular and extracellular microbial-derived carbon responses to extreme drought and sustained warming, with important implications for soil organic carbon turnover and stabilization. Our findings highlight the essential role of soil microorganisms in mediating different microbial-derived carbon pools amid escalating extreme climate.

**ABSTRACT**

Microbial growth and necromass formation are central to soil organic carbon (SOC) stabilization, but they are frequently constrained by phosphorus (P) supply and by the specific pathways microbes use to access organic and mineral P. We tested whether a pathway-aware index of microbial P-acquisition traits (EPSI; integrating *pqq*-dependent phosphatase systems and P transport/assimilation modules) can predict carbon-use efficiency (CUE) and SOC turnover across urban–peri-urban gradients. Soils will be sampled along replicated transects spanning dense urban greenspaces, peri-urban forests, and adjacent croplands, capturing contrasting P forms (labile vs. occluded) and mineral protection capacity. We quantified SOC fractions (particulate vs. mineral-associated), microbial biomass and necromass proxies, extracellular enzyme stoichiometry (C:N:P), and gross C mineralization in standardized incubations with factorial P addition and substrate pulses. Metagenomic and qPCR assays provided EPSI and key functional-gene abundances. We hypothesized that (i) higher EPSI buffers microbial P limitation, increasing CUE and shifting carbon allocation from enzyme production toward biomass growth; (ii) this promotes greater microbial necromass contribution to mineral-associated organic matter, reducing SOC vulnerability; and (iii) EPSI will outperform bulk soil P metrics in explaining spatial heterogeneity of SOC turnover. By explicitly linking microbial P pathways to carbon processing, this work offers a scalable trait-based lever for improving SOC predictions under urbanization and nutrient management.

*E-mail: wjy9276@stumail.nwu.edu.cn

**ABSTRACT**

Climate warming strongly influences soil microbial activity, yet how soil active microbial communities respond to persistent warming over multi-year time scales remains unclear, particularly in forest ecosystems. Here, we examined responses of soil active microbial communities to persistent warming spanning 3–5 years using a reciprocal soil translocation experiment in the Qinling Mountains, China. Soil microbial activity and functional dynamics were assessed using a combined 16S rRNA/DNA approach and metatranscriptomic analyses. The proportion of active soil microorganisms increased by 14.77% after three years of warming, indicating an early expansion phase with enhanced microbial activity and growth. In contrast, five years of persistent warming significantly reduced active microbial proportions (−20.28%) and markedly altered community composition. Metatranscriptomic results indicate that prolonged warming favors an endurance-oriented strategy, with increased investment in maintenance, stress tolerance, and resuscitation potential, coupled with reduced allocation to growth-related and resource-intensive pathways. Together, these findings reveal a directional transition of soil active microbial communities from expansion to endurance under persistent warming. Overall, our results demonstrate strong time-dependent responses of soil active microbial communities to warming, highlighting the importance of temporal dynamics when assessing microbial-mediated soil carbon processes under climate change.

# Microbes as engineers in modulating and preserving soil organic carbon

**Qiaoyun Huang**

*Huazhong Agricultural University, Wuhan 430070, China*

qyhuang@mail.hzau.edu.cn

**ABSTRACT**

There has been growing recognition on the central roles of microorganisms in the cycling and preservation of soil organic carbon under the regime of soil health deterioration and the dire situation of global climate change. Investigation on microbial $CO_2$ sequestration at large scale shows that $CO_2$ fixation rates in soils are highly correlated with the community composition of autotrophic bacteria and phototrophic protists. Paddy soils, supporting a larger proportion of obligate bacterial and protist autotrophs, display four-fold of $CO_2$ fixation rates over upland and forest soils. On the other hand, microbial biomass and necromass mediate the formation of various organic carbon pools in soils. Although microbial necromass carbon per se accounts for only 41- 44% of mineral associated organic carbon (MAOC) in soils of various ecosystems, MAOC accumulation is primarily regulated by microbial activity. The degradation, turnover and accumulation of organic carbon by microbial processes are profoundly influenced by their interactions with clay minerals, land utilization and environmental parameters. Clay minerals are not only the microbial habitats, but also suppress or enhance microbial growth and activity via a range of physical and chemical processes, ultimately regulating the cycling and preservation of soil organic carbon. The interplay mechanisms between microorganisms and minerals have been studied extensively over the past years. However, their impacts and contributions to the long-term storage of soil organic carbon have largely been unknown. Further studies are required to evaluate and quantify microbial contribution to soil stable C pool and to parse the in-depth mechanisms of microbial processes and their interactions with minerals in soil carbon accrual from microscale to different landscapes by virtue of various chemical, spectroscopic and microscopic techniques, and modelling. Incorporation of microbial indices such as physiological, biological attributes and functional genes and also their interactions with soil minerals in the modelling of soil organic carbon will improve the Earth System Model.

**ABSTRACT**

Freeze-thaw events represent an important phenomenon in terms of soil hydrology and thermodynamics. The change in environmental conditions associated with these events may induce stress within the soil microbial community. Previous studies have shown freeze-thaw cycles increase DOC concentrations. The increase of DOC in soil may be associated with microbial death or the release of cryoprotectants (osmolytes) into soil solution. Surviving microbes can then take up the DOC and release $CO_2$ via respiration, with important implications for soil carbon storage and greenhouse gas emissions.

Some studies have shown most microbial damage by freeze-thaw occurs within the first 1 or 2 freeze-thaw cycles. In this study, we investigated the effect of repeated (3 times) freeze-thaw cycles on soil microbial communities, and to see whether repeated freeze-thaw cycles have a cumulative effect relative to a single freeze-thaw event. We observed that DOC, TDN, amino acids and $NH4^+$ increased on thawing from both single and repeated severe freeze-thaw events, and that the effects of repeated freeze-thaw events were greater than a single freeze-thaw cycle. Soil metabolomes changed after both freeze-thaw events. A single severe freeze-thaw recovered soil metabolomes within 5 days whilst repeated severe freeze-thaw did not recover at all.

**ABSTRACT**

Soil organic carbon (SOC) stability is essential for ecosystem function in eroded landscapes. Erosion reshapes soil carbon dynamics by depleting surface SOC in erosion zones, supplying fresh carbon to depositional areas, and altering soil microenvironments that regulate microbial necromass carbon (MNC), a major contributor to SOC stability. However, the vertical distribution of MNC and its controlling factors in erosion and depositional environments remain unclear. We investigated 4-m-deep soil profiles from erosion and depositional zones on the Loess Plateau to determine how erosion shapes vertical distribution and controls of MNC. The MNC/SOC ratio generally exceeded 50%, indicating MNC is a major SOC component. MNC showed strong vertical stratification in erosion zones (Topsoil > Subsoil > Deepsoil), while depositional zones had weaker vertical differentiation with more accumulation in deepsoils, reflecting lateral transfer and burial. Additionally, Microbial factors were the main drivers of MNC accumulation. In erosion zones, topsoil MNC was mainly influenced by bacterial composition and microbial biomass, while deepsoil MNC was controlled by multiple microbial groups and their functions. In depositional zones, microbial regulation was more localized, primarily influencing deepsoils. Our results suggest that erosion-induced redistribution and burial of MNC are crucial for its vertical organization and long-term SOC stabilization.

## ABSTRACT

Microbial growth and carbon use efficiency (CUE) are central to soil organic carbon (SOC) cycling as they control the formation of microbial residues that can become stabilized and contribute to persistent SOC pools. Land use and its intensification are known to affect above- belowground biodiversity and functions, thereby modifying the role of microbial traits in SOC formation. However, it remains unknown how changes in the quantity and quality of plant litter input, or management, influence microbial physiological traits, and how these changes interact with SOC persistence at a quantitative and mechanistic level. Within the Biodiversity Exploratories framework which was established since 2006, we present an integrated assessment of how land-use type, management intensity, and soil properties regulate microbial physiological traits and their implications for SOC quantity and potential quality in grassland and forest soils across 300 plots in three different regions in Germany. Grasslands exhibited significantly higher total microbial growth and respiration, as well as higher specific respiration, but showed no differences in CUE compared to forests. In forest ecosystems, tree species identity exerted strong effects on microbial physiology, with deciduous stands exhibiting higher microbial growth and CUE than coniferous stands. Management intensity in grasslands, particularly nitrogen inputs, exerted positive indirect effects on microbial growth and carbon use efficiency (CUE), whereas in forests, management had predominantly negative effects on CUE, acting both directly and indirectly through changes in abiotic soil properties. Across ecosystems, microbial biomass carbon and soil pH emerged as key regulators of microbial physiological traits in forests, while grasslands showed more dynamic responses, likely reflecting stronger controls by resource availability and limitation in managed systems. Overall, our findings demonstrate that microbial carbon dynamics are governed by distinct regulatory mechanisms across land-use types and management regimes.

**ABSTRACT**

Enhancing soil organic carbon (SOC) sequestration through crop straw return is a critical strategy for sustainable agriculture and climate change mitigation. However, the synergistic mechanisms through which straw quantity and application frequency jointly regulate microbial life-history strategies and ultimately drive SOC formation and persistence remain inadequately understood. This study integrates findings from two complementary field experiments in black soil regions to address the questions of "how much" and "how often" straw should be returned to maximize SOC accrual. Our results demonstrate that while any straw return increases microbial biomass and diversity, only an optimal quantity (approximately 67% of generated straw) efficiently couples rapid microbial response with long-term carbon transformation processes, leading to the highest continuous conversion efficiency from microbial biomass to necromass and, consequently, the greatest SOC accumulation. Simultaneously, we found that high-frequency straw application reshapes the microbial community toward a more copiotrophic-dominated assembly, fosters a more complex and tightly connected ecological network, and diversifies potential functional traits. This "little and often" strategy minimizes nutrient waste and enhances the efficient channeling of microbial biomass into stable residual carbon. By integrating these findings, we propose a novel Microbial Efficiency-Framework for straw management. This framework posits that the interactive effects of optimal quantity and high frequency synergistically steer microbial communities toward strategies that maximize the efficiency of the "microbial growth-to-necromass" pipeline, thereby optimizing the SOC sequestration potential. This work provides a mechanistic basis for precision straw management in black soil conservation and offers actionable insights for achieving agricultural dual-carbon goals.

## ABSTRACT

The soil carbon dynamics in karst ecosystems were an important component of the global terrestrial carbon cycle. Microbial necromass carbon played a crucial role in the accumulation of organic carbon. Determining the microbial necromass carbon content in different forest soils and exploring the factors that influenced it helped predict the potential of forests as carbon sinks. However, the contribution ratio of soil microbial necromass carbon to organic carbon under artificial afforestation in karst stony desertification areas and its variation with forest age were still unclear. To address this gap, this study focused on *Dalbergia odorifera* plantations with different planting ages (4, 11, and 18 years) in Pingguo City, Guangxi, as well as nearby naturally restored secondary forests. We utilized advanced biomarker techniques to accurately quantify the contribution ratio of microbial necromass carbon to organic carbon across these different forest types. Furthermore, we employed high-throughput sequencing methods to reveal the diversity of arbuscular mycorrhizal fungi (AMF), assess the complexity of their co-occurrence networks, and analyze the processes of community assembly. Building on these findings, we then explored the relationship between the characteristics of AMF communities and the contribution ratio of microbial necromass carbon. The results showed that in *Dalbergia odorifera* plantations, the microbial necromass carbon stock in the soil of the 18-year-old forest was lower than that in the 4-year and 11-year stands. With increasing forest age, the soil carbon (C): nitrogen (N): phosphorus (P) ratio and the complexity of AMF networks gradually increased, while the contribution ratio of microbial necromass carbon to organic carbon decreased, with the AMF community assembly process shifting from being dominated by stochastic processes to deterministic processes. The contribution ratio of microbial necromass carbon to organic carbon showed a significant negative correlation with C:N, C:P, N:P, and organic carbon stock ($P<0.05$). Structural equation modeling analysis suggested that forest age increased the soil C:N:P ratio, enhanced the complexity of AMF symbiotic networks, and shaped the deterministic assembly process of AMF communities. The complexity of AMF networks and the deterministic assembly process together diminished the relative contribution of microbial necromass carbon to the organic carbon pool. Through this study, we clarified the trends in microbial necromass carbon stocks and their contributions to the organic carbon pool during the artificial afforestation process in karst rocky desertified areas, revealing key driving mechanisms from the perspective of soil AMF community structure characteristics. Additionally, this research offered valuable scientific evidence and guidance for ecological restoration practices in karst rocky desertification areas.

# Nitrogen addition promotes soil microbial-derived carbon storage: A meta-analysis

## ABSTRACT

The concept of soil microbial carbon pump highlights microbial necromass as a critical and persistent source of soil organic carbon (SOC). However, the response of soil microbial necromass carbon to nitrogen enrichment, particularly regarding the contributions of bacterial and fungal necromass to SOC, remains unclear. Here, a global meta-analysis with 791 paired observations from 56 studies was conducted to evaluate the influence of nitrogen addition on soil microbial necromass accumulation and its contribution to SOC storage. Nitrogen addition increased total microbial necromass carbon by 14.6%, with bacterial and fungal necromass carbon increasing by 17.7% and 13.7%, respectively. The extent of microbial necromass accumulation increased with nitrogen application rate and was concurrently modulated by soil properties, particularly total nitrogen and the soil carbon-to-nitrogen ratio. Nitrogen addition enhanced bacterial carbon pump efficacy (i.e. the proportion of bacterial necromass carbon in SOC), indicating improved carbon retention during bacterial metabolism. However, fungal necromass remained the dominant contributor to the increase in SOC after nitrogen addition, accounting for 18.9% of the SOC increment, compared with 6.5% from bacterial necromass. Overall, nitrogen addition stimulates microbial necromass formation, thereby enhancing SOC storage. Although bacterial carbon pump efficacy significantly increases owing to nitrogen addition, fungal necromass remains the dominant contributor to SOC accumulation. This study provides new insights into microbial-derived carbon storage after nitrogen enrichment.

## ABSTRACT

The extent to which microbial processes control soil organic carbon (SOC) dynamics remains uncertain. Carbon use efficiency (CUE)—the fraction of assimilated carbon allocated to growth—has been used as a key parameter, but its relationship with SOC reflects carbon partitioning rather than the absolute magnitude of microbial fluxes. Microbial growth rate could provide a more mechanistic link to SOC accumulation, as it quantifies biomass production and reflects necromass formation. Here we combine a global $^{18}O$–$H_2O$ dataset (n = 268 paired observations) with outputs from four land surface models to test whether growth rate predicts SOC more strongly than CUE. In the incubation experiments, growth rates are more closely associated with SOC than CUE, although soil properties and climate explain equal or greater variance. Models reproduce the stronger role of growth rate over CUE but tend to underestimate the abiotic controls. The models also emphasize CUE as the main predictor of the SOC/NPP ratio, in contrast to observations, which indicates the soil's capacity to retain plant carbon inputs. Together, these findings identify microbial growth rate as a diagnostic that can help bridge models with empirical data and guide a more balanced representation of microbial and mineral controls in SOC projections.

## ABSTRACT

The preservation of soil organic carbon (OC) is an effective way to decelerate the emission of $CO_2$ emission. However, the coregulation of pore structure and mineral composition in OC stabilization remains elusive. We employed the in situ nondestructive oxidation of OC by low-temperature ashing (LTA) combined with near edge X-ray absorption fine structure (NEXAFS), high-resolution microtomography (μ-CT), field emission electron probe micro analysis (FE-EPMA) with C free embedding, and novel Cosine similarity measurement to investigate the C retention in different aggregate fractions of contrasting soils. Pore structure and minerals contributed equally (ca.50%) to OC accumulation in macroaggregates, while chemical protection played a leading roleinCretentionwith53.4%−59.2%of residual C associated with minerals in microaggregates. Phyllosilicates were discovered to be more prominent than Fe(hydr)oxidesinCstabilization.Theproportionofphyllosilicates-associated C (52.0%−61.9%) was higher than that bound with Fe(hydr)oxides (45.6%−55.3%) in all aggregate fractions tested. This study disentangled quantitatively for the first time a trade-off between physical and chemical protection of OC varying with aggregate size and the different contributions of minerals to OC preservation. Incorporating pore structure and mineral composition into C modeling would optimize the C models and improve the soil C content prediction.

**ABSTRACT**

The stabilization of plant-derived carbon (C) and the modification of native soil organic matter (SOM) by fresh C input are key processes controlling soil C dynamics, yet the underlying mechanisms are not fully understood, particularly for the subsoil. Here, we conducted a two-year field incubation of $^{13}$C-labelled *Lolium perenne* roots in three grasslands (one alpine and two temperate), to study the incorporation of root-derived C into different SOM fractions and its effect on native SOM dynamics in top- (0–10 cm) versus subsoils (30−40 cm). After two years, the subsoil retained a higher proportion of the initial root C input (19.0 ± 0.8%) than did the topsoil (11.0 ± 1.7%), of which a greater fraction directly sorbed to the mineral-associated organic matter (MAOM) without prior microbial processing. The formation of root-derived MAOM was independent of the decomposition of root-derived light fraction (LF) and particulate organic matter (POM). In contrast, root inputs stimulated the microbial conversion of native POM and LF, leading to their stabilization as microbial-derived MAOM. Our results highlight the critical role of the subsoil in soil C sequestration and reveal that fresh C inputs enhance MAOM accrual via sorption of new C and microbial-mediated transformation of native soil C.

## ABSTRACT

Soil organic carbon (SOC) mineralization is a key driver of the climate-carbon feedback. Enhanced microbial activity is considered to be the primary cause of SOC loss under warming. However, microbial trait changes often cannot fully explain SOC responses. Warming-enhanced root exudation of organic acids may destabilize mineral-associated organic carbon (MAOC) and promote SOC mineralization. However, this process remains poorly constrained both empirically and in Earth system models, impeding accurate predictions of soil carbon dynamics under climate change. To address the above gaps, here we integrate global data synthesis (8,846 observations from 112 studies) with laboratory quantification of organic acid-induced destabilization across diverse soils. We show that unlike carbohydrates that stimulate microbial growth, organic acids greatly accelerate SOC mineralization by increasing native carbon availability without enhancing microbial biomass or enzyme activity. By further quantitatively incorporating this abiotic pathway into the Millennial model, we find that organic acid-induced destabilization contributes 9% ± 1% (mean ± standard deviation) of SOC mineralization, surpassing direct warming effects by 25%–44% in climate projections (SSP1-2.6 and SSP5-8.5 scenarios), particularly on MAOC mineralization (by 81%–110%). Our study provides the first direct quantification of MAOC destabilization by root-exuded organic acids and shows its strong contribution to SOC loss across diverse soils in both laboratory observations and process-based models. Neglecting this pathway leads to an underestimation of SOC vulnerability, particularly for the slow-cycling MAOC pool. Laboratory experiments that exclude plant–soil interactions may also underestimate SOC loss by failing to capture root-induced destabilization.

# Multi-element evidence that soil organic matter persistence is not attributed to selective preservation or loss but an ecosystem property

**ABSTRACT**

Soil organic matter (SOM) persistence played a central role in global carbon (C) cycle and soil productivity, but the mechanisms underlying SOM stability remain unclear. We revisited the emerging views about SOM persistence by combining a space-for-time substitution study with physical and density fractionation of SOM, wet-chemical extractions and non-destructive near edge X-ray absorption fine structure (NEXAFS) spectroscopy to characterise SOC functional groups and S chemical speciation. Soil samples were collected at three depths (0-10, 10-20 and 20-30 cm) from the forest, and adjoining cropping and grazing lands at the Brigalow Catchment Study (BCS) in subtropical Australia. Bulk soil was then fractionated into free particulate organic matter (fPOM), occluded POM (oPOM), fine mineral fraction (f-MF) and coarse MF (c-MF). We found that cropping and grazing markedly decreased SOC and S concentrations in soil from the forest (especially at 0-10 cm), with the decrease being much more prominent for fPOM compared to oPOM or f-MF. Furthermore, even though the SOC functional group composition and organic S speciation differed significantly between the various soil fractions, they remained comparatively constant following land use change. Thus, despite losing up to 43% of the SOC, our observation that the speciation of both organic C and organic S did not change suggests that this loss of SOM was not associated with selective preservation (or selective loss) of particular forms of SOM, but rather highlighting the likely important role of physicochemical protection. Interestingly, cropping and grazing greatly simplified the interconnectivity networks of SOC functional groups and S chemical species for the forest soil, potentially indicating that SOM persistence was profoundly influenced by the interactions of multielements. We also observed that C-bonded S was positively correlated with the Shannon diversity index and aromaticity of SOC, suggesting an intrinsic linkage between SOC cycling and S. Our findings support Schmidt et al. (2011) that SOM persistence is an ecosystem property and not a molecular property, and extend their conclusions through multi-element analysis of SOM composition and speciation.

**ABSTRACT**

Grass cover profoundly modifies rhizosphere carbon cycling, yet the mechanistic links between root exudate chemistry and soil carbon stabilization remain elusive. A field experiment was conducted in a citrus orchard (Sichuan Province, China) with purple soil (pH 4.55) to investigate how root exudates modulate microbial networks and carbon fractions, using four grass species—natural grass (*Gnaphalium affine*), *Lolium multiflorum*, *Trifolium repens*, and *Vicia villosa*—and clean tillage as the control. Among all treatments, the leguminous *Vicia villosa* exhibited the most pronounced effect on carbon sequestration: compared with clean tillage, it markedly increased soil organic carbon (SOC), particulate organic carbon (POC), and mineral-associated organic carbon (MAOC) by 6.92, 4.37, and 2.55 g $kg^{-1}$, respectively, and elevated the POC/SOC ratio by 25%. Grass-specific root exudates were dominated by lipids (27.7%) and organic acids (19.2%), while *Vicia villosa* uniquely released nitrogen-rich metabolites such as lysine–leucine and adenine. These metabolites enriched keystone bacterial taxa (e.g., *Bacilli*, *Acidimicrobiia*), enhanced bacterial network connectivity (with higher positive edge proportions and natural connectivity), and promoted metabolic cross-feeding and organo-mineral complex formation. Partial least squares structural equation modelling (PLS-SEM) confirmed that root exudates strongly regulated bacterial networks (path coefficient = 0.78, $p < 0.001$), which directly increased POC (path coefficient = 0.46) and MAOC (path coefficient = 0.55); in contrast, fungal networks exerted negligible effects on both carbon fractions. Our findings elucidate a root exudate–bacterium co-regulation mechanism underlying soil carbon stabilization and provide a mechanistic basis for designing carbon-smart orchard management strategies through legume-based grass cover.

**ABSTRACT**

Estimating aggregate-associated mineral-associated organic carbon (MAOC) and microbiome structure provides critical insights into soil organic matter (SOM) stabilization in biogenic aggregates, particularly in sandy soils lacking 2:1 clay minerals and carbonates. The accumulation or loss of MAOC, and thus the capacity for SOM stabilization depends on the balance between microbial catabolic mineralization and anabolic processes. By linking snapshot microbiome structure with in-field soil respiration measurements, we obtained a reliable indicator of a land use system's potential for SOC stabilization. This study tested the hypothesis that biogenic soil aggregation in sandy soils is highly responsive to management practices. We compared poorly managed intensively grazed lands (IGLs), with high grazing pressure and continuous nitrogen fertilization, to optimally managed IGLs featuring lower grazing pressure and legume integration. Weekly field-based $CO_2$ emission measurements over one year were paired with assessments of aggregate stability, MAOC, particulate organic carbon (POC), and microbial community structure, comparing long-term IGLs to a forestry site.

The results revealed that soil aggregation increased in heavily grazed systems, yet total MAOC levels were inversely affected. The highest MAOC was observed in optimally grazed IGLs, with small micro and clay-silt aggregates storing 45% and 41% of total MAOC, respectively, while large macro aggregates held the remainder. Although overall microbial diversity and structure did not vary significantly among aggregate fractions, aggregates with lower MAOC showed a higher abundance of copiotrophic microbes. In-field soil respiration data further indicated that systems with higher soil respiration tended to accumulate lower MAOC, even when exhibiting a higher aggregate stability index, whereas systems with lower soil respiration accumulated higher MAOC. These findings suggest that in sandy soils, MAOC formation is governed more by microbial community structure and activity, which are influenced by nutrient inputs from grazing than by the presence of biogenic aggregates alone.

**ABSTRACT**

Earthworms are key decomposers in forest ecosystems influencing litter breakdown and nutrient cycling through their consumption of soil, microbes, and organic matter, as well as through bioturbation and cast production. This study investigated the short-term effects of *Amynthas* earthworms on $CO_2$ emissions in a *Quercus* spp. dominated mixed temperate forest over a 50-day period from September 9 to October 28, 2025. Eight cylindrical chambers (18L) with mesh bodies were embedded in the forest floor consisting of two treatments: control (soil + *Quercus acutissima* litter) (S, n=3) and earthworm-added (soil + *Q. acutissima* litter + earthworms) (SE, n=5) treatments. Soil $CO_2$ emissions were measured 16 times on days 1, 2, 3, 4, 6, 8, 10, 13, 15, 18, 21, 24, 31, 37, 43, and 50. *Amynthas* earthworms showed temporally variable effects on $CO_2$ emissions over the period. To examine temporal patterns, we divided the period into early (days 0-24) and late (days 25-50) phases based on observed shifts in $CO_2$ emissions. Earthworm effects were negligible during the early decomposition phase ($P = 0.375$) but became highly significant during the late phase ($P = 0.002$). Cumulative $CO_2$ emissions in SE reached $11.2 \pm 0.4$ g C $m^{-2}$ compared to $8.0 \pm 0.4$ g C $m^{-2}$ in S by day 50 representing a 39.5% increase. Both treatments exhibited an initial $CO_2$ emission peak during the first week following litter addition followed by a gradual decline after day 31. However, during the late phase, SE maintained relatively higher $CO_2$ emissions compared to S suggesting that earthworms sustained microbial decomposition activity after depletion of readily available substrates. These results indicate that earthworm effects on carbon mineralization are most pronounced during the late phase of litter decomposition with implications for organic matter turnover and nutrient availability though the underlying mechanisms should be further investigated.

# Straw input altered the composition of aggregate-associated organic carbon in soils with different initial carbon status

**Xu Liu [a], Tingting An [a], Shuangyi Li [a], Jingkuan Wang [a]**

[a] *Key Laboratory of Arable Land Conservation (Northeast China), College of Land and Environment, Shenyang Agricultural University, Shenyang* 110866*, China*

**A B S T R A C T**

Initial soil carbon (C) status affects microbial utilization for plant residue. Meanwhile, the retention of organic components from plant and microbial sources are also regulated by soil aggregates. Nevertheless, the information about how crop straw incorporation affects aggregates-associated organic C sources and composition is poorly understood, especially in soils with different initial soil C status. Here, the initial low and high C soils were incubated with or without the addition of maize straw for 360 days. We investigated the accumulation of lignin phenol and microbial necromass and the chemical composition of organic C within soil aggregates (macroaggregates, >0.25 mm; and microaggregates, < 0.25 mm) in initial low and high C soils following maize straw addition. Maize straw addition increased the organic C-normalized content of total lignin phenol within macroaggregates by 39% in initial low C soil, but decreased that content within both macroaggregates and microaggregates by 18% and 41% in initial high C soil, respectively. Independent of initial soil C status, maize straw addition increased the contributions of amino sugar and fungal necromass C to organic C within macroaggregates. Furthermore, maize straw addition increased the relative proportion of O-alkyl C in organic C within microaggregates in initial low and high C soils. Overall, the accumulation of plant lignin components was important for macroaggregate-associated organic C pool after adding maize straw to initial low C soil. Microbial necromass and labile organic components played divergent roles of in mediating aggregate-associated organic C in soils following maize straw addition.

# Ferrihydrite-mediated carbon stabilization and plant responses in an alkaline soil

**Zeinab Ghasemzadeh[1*], Matthias Johannes Salomon[1], and Zhe Han Weng[1]**

[1] *The University of Adelaide, Adelaide, Australia*

* Zeinab.ghasemzadeh@adelaide.edu.au

**ABSTRACT**

Alkaline soils, which cover over 1.38 billion hectares globally, often constrain agricultural productivity due to their high pH and associated issues such as nutrient imbalances (e.g., reduced availability of P, Ca, and Mg), boron toxicity, poor soil structure, and limited root growth. While their low organic carbon (OC) content is a secondary outcome of these limitations, the role of reactive iron (Fe) minerals in stabilizing OC within such soils has been traditionally underestimated. However, recent evidence challenges this view, suggesting that Fe oxyhydroxides play a significant role in mineral-associated organic carbon (MAOC) stabilization in arid soils.

To address this knowledge gap, we conducted two experiments. The first investigated the effect of ferrihydrite (Fh) and a redox mediator (AQDS) on OC stabilization. We hypothesized that Fh would form Fe-bound OC complexes that protect OC from microbial degradation and AQDS would further reduce $Fe^{3+}$ to $Fe^{2+}$, therefore enhancing Fe-OC formation. In the second experiment, a subsequent 100-day pot experiment with wheat (*Triticum aestivum* L.) in alkaline soil was conducted, using Fh amendments (0.1% and 0.5% Fh). We traced the fate of carbon in the rhizosphere with increasing Fh amendments (0.1% and 0.5% w/w).

The results of the incubation experiment showed that the combined Fh and AQDS treatment enhanced Fe-OC complex formation while reducing basal soil respiration by 32% compared to the control. Synchrotron-based spectroscopy confirmed that carboxyl and phenolic functional groups contributed to the rapid adsorption of OC onto Fe surfaces, and therefore the stabilization of OC.

In the second experiment, the Fh 0.5% treatment significantly improved plant growth, increasing shoot and root biomass by over 40% by Week 13. Two $^{13}CO_2$ pulse-labelling campaigns were conducted at Weeks 7 and 13 to trace rhizodeposited-$^{13}C$. Through C source partitioning, Fh stimulated active C cycling, by increasing rhizodeposit-derived respiration and root respiration early in the growth cycle. We will further quantify the $^{13}C$ allocation into MAOC and particulate organic carbon pools and assess changes in water-stable aggregate stability. This work demonstrates that Fh amendments affect organo-mineral and biological processes in the rhizosphere to enhance C sequestration, highlighting a promising strategy to improve soil carbon stabilization and resilience in global dryland agriculture.

## ABSTRACT

Agricultural fertilizer regimes can dictate soil's carbon storage capacity, but the mechanisms are complex and unclear. Long-term studies on dissolved organic matter (DOM) components and microbial decomposers are needed to improve soil carbon sequestration. Towards addressing these ends, Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS) combined with high-throughput sequencing could elucidate variations of DOM chemo-diversity, biodiversity, and their interactive effects on $CO_2$ emissions. A 29-year fertilized field experiment included four regimes (non-fertilization, CK; chemical fertilization, NPK; NPK with manure, NPKM; and NPK with stover return, NPKS). Results revealed organic amendments strongly increased $CO_2$ emissions by 19%–33% compared with NPK treatment. The relative abundance of recalcitrant DOM was depleted while the relative abundance of labile DOM components significantly increased in organic amendment treatments compared with the NPK treatment, as confirmed by decreases metrics of DOM chemical complexity, including SUVA254, Shannon index, and the nominal oxidation state of carbon. Organic amendments significantly increased the relative abundances of Acidobacteria, Chloroflexi, and Ascomycota compared with NPK treatment. Network analysis revealed that the organic fertilizer network had fewer DOM-microbial positive interactions compared with no-organic fertilizer networks, indicating a decreased specialization of DOM production. Conversely, higher DOM-microbial negative interactions indicated an increased specialization of DOM decomposition. These were attributed to an increase/decrease in the relative abundance of key microbes in the networks. Consequently, these findings revealed that the most of $CO_2$ in soils treated with organic amendments derived from recalcitrant components, which were decomposed by persistent DOM decomposers. This research highlights the significance of organic amendments responsive taxa in changes of DOM chemo-diversity and carbon loss.

# A repeat-pulse field labeling study to trace the fate of $^{13}C$ and $^{15}N$ labelled canola and durum crop residues in plant and soil organic matter on the Canadian Prairies

## ABSTRACT

Soil organic carbon (SOC) plays a central role in maintaining soil health and fertility in agroecosystems, and its stability significantly influences the sustainability of agricultural production. The persistence of SOC depends on a number of factors, chief among them being the plant biomass C and nitrogen (N) inputs that are then stabilized within the soil. Producers on the Canadian prairies are moving towards more diversified cropping systems, which can increase ecosystem services and affect overall crop residue C and N inputs to soil, thereby impacting SOC status. There is a knowledge gap regarding the fate of C and N from crop residues in SOC, particularly for canola and durum in diversified cropping systems. We addressed this gap using an *in-situ* stable isotope ($^{13}C$ and $^{15}N$) labeling technique to label both above-and below-ground of durum and canola and swap between control (unenriched crop) and enriched crop above-ground residues in intensified and diversified cropping systems under field conditions. The study, conducted over three years (2023–2025) at the AAFC Swift Current Research and Development Centre in SK investigated three rotations: (1) conventional rotation system (Durum-Fallow-Durum-Malt barley); (2) a pulse-intensified system (Durum-Lentil-Durum-Chickpea); and (3) a multiple-commodity diversified system (Canola-Pea-Durum-Lentil). Results showed that crop above-ground production differed significantly among rotations but was unaffected by the repeat pulse field labeling. The concentrations (atom%) of $^{13}C$ and $^{15}N$ in straw, grain and root of labelled durum and canola were significantly greater than those in control treatments without isotope labelling. The averaged $^{13}C$ in soils with enriched plant root inputs at 0-7.5 and 7.5-15 cm were significantly greater than those in control treatments without enriched plant root inputs at time 0, 6 and 18 months crop above-ground residues returning to soil. This demonstrates that root C inputs contribute more to SOC than above-ground biomass C inputs due to greater root C decomposition. The $^{13}C$ and $^{15}N$ repeat-pulse field labeling is a powerful tool to trace above-and below-ground plant C and N allocation and estimate root C and N inputs to soil, shedding light on the fate of photosynthesized C inputs in SOC, therefore accurately estimate C footprint of diversified cropping system.

# Soil Carbon Dynamics and the Observer Effect

**Ronald Amundson[1*], Maedeh Chitsaz[1], and Anna Abramova[1]**

*[1] Department of Environmental Science, Policy, and Management, University of California, Berkeley, CA, USA.*

**ABSTRACT**

To better predict soil C response to management and climate change, soil C scientists have striven to develop chemical and/or physical procedures to separate and quantity pools that cycle at largely differing rates. However, do these observational methods achieve the goal of probing the C dynamics of the *in situ* soil system? Here, soil is viewed as a complex, functioning, 3d system, with two domains of water and C flow that appear to function at differing rates, and which in turn control soil C response to perturbations. In contrast, all physical fractionation schemes are essentially post-mortem analyses of the soil system following an enormous observer-induced impact on the natural system, and these methods separate C fractions that are orthogonal to the natural functioning *in situ* system. The ever-growing databases of physical fractions and their chemistry reveal that they appear to identify the transformation of C from the plant to highly altered compounds, but that these physical fractions have only modest differences in their dynamics. A challenge for 21st century soil C science is to strategize ways of probing soil C dynamics of the *in situ* soil system while simultaneously reducing observer-induced artifacts to the resulting observations.

**ABSTRACT**

This study aims to assess the co-evolution of soil development and soil organic carbon (SOC) accumulation along a postglacial soil chronosequence in southeast Alaska. We hypothesize that in the early stages of soil development, a larger SOC pool is predominantly distributed in surficial soil horizons and gradually migrates to subsurface horizons. Seven moraines were dated using dendrochronology, yielding ages of 73, 82, 89, 128, 155, 207, and 247 years. SOC and pedogenic Fe oxyhydroxide values from mature Spodosols, sampled outside the chronosequence, were used as a References for the steady state of Spodosols in the region. From 73 to 128 years, soils were classified as Typic Cryorthents; by 155 years, as Spodic Dystrocryepts; and as Typic Haplocryods in the older moraines. A shift in SOC accumulation rates and depth distribution occurred once spodic properties developed. During the Entisol phase, most SOC stocks were concentrated in surficial horizons. After meeting spodic criteria, there was a shift toward subsurface mineral horizons, hosting over 50% of SOC stocks. This shift in SOC depth distribution was supported by a significant positive relationship between subsurface SOC stocks and age, but not with surficial SOC stocks. Similarly, surficial SOC accumulation rates were elevated during early pedogenesis (e.g., 0.26 Mg C $ha^{-1}$ $yr^{-1}$), while subsurface SOC accumulation was lower (0.05 Mg C $ha^{-1}$ $yr^{-1}$), increasing to 0.19 Mg C $ha^{-1}$ $yr^{-1}$ once spodic properties were met. A significant positive correlation between pedogenic Fe and age highlights the role of SOC in enhancing the weathering of Fe-bearing minerals. Our findings support the hypothesis that subsurface SOC stocks rapidly become dominant over time with Spodosol development. This study underscores the consequences of glacier retreat on a portion of the terrestrial ecosystem, with direct impacts on carbon and nutrient cycling.

## ABSTRACT

Changes of soil labile organic carbon (LOC) and soil organic carbon(SOC) sequestration plays an important role in regulating rice yield and terrestrial carbon cycling. The changes in soil fertility level may impact the accumulation characteristics of LOC fractions in paddy profiles. However, the characteristics of LOC change in paddy profiles under different soil fertility levels remain unclear. In the study, Ten soil samples were collected in coastal saline paddy profiles at 0-20, 20-30, 30-40 and 40-50 cm depths in Panjin, Liaoning Province, China, for high-fertility (more than 9 tons yield per hectare) and low-fertility (less than 6 tons yield per hectare) soil, respectively. This study compared the changes in SOC and LOC fractions across different soil fertility-levels and explored interrelationships of these soil factors. The results showed that the SOC and most LOC fractions content in both high and low fertility soils decreased significantly as soil depth increasing, with notable differences between the 0-20cm depths layer and other deeper layers, except for those of dissolved organic carbon(DOC). The easily oxidizable carbon (EOC) with high-fertility paddy was higher than that of low fertility paddy in each soil layer. The microbial biomass and carbon (MBC) content in high and low fertility paddy both dramatically reduced with the increase of layer depth ($p=0.001<0.05$), and there was no significant difference between 30-40 cm and 40-50 cm soil layers. The DOC content was not related to the changes of soil depth.

Correlation analysis indicated that SOC content exhibited highly significant positive correlations with EOC content in each layer and MBC content in the 0-20 cm layer ($P < 0.01$), but showed no correlation with DOC content because of its most active component in the LOC fractions (Huang W.Z., 1998).

In summary, The EOC and MBC in LOC fractions influences SOC storage through soil fertility levels, which in turn alters the distribution of SOC and LOC fractions at the soil layer scale. This study highlights the important role of soil fertility levels modifications in paddy carbon storage and cycling processes, providing valuable insights for coastal saline paddy restoration and management.

## ABSTRACT

Soil physical fractionation serves as a fundamental tool in characterizing the structure and stability of soil organic carbon pools. However, the absence of standardized critical parameters, particularly regarding flotation density and dispersion energy input, has significantly hindered cross-study comparability. To address this methodological gap, we systematically evaluated the separation efficiency of different combinations of flotation density (1.6 vs. 1.85 g $cm^{-3}$) and dispersion energy (100–500 J $mL^{-1}$) on forest, grassland, and wetland soils, respectively. By integrating a complementary long-term nitrogen (N) addition experiment, we independently validated the ecological relevance of the fractionation schemes. This effort aimed to establish a standardized protocol that is both universally applicable and ecologically meaningful. Our results revealed that the recovery of light particulate organic matter (LPOM) was primarily controlled by flotation density, whereas heavy particulate organic matter (HPOM) was highly sensitive to dispersion energy. The mineral-associated organic matter (MAOM) fraction was governed by both parameters. Importantly, the responses of all these fractions to parameter changes exhibited ecosystem dependence. Based on these findings, we propose optimized parameter sets tailored to different ecosystems. For instance, a combination of low density (1.6 g $cm^{-3}$) and low-to-medium dispersion energy (200–300 J $mL^{-1}$) is recommended for forest and grassland systems, while the optimal density for wetland systems requires selection based on the specific fractionation objectives. Further validation via the long-term N addition experiment demonstrated that this optimized scheme successfully captured predictable response patterns of each SOM fraction to N enrichment, confirming its strong ecological explanatory power. The standardized fractionation protocol established in this study offers a robust methodological framework for the accurate assessment and prediction of soil carbon cycling responses to global change across diverse ecosystems.

# Straw-Induced Carbon Dynamics in Saline Soils: Insights from $CO_2$ Emissions to Soil Organic Carbon Sequestration

**Cailing Shi[1*], Wenjun Xie[1], Yinglu Tao[1], Gaoqi Li[1], and Xiangrui Wang[1]**

[1] *School of Environmental and Municipal Engineering, Qingdao University of Technology, Qingdao, China.*

**ABSTRACT**

Straw application is an efficient strategy for reclaiming saline soils and enhancing soil organic carbon (SOC) sequestration. However, the influence of salinity on straw-derived carbon turnover remains unclear, thereby limiting our ability to accurately assess the carbon sequestration in saline agroecosystems. A soil incubation experiment was thus conducted using $^{13}C$-labeled maize straw. Four salinity levels were arranged: low salinity (LS, 3.0 g $kg^{-1}$), moderate salinity (MS, 5.0 g $kg^{-1}$), high salinity (HS, 10.0 g $kg^{-1}$), and severe salinity (SS, 15.0 g $kg^{-1}$). During soil incubation, straw-derived carbon mineralization to $CO_2$ and conversion into different SOC fractions: free particulate organic carbon (fPOC), occluded particulate organic carbon (oPOC), and mineral-associated organic carbon (MAOC) were investigated. Compared with the LS treatment, salinity significantly inhibited the cumulative $CO_2$ emissions and the amount of mineralized straw by 3.6%-26.8% and 2.7%-15.6% respectively. Meanwhile, the priming effect decreased by 3.4%-26.5% and its duration obviously increased. With increasing salinity, straw conversion into fPOC and MAOC fractions boosted by 21.7%-72.1% and 0.6%-29.5% compared to the LS treatment. The activities of soil dehydrogenase, cellulase, and β-glucosidase were significantly inhibited under high salinity conditions. Correlation analysis and structural equation modeling confirmed the decrease in straw conversion into SOC pools was mainly ascribed to enzymatic activity reduction (path coefficient = -0.844, $P<0.01$). In a word, soil salinization significantly inhibited straw mineralization and conversion into oPOC and MAOC fraction, while increased straw conversion into fPOC fraction. The findings provide insights into SOC dynamics under different saline conditions, which could help us assess carbon sequestration potential and improve saline soil ameliorating efficiency through straw application.

# Organic materials combined with microbial inoculants suppress priming effect and enhance SOC sequestration in sandy soil

**Xiaohong Tian[1*], Xiangtian Meng[1], Binbin Cao[1], Yapeng Jiao[1], Yunuo Li[1]**

[1] *(College of Natural Resources and Environment, Northwest A&F University, Yangling, Shaanxi, China)*

*Xiaohong Tian, Email: txhong@nwafu.edu.cn

**ABSTRACT**

Soil organic carbon (SOC) sequestration plays a vital role in enhancing soil fertility and mitigating climate change. The application of organic materials, particularly straw return, has been a widespread practice to enhance SOC stocks. However, the sequestration potential of straw carbon remains suboptimal. It is generally agreed that microbial inoculants application is capable to facilitate decomposition of organic materials and soil nutrient release, yet the mechanisms by which the co-application of microbial inoculants and organic materials enhance SOC sequestration, especially in coarse-textured soils, remain inadequately understood.

We conducted a 90-day incubation experiment employing $^{13}$C-labelled maize straw and microbial inoculants in two contrasting soils: a fine-textured clay loam and a coarse-textured sandy soil.

Our results indicate that the co-application of microbial inoculants and straw significantly enhanced SOC sequestration. Specifically:

1. Compared to straw addition alone, microbial inoculants accelerated straw mineralization and suppressed PE by 8.98% in clay loam and 43.98% in sandy soil. This PE suppression was driven by alleviated microbial nutrient limitation and shifted the microbial community (lower $^{13}$C incorporation into the PLFAs of gram-positive bacteria vs. gram-negative bacteria). Microbial inoculants combined with straw further increased net SOC gain (clay loam soil: +6.7%, sandy soil: +619%) relative to straw alone. The superior SOC gain in sandy soil was attributed to its heightened responsiveness to microbial inoculants, leading to a greater increase in microbial carbon use efficiency (CUE) and $^{13}$C incorporation into phospholipid fatty acids ($^{13}$C-PLFA).

2. The combination of microbial inoculants and straw significantly increased SOC content in two soils. Specifically, compared with straw addition alone, straw combined with microbial inoculants boosted microbial necromass carbon (MNC) accumulation by 12.6% in clay loam and 28.6% in sandy soil, respectively. Although the contribution of MNC to SOC in sandy soil was lower than that in clay loam soil, the contribution of plant-derived C to SOC in sandy soil reached 40% (compared to less than 23% in clay loam soil). This suggested that in soils with lower clay content, plant-derived C is more readily preserved, whereas the MNC accumulation is comparatively less efficient. Additionally, the pathways of SOC stabilization were soil texture-dependent: in the clay loam soil, the increased MNC was strongly associated with mineral-associated organic carbon (MAOC) formation, while in the sandy soil, it was primarily stabilized within particulate organic carbon (POC) due to the scarcity of reactive mineral surfaces.

This study revealed that microbial inoculants with organic materials optimize SOC sequestration by suppressing PE and promoting MNC, but long-term SOC stabilization is contingent on soil texture. Overall, our findings offer critical insights and practical approaches for sustainable agricultural management of sandy soils.

# Reframing Manure Amendments and Nitrogen Inputs as Co-Determinants of Persistent Soil Organic Carbon in Semi-Arid Agroecosystems

**Xiaohong Tian[1*], Xiangtian Meng[1], Yapeng Jiao[1], Binbin Cao[1], Yunuo Li[1], and Rui Yin[1]**

[1] *(College of Natural Resources and Environment, Northwest A&F University, Yangling, Shaanxi, China)*

**ABSTRACT**

Achieving durable stabilization of soil organic carbon (SOC) remains a major challenge in dryland agroecosystems where substrate inputs, nutrient stoichiometry, and mineral–microbial interactions jointly constrain carbon persistence. Using a 20-year manure and nitrogen (N) fertilization experiment on the semi-humid Loess Plateau, integrated with microbial trait measurements, necromass biomarkers, lignin phenol profiling, extracellular enzyme stoichiometry, and aggregate–mineral fractionation, we establish a unified framework describing how multiple controls shape persistent SOC pools.

We first demonstrate that manure inputs, despite increasing total SOC, can lower SOC stability. High-C/N manure imposed chronic microbial N limitation, promoted resource-acquisition strategies, stimulated N-acquiring enzymes, and reduced microbial carbon use efficiency. These responses accelerated the decomposition of both labile substrates and microbial-derived compounds, weakened necromass stabilization, and diminished mineral-associated organic carbon (MAOC) formation.

Manure–N co-application fundamentally altered these pathways. Moderate N rates alleviated N limitation, suppressed N-degrading enzymes, improved microbial metabolic efficiency, and favored growth-yield strategies. Enhanced biomass turnover increased necromass production and promoted its incorporation into MAOC, and strengthened mineral-associated protection through elevated Fe/Al oxides and exchangeable Ca.

The optimal stabilization occurred under moderate manure with moderate N input, whereas high N addition diminished stability under high manure supply, highlighting a nonlinear nutrient–carbon interaction previously overlooked in SOC stabilization frameworks.

Aggregate-mediated protection displayed a threshold response. Combined manure and N inputs increased microaggregate formation and mineral–organic associations via elevated extracellular polymeric substances and glomalin-related proteins, whereas excessive N reduced these binding agents and decoupled physical structure from carbon protection. Machine-learning results indicated that chemical protection exerted the strongest direct influence on SOC stability, with microbial efficiency and physical protection acting as synergistic regulators.

Overall, this work integrates nutrient stoichiometry, microbial strategies, necromass dynamics, and mineral–aggregate interactions into a coherent explanation of SOC persistence. The findings refine current understanding of manure and N management and support strategies aimed at enhancing long-term carbon retention under climate-smart agriculture.

## ABSTRACT

Since large-scale agricultural reclamation, the quantity and quality of soil organic matter (SOM) in Mollisols have dramatically declined, leading to reduced stability. The application of organic amendments promotes soil aggregate formation and enhances carbon sequestration potential. However, how the molecular characterizations of SOM respond to organic material application across different years remains unclear. This research investigated farmland Mollisols subjected to different organic amendment practices (organic manure and straw return), analyzing the molecular structure, composition, and sources of SOM in topsoil (0-20 cm) using nuclear magnetic resonance (NMR), molecular mixing models, Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS), and biomarker techniques.

Results indicated that, for SOM in bulk soils, compared to chemical fertilizer application, short-term (6 years) straw return significantly reduced the SOM degradation degree by 14.7%, attributable to a 70.7% decrease in char and a 12.9% increase in carbohydrates. Relative to initial year, long-term (12 years) organic manure application significantly reduced soil hydrophobicity by 5.8% through accumulating lignin (+7.3%) and depleting carbohydrates (-7.8%). In contrast, straw return significantly and persistently reduced the soil lipidization degree by 13.5%-15.3% through increasing char and carbohydrates (by 39.5-187.7%) and decreasing lignin (by 12.4-13.6%).

For soil dissolved organic matter (DOM), compared to chemical fertilizer application, short-term organic manure application significantly reduced the DOM degradation degree by 10.2%, associated with a 22.8% decrease in lipid-like compounds. In contrast, long-term straw return significantly increased the DOM degradation degree by 17.1%, due to substantial increases in lipid-, carbohydrate-like compounds, and unsaturated hydrocarbon content (+1.1-3.4 fold) and a 41.3% decrease in lignin-like compounds. Relative to the initial year, organic manure led to the depletion of protein-like compounds and unsaturated hydrocarbons, whereas straw return resulted in dramatic enrichment of lipid-, protein-like compounds, and unsaturated hydrocarbons, alongside sharp decreases in lignin- and tannin-like compounds.

Regarding organic matter sources, compared to chemical fertilizer application, organic manure application consistently increased the content of three lignin phenol monomers and total lignin phenols (by 70.2-532.5%), significantly elevating their proportion in SOM (by 59.4-76.6%). Simultaneously, it markedly altered the composition of microbially derived carbon: short-term application reduced the content of microbial residue carbon such as amino sugars, while long-term application increased the fungal-to-bacterial residue carbon ratio by 40.7% and consistently decreased the proportion of amino sugars. In contrast, straw return primarily influenced organic matter sources by altering lignin phenol monomer ratios and reducing the acid-to-aldehyde ratio of vanillyl phenols by 11.5%, while consistently decreasing the content of muramic acid and galactosamine by 20.2-31.8%.

In conclusion, this study demonstrates that long-term organic fertilization drives the molecular composition of SOM from "microbial-derived dominant" to "plant-derived dominant." Organic manure tends to accumulate recalcitrant plant-derived components and shifts the microbial community toward a fungal-dominated pathway, favoring long-term SOM stability. Conversely, straw return strongly stimulates a bacterial-dominated microbial cycle, enhancing DOM activity and accelerating the chemical transformation of SOM. These findings provide important theoretical insights into the microscopic mechanisms governing soil carbon sequestration and turnover under different organic management strategies.

## ABSTRACT

Soil C sequestration is determined by the balance between microbial mineralization and stabilization of exogenous organic matter (OM) inputs. We investigated the factors regulating the mineralization and stabilization of residue-derived C in OM fractions across soils differing in native organic matter content and mineralogical properties.

We used topsoil (0–15 cm) and subsoil (20–40 cm) from 8 sites along an elevation gradient of the Sierra Nevada in California. The soils, developed on andesitic lahar deposits, exhibited a wide range of soil organic C (SOC) (11–116 g C $kg^{-1}$) and oxalate-extractable Al/Fe ($Al_o$ + $Fe_o$) (10–127 cmol $kg^{-1}$). The soils were incubated with $^{13}C$-labeled plant material (8.4 mg per 20 g soil, equivalent to about 1 Mg OM $ha^{-1}$) at 25°C for 343 days. We measured the amounts of C and the $^{13}C$ ratio in $CO_2$ released during incubation, and in OM fractions (particulate OM, POM; mineral-associated OM, MAOM) and whole soil on days 28, 175, and 343. Spearman partial correlation analysis was used to test the effects of soil properties on the mineralization of added plant material and its stabilization in OM fractions.

The added plant material was predominantly mineralized within the first 28 days, accounting for more than 50% of the total mineralization. During this initial phase, SOC was positively correlated with plant-derived C in POM ($r$ = 0.75**) after controlling for $Al_o$ + $Fe_o$. $Al_o$ + $Fe_o$ generally showed negative correlations with the decomposition of the added plant material and positive correlations with remaining plant-derived C. Specifically, controlling for SOC, $Al_o$ + $Fe_o$ was negatively correlated with the mineralized plant material on days 28 ($r$ = –0.79***), 175 ($r$ = –0.66**), and 343 ($r$ = –0.71**), and positively correlated with the remaining plant-derived C in whole soil ($r$ = 0.78***). Furthermore, $Al_o$ + $Fe_o$ correlated positively with plant-derived C in MAOM on days 175 ($r$ = 0.70**) and 343 ($r$ = 0.53*) and with plant-derived C in POM on day 343 ($r$ = 0.58*) after controlling for SOC. In contrast, SOC showed positive correlations with mineralization and negative correlations with stabilization. Controlling for $Al_o$ + $Fe_o$, SOC was positively correlated with the mineralized plant material on days 28 ($r$ = 0.62*), 175 ($r$ = 0.74**), and 343 ($r$ = 0.79***) and negatively correlated with the remaining plant-derived C in whole soil ($r$ = –0.55*). SOC also showed negative correlations with plant-derived C in MAOM on days 175 ($r$ = –0.81***) and 343 ($r$ = –0.69**) after controlling for $Al_o$ + $Fe_o$.

In summary, at the early stage of incubation (around one month), soils with high SOC-accumulated exogenous OM in POM, which was subsequently decomposed. Our long-term incubation demonstrated that high SOC limited the incorporation of exogenous OM into MAOM and enhanced its mineralization. Conversely, $Al_o$ + $Fe_o$ suppressed the mineralization of exogenous OM and promoted its stabilization within both MAOM and POM.

**ABSTRACT**

Effective carbon sequestration strategies are pivotal in mitigating climate change, while current approaches often overlook the critical role of soil minerals-the backbone of soils, in stabilizing organic carbon. Our study introduces a comprehensive framework to quantify the soil "Mineral Carbon Pump" (MnCP) [1], a previously unquantified mechanism by which soil minerals facilitate organic carbon stabilization. We first utilized data from 152 standardized pairs of soil organic carbon (SOC) and mineral-associated organic carbon (MAOC) collected from 15 globally distributed sites. These sites encompass diverse soil chronosequences, depth profiles, and land management practices. This was complemented by an analysis of 2,708 MAOC measurements across zones grouped by high or low mineral reactivity. Our findings demonstrate that the MnCP contributes between 19% and 230% to SOC sequestration. Soils with high-reactivity minerals exhibit a carbon sequestration potential of 70~85 g C $kg^{-1}$ soil, which is more than 1.6 times that of soils with low-reactivity minerals. This enhanced potential is equivalent to approximately 32~48 times the carbon dioxide emissions from anthropogenic activities in 2023. This study provides novel mechanistic understanding of the role of minerals in the soil carbon sink and has implications for the development of mineral-informed strategies for enhancing soil carbon sequestration.

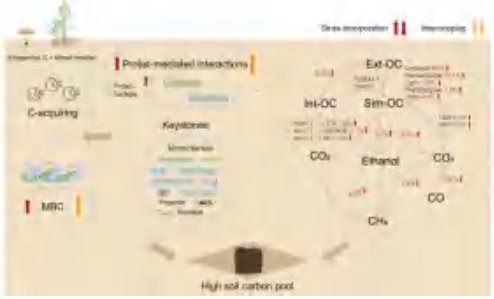
**ABSTRACT**



*Background and aims* The soil carbon pool, being the largest and most active carbon pool in terrestrial ecosystems, stores approximately 2000 Pg of carbon in the form of soil organic carbon (SOC). The sequestration of soil organic carbon is recognized as a powerful tool to mitigate climate warming, improve the quality of cultivated land soil, and achieve food security. Intercropping has been shown to significantly increase SOC content; however, the SOC sequestration process in such systems is often slow. Integrating straw incorporation offers a synergistic approach to enhance SOC more effectively by increasing exogenous carbon inputs. Yet, the underlying mechanisms by which intercropping combined with straw incorporation promotes SOC, particularly through microbial and micro-food web pathways, remain inadequately understood.

*Methods* Based on a long-term field experiment initiated in 2012 in Zhangye City, Gansu Province, we conducted a two-factor randomized block design with four replicates. The main-plot factors were different management practices, including nitrogen and phosphorus fertilizer application alone (NP), nitrogen and phosphorus fertilizer combined with straw incorporation (NP+ST). The sub-plot factors were different cropping systems, including pea monoculture, maize monoculture, and pea/maize intercropping. Bulk soil samples were collected during the bloom stage of peas. We integrated soil carbon-related indicators, amplicon and metagenomic sequencing data to explore how intercropping combined with straw incorporation enhances soil carbon sequestration by regulating soil food web and its functions.

*Results* Compared with monoculture, intercropping significantly increased SOC and soil mineral-associated organic carbon (MAOC) contents by 3.7% and 4.8%, respectively. Relative to the NP treatment, NP+ST significantly increased SOC and MAOC contents by 18.6% and 19.5%, respectively, and also enhanced soil particulate organic carbon (POC) and dissolved organic carbon (DOC) contents. Intercropping significantly increased soil microbial carbon (MBC) content and C-acquiring enzyme activity under NP+ST but not under NP treatment; enzyme activity was positively correlated with MBC content. Furthermore, random forest modeling identified MAOC and MBC as key predictors of SOC content.

Network analysis showed that intercropping enhanced cross-trophic interactions compared with monoculture. Under NP+ST treatment, intercropping significantly increased protist-mediated interactions and exhibited a greater number of keystones. These keystones were significantly positively correlated with soil carbon, Cercozoa and Ciliophora played dominant roles. Additionally, NP+ST increased the abundance of carbon fixation modules compared with NP treatment. Under NP+ST treatment, intercropping enriched more carbon fixation genes, among which *KorA*, *accC*, and *accD* were significantly positively correlated with soil carbon. Straw incorporation also significantly increased the abundance of plant-derived carbon degradation genes (cellulose and hemicellulose). Under NP+ST treatment, intercropping enriched hemicellulose degradation gene was significantly positively correlated with soil carbon. The abundance of key genes were significantly positively correlated with keystones.

*Conclusion* Straw incorporation can stimulate the intercropping effect and improve soil carbon sequestration by modulating potential keystones with carbon fixation and plant-derived carbon degradation functions. Our study provides theoretical support for enhancing the soil carbon pool by intercropping integrated with suitable conservation tillage practices.

## ABSTRACT

Intensive agriculture has led to substantial phosphorus (P) accumulation in Flemish (Belgium) cropland soils, yet its impact on soil organic carbon (SOC) storage remains uncertain. We hypothesize that excess P reduces SOC storage through diminished rhizodeposition, enhanced mineralization and competition between phosphate and organic anions for mineral-binding sites.

To evaluate this hypothesis, the influence of the degree of phosphate saturation (DPS) on C-stability and long-term SOC storage was assessed after approximately 30 years. The study focused on sandy, acidic agricultural soils in Flanders, where pedogenic Fe and Al (oxy)(hydr)oxides are the main sorbents for SOC and orthophosphate. A historical dataset of over 3,000 Flemish sandy agricultural soils, sampled in the 1990s, served as the basis for this study. A total of 83 fields were selected to represent a DPS gradient while maintaining comparable pH, clay content and sorption capacity. Cropping history of these fields included maize for at least 16 years. The soils on the selected fields were resampled at 0-30, 30-60 and 60-90 cm. The DPS for the resampled soils was determined using ammonium-oxalate extractions[1]. Subsequently, C-content and $\delta^{13}C$ values were measured via EA-IRMS for both the resampled and historical soils, allowing the estimation of 'new' maize-derived C using a $^{13}C$ mass balance[2]. Maize-derived C conversion efficiency (Maize-C CE) was defined as the proportion of maize-derived carbon retained in soil relative to the total estimated maize-C input over the study period.

Average Maize-C CE values over the past 30 years were 9.09 ± 6.15%, 31.58 ± 24.45% and 11.57 ± 12 % for the 0–30, 30–60 and 60–90 cm layers, respectively, and were not significantly affected by DPS. Given the large variability, we will investigate whether other parameters better predict the Maize-C CE. To further investigate SOC-P competition for mineral-binding sites, analyses are ongoing on A-horizon soils. Particle-size fractionation isolates the mineral-associated organic matter (MAOM) fraction to assess the relationship between DPS and C storage within this pool. Hydroxylamine extractions quantify C bound to Fe and Al (oxy)(hydr)oxides, providing insight into SOC-P interactions at elevated DPS. Furthermore, incubation experiments will be performed to assess the stability of maize-derived C, while batch-sorption experiments will test whether DPS influences the sorption capacity for different organic molecules.

**ABSTRACT**

Climate change significantly affects soil organic carbon (SOC) stock and vulnerability, as well as microbial biodiversity, across different agro-ecosystems including vineyards. Due to the wide cultivation of wine grapes, the wine sector is now called upon to reconcile environmental protection, competitiveness, and resilience to global warming. The SUSTAIN project aims at determining the potential of vineyards, characterized by different pedoclimatic conditions and cultivars, on SOC accumulation in the context of climate change scenarios. A randomized block design, consisting of 3 blocks composed of 8 plots each, and 2 factors, i.e., land management practice (amendment with digestate, cover crop, bare soil) and climate manipulation (ambient temperature, warming), was set up in three study areas within the Veneto region (North of Italy). Open top chambers (OTC) were used to obtain a temperature increase of ~2 °C (SSP2-4.5). Soil samples have been collected at four times (after 0, 6, 12, and 18 months from the OTC placement) and at 3 depths (0-15, 15-30, and 30-45 cm) and characterized from the physical, chemical and microbiological point of view. From each sample, particulate and mineral-associated organic matter (POM and MAOM, respectively) were isolated and characterized by elemental and thermal analysis. DNA was extracted from topsoils, and metagenomic analyses and enzymatic assay were carried out.

The preliminary results indicated no significant differences in SOC stocks following short-term warming. On the opposite, a general and slight increase in SOC concentration already occurred after 6 months in plots with cover crops, where POM played a greater role in SOC accrual. Thermal analysis, which was used to evaluate SOC stability, underlined that, regardless of vineyard and agronomic management, POM is the more labile fraction, while MAOM showed an increase of stability with depth. On the other hand, no significant differences were observed among treatments and climate manipulations.

It is expected that results obtained at the end of experiment will help to better understand the SOC and microbial dynamics in vineyards as a function of future climate change scenarios. In addition, Life Cycle Assessment (ISO14040), which integrates experimental data and company inventories, will estimate the carbon footprint of the vineyards management. Ultimately, these outcomes will enable the identification of soil-management strategies that strengthen long-term carbon storage while substantially reducing the environmental impact of viticulture.

**ABSTRACT**

Soils mineral-associated organic carbon (MAOC) constitutes over 50% of total soil organic carbon (SOC) and serves as a key determinant of its long-term stabilization. Although soil pH is recognized as a "master variable" in biogeochemical cycles, it remains unclear how soil pH influent MAOC and SOC stabilization at large spatial scales. To address this knowledge gap, we conducted a continental-scale survey in China and synthesized global observations from literature, totaling 1300 independent observations. By analyzing the relationships between SOC and MAOC across a pH gradient, along with the contributions of other environmental factors to MAOC variability, we found that while higher SOC content generally correlates positively with higher MAOC, this relationship is shaped by soil mineralogy, texture, and climatic conditions. Specifically, we identified two stabilization pathways governed by pH: in acidic soils (pH $\leq$ 5.5), Fe/Al (hydr)oxides explain most of the variation in MAOC content and MAOC/SOC ratio. Net primary productivity (NPP) and belowground NPP (BNPP) augment the particulate organic carbon (POC) pool, thereby diluting the MAOC fraction. In neutral-to-alkaline soils (pH > 6.5), however, clay content and mean annual temperature emerge as the primary regulators. This divergence challenges the universal applicability of clay-centric SOC models. Our findings provide a refinement information for biogeochemical models, urging the integration of pH-dependent metal oxide dynamics to improve predictions of SOC persistence under diverse future scenarios.

## ABSTRACT

Rational bio-organic fertilizer combination with chemical fertilizer has important advantages in enhancing chemical fertilizer use efficiency, inhibiting soil pathogen, improving soil fertility and crop yield and quality, is considered a key practice for improving soil health and crop green production. To investigate the effects of long-term chemical fertilizer reduction combined with bio-organic fertilizer on soil organic carbon fractions and soil aggregate stability in tobacco planting soil, a 12-year continuous field positioning experiment was conducted with five treatments: no fertilization control (CK), local conventional recommended fertilization (CF), 20% chemical fertilizer reduction (CR), 20% chemical fertilizer reduction combined with organic fertilizer (OF), and 20% chemical fertilizer reduction combined with bio-organic fertilizer (BOF). Soil samples were collected from the 0–20 cm layer to determine the contents of soil total organic carbon (SOC), dissolved organic carbon (DOC), labile organic carbon (LOC), and microbial biomass carbon (MBC).The soil organic carbon stock and sequestration, carbon pool management index (CPMI), and carbon pool sensitivity index (CSI) were analyzed The wet sieving method was employed to determine soil aggregate distribution, and the mean weight diameter (MWD), geometric mean diameter (GMD), fractal dimension (D), and R0.25 were calculated to characterize aggregate stability. The results showed that, compared with the local conventional recommended chemical fertilizer application (CF), 20% chemical fertilizer reduction combined with organic fertilizer (OF) and bio-organic fertilizer (BOF) increased the contents of SOC and all organic carbon fractions and sequestration . The BOF showed the most significant effects, with SOC, DOC, LOC, and MBC contents increased by 16.8%, 49.6%, 84.3%, and 53.4%, respectively, compared to the CF. Compared to the CF, the BOF increased the soil organic carbon stock and carbon sequestration amount by 32.2% and 55.7%, respectively. The CPMI increased by 86%, while the CSI was decreased by 10.3%. The BOF significantly increased the content of water-stable aggregates larger than 0.25 mm, with a 20% increase compared to the CF. The aggregate MWD, GMD, and R0.25 of the BOF were significantly higher than that of the CF by 26.1%, 11.1%, and 20.52%, respectively, while the fractal dimension (D) decreased by 2.5%. Correlation analysis revealed that, MWD, GMD, R0.25, and the content of water-stable aggregates were significantly positively correlated with the contents of DOC, LOC, and MBC, whereas the fractal dimension (D) was significantly negatively correlated with these indicators. In conclusion, long-term 20% chemical fertilizer reduction combined with bio-organic fertilizer can significantly increase the contents of various soil organic carbon fractions, effectively promote the formation of large soil aggregates, substantially enhance the water stability of soil aggregates, thereby synergistically enhance the soil carbon sequestration and improve the soil structural quality of tobacco-planting soil.

**ABSTRACT**

Soil organic matter (SOM) represents the largest carbon (C) pool in terrestrial ecosystems, and mineral-associated organic matter (MAOM) is a key fraction that governs long-term C storage. Soil acidity, arising from both natural and anthropogenic processes, acts as a major regulator of SOM dynamics by altering microbial activity and organo-mineral interactions. Conventionally, high soil acidity has been thought to suppress litter decomposition, leading to the accumulation of less decomposed organic matter. However, our previous studies revealed that both particulate organic matter (POM) and MAOM exhibit higher degrees of decomposition in soils with low acid buffering capacity (low-ABC, pH < 5) than in soils with high-ABC (pH > 5) in plantations of two dominantly planted coniferous species in Japan, *Cryptomeria japonica* and *Chamaecyparis obtusa*. The low-ABC soils showed enhanced degradation of aromatic compounds during the transformation from POM to MAOM in soils of 0–10 cm depth at *C. japonica* stands and microbially metabolized MAOM with low stocks throughout the soil profile (0–40 cm depth) at *C. obtusa* stands. These findings suggest either high activity of specific microbes such as lignin-degrading fungi or long exposure to microbial decomposition in acidic soils. The latter may be attributed to the low efficiency of organic matter stabilization by soil minerals under acidic conditions, but the status of the organo-mineral association remains poorly investigated in the fields with different soil acidity. Thus, we aimed to clarify how soil acidity affects the stabilization of MAOM, as inferred from the ratios of C to extractable Al and Fe.

We collected soil samples from three depths (0–10, 10–20, and 20–40 cm) at 11 stands of *C. japonica* (7 stands for low-ABC soils and 6 stands for high-ABC soils) and 7 stands of *C. obtusa* (4 stands for low-ABC soils and 3 stands for high-ABC soils) in temperate central Japan. A total of 54 bulk soil samples were separated into three density fractions: a light fraction (LF, <1.8 g $cm^{-3}$) dominated by POM, a middle fraction (MF, 1.8–2.4 g $cm^{-3}$) rich in MAOM, and a heavy fraction (HF, >2.4 g $cm^{-3}$) primarily composed of minerals with minimal organic matter. For the MF and HF, Al and Fe associated with organic matter were sequentially extracted using pyrophosphate (PP, mainly organo-metal complexes), acid oxalate (OX, mainly short-range-order minerals), and dithionite-citrate (DC, mainly crystalline iron oxides) solutions. These reactive metal phases are known to exert strong control on SOM stability in acidic soils. Concentrations of the extractable Al, Fe, and co-dissolved C and N were determined to examine the mode and degree of organo-mineral associations as affected by soil acidity, depth, and tree species. We will report the results of these analyses to discuss how soil acidity controls the balance between organic matter decomposition and stabilization.

## ABSTRACT

The phaeozem in Northeast China contain a large amount of soil organic carbon (SOC), but there is an long-term excessive use of chemical fertilizers, which in turn causes soil acidification. The relationship between soil acidification and SOC stability remains unclear. This study, based on a 16-year field experiment with five degrees of soil acidification (6.54 to 5.32) induced by nitrogen fertilizer rates, analyzes changes in the stability mechanism of SOC using aggregate grading and $^{13}C$ NMR spectroscopy. Results demonstrated acidification-induced reductions in macroaggregates (>2 mm) by 4.8-14.6% and increases in aggregate instability indices (PAD, $E_{LT}$) by 9.7-13.4%. Mean weight diameter (MWD) and geometric mean diameter (GMD) exhibited significant declines ($p < 0.05$) with decreasing pH. According to the $^{13}C$ NMR analysis, the SOC was predominantly composed of O-alkyl carbon and aromatic carbon. At pH 5.32, the Alip/Arom values decreased, and the molecular structure of SOC became more complex under different levels of acidification. In addition, the increase of [Fe(Al)-OC] (31.4-71.9%) complex indicates a shift in the stability of organic carbon from physical protection to organic mineral binding. Overall, soil acidification resulted in the decline of soil aggregate stability and the increase in SOC aromaticity. This droves the shift of the stabilization mechanism of SOC in the black soil ecosystem of Northeast meadows from physical protection to chemical stability.

**ABSTRACT**

Soil organic carbon (SOC) is a fundamental component of the global carbon cycle, acting as both a major carbon sink and a key determinant of soil health. Thus, it is crucial to understand how carbon storage in soils is controlled. Recent studies have suggested that long-term SOC persistence is primarily regulated by microbial accessibility rather than intrinsic chemical recalcitrance of different compound classes [1]. However, the physico-chemical mechanisms protecting various SOC compounds [2,3] and the limits of soil stabilisation capacity remain unclear. If such limits exist, they will constrain the potential of land management to increase SOC storage. Moreover, the current key SOC models, such as Rothamsted C model (RothC), do not incorporate these limits.

This study combines physical fractionation methods separating soil aggregates and mineral-protected pools, with advanced compound-specific radiocarbon analysis (CSRA) to directly determine the residence time of different SOC compound classes with varying polarities and sizes. By utilising well-controlled modern and historical soils from Long-Term Experiments at Rothamsted Research (RRes), we aim to understand how different SOC compounds are stabilized, assess whether soils have a maximum capacity for carbon storage and if these limits are influenced by soil properties or management practices. Based on these new understandings, we aim to refine the RothC model to improve predictions of SOC sequestration, which will enhance land management strategies for long-term carbon storage.

**ABSTRACT**

Understanding the factors controlling the temperature sensitivity ($Q_{10}$) of soil organic carbon (SOC) decomposition is critical in the context of global warming. This study examines how elevation-driven variations in climate, mineral phases, and organic matter composition regulate $Q_{10}$.

Topsoil and subsoil samples were collected from 8 sites across an elevation gradient (200–2800 m) in the Sierra Nevada. The soils developed from andesitic lahar deposits under mean annual temperature and precipitation of 2.9–16.6°C and 670–1330 mm, respectively. SOC respiration was measured during laboratory incubations with moisture maintained at 55% water holding capacity at 25°C, 17.5°C, and 10°C. The decomposition curves of SOC were generated by fitting the respiration data to a kinetic model. $Q_{10}$ values were calculated for the cumulative decomposition over the entire incubation period, as well as for the decomposition rates on days 7, 28, and 343. Soil properties, including active Al/Fe (oxalate-extractable Al/Fe), were determined. The chemical composition of organic matter was evaluated using pyrolysis-GC/MS.

SOC and active Al/Fe ranged 20–114 and 3–35 g $kg^{-1}$ in topsoil and 14–71 and 3–31 g $kg^{-1}$ in subsoil, respectively, both peaking at mid-elevations (1600–2300 m). In the topsoil, $Q_{10}$ showed no evident correlation with active Al/Fe during the early incubation stage but developed a strong positive association in the later stage, whereas the subsoil exhibited a consistently strong correlation between $Q_{10}$ and active Al/Fe throughout the entire incubation period. These contrasting patterns indicate that mineral-organic associations in the subsoil exert a stronger influence on $Q_{10}$. Accordingly, the tighter organo-mineral binding in subsoil is likely a major driver of the higher temperature sensitivity. Despite these clear links to active Al/Fe, $Q_{10}$ showed no direct relationships with climate variables, pH, physical properties, or the chemical composition of organic matter. Collectively, these patterns suggest that organo-Al/Fe interactions enhance the temperature sensitivity of SOC decomposition by stabilizing the SOC pool and mediating more complex, high-activation-energy reactions.

**ABSTRACT**

Polyphenols represent an important component of soil organic matter (SOM) that widely originates from plants. Birnessite, a ubiquitous manganese (Mn) oxide, effectively facilitates the oxidative decomposition and polymerization of polyphenols. However, the impact of pH and molecular structure of polyphenols on such processes, as well as the characterization of the degradation products, has not been fully elucidated. Therefore, we performed batch sorption experiments under environmentally relevant pH conditions to investigate the interactions between birnessite and two polyphenol isomers: catechol and hydroquinone. Results revealed that catechol was more effective in reducing Mn and dissolving Mn-oxide than hydroquinone, particularly under lower pH conditions. Correspondingly, a greater amount of carbon was lost from the aqueous system due to sorption and/or oxidative decomposition during catechol reactions than hydroquinone. Spectral data support the concomitant formation of polymers and aliphatic degradation products for both compounds studied. Two-dimensional nuclear magnetic resonance (NMR) and ultra high-performance liquid chromatography-high-resolution accurate mass (UHPLC-HRAM) spectrometry analysis provided direct molecular-scale evidence of pH-dependent reaction pathways. Overall, lower pH conditions increased the degree of oxidation and proportion of low-molecular-weight species formed. The ortho positioning of hydroxyl groups in catechol facilitated more effective complexation and electron transfer to birnessite than the para configuration of hydroxyls in hydroquinone. While alkaline pH (7–8) favored oxidative coupling and polymerization, forming high-molecular-weight oligomers. This study provides valuable insights into the fundamental, pH-controlled pathways of organo-mineral associations involving Mn-oxides and their role in (de)stabilizing SOM.

## ABSTRACT

Mitigating climate change requires soil-based C removal strategies that do not depend on ever-increasing N inputs and their associated non-$CO_2$ emissions from fertilizer use. Biochar and Fe minerals are emerging as important levers for durable soil C storage because both can stabilize organic matter via organo–mineral associations and aggregate protection rather than through N-driven biomass accumulation. Although individual mechanisms of Fe- and biochar-mediated C stabilization are increasingly well understood, limited knowledge exists regarding their combined effects, especially with engineered Fe-modified biochars. Biochar may act as an electron shuttle that modulates Fe redox cycling and promotes the formation of Fe-bound organic C domains in amended soils. Conversely, Fe (hydr)oxides can precipitate on or around biochar particles and bridge them with fresh organic inputs, co-stabilizing biochar-derived and plant-derived C within Fe–C microdomains and soil aggregates.

In a 21-day incubation using an alkaline, sodic soil (pH 8), soil respiration was measured following amendment with goethite, an engineered Fe-enriched char (wheat straw, 500 °C, 120,000 mg/kg Fe), and its non-Fe enriched pair. Fe-enriched char was applied at 2% w/w; unmodified biochar and goethite were applied at rates matching the C and Fe supplied by Fe-enriched char (0.382% and 1.33% w/w, respectively). Four $^{13}C$-labelled model root exudates (glucose, oxalic acid, L-leucine, and salicylic acid) were added at 130 mg C per kg soil across four replicate microcosms per treatment. C stabilization was assessed by combining cumulative $CO_2$–C fluxes with $^{13}C$ source partitioning to quantify the proportion of amendment-derived versus exudate-derived C remaining in soil.

We revealed that Fe-enriched char best stabilized three of the four substrates (glucose, oxalic acid, and L-leucine), reducing cumulative $^{13}C$–$CO_2$ loss by approximately 6–57% relative to non-Fe enriched biochar. This broad response indicates that Fe-bearing phases on biochar surfaces provide sorptive and redox-active domains capable of protecting labile carbohydrates, low-molecular-weight organic acids, and simple N-containing compounds from rapid mineralization. In contrast, the structurally complex phenolic compound salicylic acid was most effectively stabilized by goethite, which reduced $^{13}C$–salicylic acid mineralization by approximately 48% relative to Fe-enriched char. This highlights a specific role for crystalline Fe oxides in binding and protecting aromatic molecules. Together, these patterns point to complementary mechanisms: Fe-modified biochar preferentially stabilizes a wide range of labile exudate C via Fe–organic complexes and electron-shuttling effects on Fe redox cycling, while discrete Fe minerals such as goethite are particularly important for protection of phenolic C within Fe–C microdomains and aggregates.

To further elucidate mechanisms of C stabilization under future climate scenarios, a steady-state [15 atom %] $^{13}C$-$CO_2$ growth chamber trial was undertaken to evaluate biochar and Fe-mediated stabilization (using the same amendments as the incubation study) in unplanted and wheat-planted systems under ambient (450 ppm), elevated (675 ppm), and extreme (900 ppm) $CO_2$ scenarios. In the unplanted system, autotropic $CO_2$ capture was quantified, while the planted system traced stabilization of photosynthetically fixed C. The allocation of new, native, and amendment-derived C across POM, MAOM, and Fe-bound SOC was quantified.

**ABSTRACT**

Cellulose–rich rice straw (RS) is readily decomposed with high C losses as $CO_2$ and low fraction stabilized in soil organic C (SOC). Mixing of RS with N stimulates microbial growth and turnover that can lead to retention of the straw–derived C in soil and decrease the priming effect (PE), i.e., stimulation of SOC decomposition by freshly added straw. We determined the effect of soil application of mixed RS with various N sources on decomposition–related microbial processes with the following hypotheses. (1) The addition of organic or mineral N together with RS will alter microbial processes, leading to higher microbial C storage efficiency (CSE), resulting in higher SOC stabilization compared with RS alone (2) the mixture of RS + N–rich groundnut stover (GN) will reduce PE compared to the RS and GN applied alone. A 112–day incubation microcosm experiment included unamended $^{13}C$–enriched C4 soil (CT), soil amended with single $^{13}C$–depleted residues of C3 plants, RS and GN, and the following combinations of N amendments with RS: RS+GN, and RS+ urea fertilizer. We determined soil microbiological parameters including $CO_2$–C evolution, microbial biomass (MB) C and N, microbial metabolic quotient ($qCO_2$) and PE. The mixture treatments had lower $CO_2$–C evolution than the single residue treatments starting from 42 days after amendment incorporation (DAI). Microbial biomass (MB) C and N were higher in mixed treatments than those of RS alone. Microbial metabolic quotient ($qCO_2$) (i.e., the inverse of CSE) decreased as decomposition proceeded. The mixed treatments had lower $qCO_2$ or higher CSE than RS alone at all decomposition stages. The mixture of RS+GN decreased PE below the single residue treatments from 21 until 112 DAI. We concluded that mixing RS with N-rich materials increased CSE relative to RS alone and RS mixed with groundnut reduced PE. The application of rice straw together with groundnut stover in sandy soils thus helps sequester C and decrease C losses as compared to RS alone.

# Conversion of coastal marshes to croplands shifts the pool, composition and functional groups of soil organic matter

**ABSTRACT**

Reclamation of coastal marshes to croplands generally shrinks the pool of soil organic matter (SOM). However, it is not clear how marsh reclamation shifts the SOM composition (i.e., glycoproteins and iron-bound OM) and functional groups. Here, we investigated this issue in two coastal marshes (Qilihai, seasonally flooded; Beidagang, permanently flooded) and adjacent reclaimed croplands (over 60 years) on the coast of Bohai Bay, China. Two SOM fractions were separated by ultrasound: particulate (POM, > 0.053 mm) and mineral-associated carbon (MAOM, <0.053 mm). Reclamation reduced the contents of SOM (-8.7–96.4%) and glomalin-related soil proteins (GRSP, glycoproteins secreted by arbuscular mycorrhizal fungi) (-21.2–84.7%) in both bulk soil and its fractions, particularly at the Beidagang site. Reclamation suppressed iron-bound organic carbon (Fe-OM) in both bulk soil and its fractions at the Beidagang site, while having minimal effect at the Qilihai site, likely due to contrasting initial flooding regimes. Moreover, SOM increased with GRSP and amorphous iron at both sites (except for MAOM at the Qilihai site), and with Fe-OM exclusively at the Beidagang site. After reclamation, the relative absorbance of alcohol C-OH/C-NH decreased, while polysaccharide C-O increased, leading to a reduction in aromaticity with minimal impact on recalcitrance. Despite the initial differences in flooding conditions, both SOM and GRSP, along with aromaticity, decreased synergistically in bulk soil and MAOM following marsh reclamation. In contrast, the responses of Fe-OM varied depending on the distinct waterlogging conditions. These findings enhance our understanding of the interactions between SOM composition and functional groups during different floodplain wetland conversions and provide valuable insights for the management of coastal wetlands.

## ABSTRACT

Soil aggregates stabilization and soil organic carbon (SOC) sequestration are essential for saline-alkali soil amelioration (Zhang et al. 2025), yet the role of humic acid (HA) remains unclear. A three-year field experiment investigated how the structure and properties of HA within aggregates influence SOC sequestration and aggregate stability under different organic materials applications. Treatments included no fertilization (Control), chemical fertilizer (NPK), organic fertilizer (OF), maize straw (MS) and cow manure (CM), among which the carbon (C) application of OF, MS and CM was 2000 kg C $ha^{-1}$. The results show that: Compared with Control, the mean weight diameter and SOC stock increased by 15.96% - 36.17% and 5.98%-10.38% with the organic materials application. Furthermore, these applications promoted the conversion of protein-like substances to humic-like substances, and enhanced the aromaticity, hydrophobicity and humification of HA. HA under OF was dominated by humic-like substances and fulvic-like substances, whereas protein-like substances were predominant under CM. HA in MS and OF treatments originated from a plant-microbial mixture, while in CM it was primarily from exogenous substances. The increase of Aliphatic-C and protein-like substances of HA in aggregates promoted soil agglomeration. Redundancy analysis revealed a strong correlation between MWD and the structure and properties of HA. In conclusion, the structure and proporties of HA are sensitive indicators for fertilizer management in saline-alkali soils, directly influencing SOC sequestration and aggregate stability.

**ABSTRACT**

Soil organic matter (SOM) is a major determinant of soil fertility, as it regulates fundamental properties such as bulk density, water-holding capacity, aggregation and nutrient cycling. However, SOM declines in agricultural systems, reducing soil fertility and transforming soils from carbon (C) sinks into emitters. A common strategy to mitigate SOM losses is the amendment of soils with organic matter rich materials such as sewage sludge or compost, yet the underlying mechanisms remain poorly understood. Recent evidence suggests that phosphorus (P) in these materials is a key regulator of SOM dynamics[1]. We hypothesized that SOM formation and stabilization is influenced by the chemical characteristics of organic amendments. We developed a sodium polytungstate (SPT) based soil size-density fractionation method compatible with SOM and P analyses that yields six SOM fractions. This method was then applied to Luvisols from a two-decade long field experiment receiving sewage sludge or household waste compost, where sustained increases in SOM have been observed, as well as to unfertilized control soils. Coarse particles (50 µm-2 mm) were separated into fractions CL (< 1.8 g $cm^{-3}$), CDA (> 1.8 g $cm^{-3}$), and CDB (≫ 1.8 g $cm^{-3}$), while fine particles (< 50 µm) were separated into fractions FL (< 2.4 g $cm^{-3}$), FDA (> 2.4 g $cm^{-3}$), and FDB (≫ 2.4 g $cm^{-3}$). We calculated the recovery of C, N, P, and other elements fractions relative to the bulk soil, as well as their δ $^{15}N$. Organic amendments influenced soil C stocks, with compost amended soils reaching 3.5% C, sludge amended soils 2.2%, and unfertilized soils 1.2%. The C % in sludge amended soils is particularly notable given that, over two decades of annual applications, the sludge treatment received only one quarter of the cumulative C inputs received by the compost treatment[2]. The isotopic signatures of compost and sludge were reflected across all C containing fractions, demonstrating that fertilizer-derived C was incorporated throughout the soil matrix. We found that size-density fractions were influenced by the type of organic amendment: FL was proportionally larger under compost fertilization, whereas FDB was larger under sewage sludge fertilization. Fraction FDA despite representing only 15-22% of total soil mass, contained up to 50% of total soil C and N and approximately 30% of soil P. Sewage sludge fertilization resulted in greater C incorporation into FDB compared with compost, concurring with increased iron (Fe) and P recoveries in that fraction and treatment. Across treatments and in most fractions, C recoveries were strongly correlated with P recoveries ($R^2$= 0.74 - 0.85). Results indicate that the presence of additional elements in the amendments, such as P and Fe, may influence the amount of C that can be retained in soil. This finding opens the door to more detailed investigation aimed at elucidating the mechanisms linking C retention in soils to these elements.

## ABSTRACT

Mineral-associated organic matter (MAOM) is the largest and most stable soil carbon reservoir, playing a central role in soil health and climate mitigation. Yet, quantitative understanding is lacking for the two fundamental processes forming MAOM — sorption of dissolved organic matter (DOM) on mineral surfaces, and aggregation of insoluble particulate and hydrophobic materials with mineral particles in microaggregates (<53 μm) — and how each process incorporates plant- versus microbial-derived carbon. Analyzing soils from diverse ecosystems across North America, we found that both pathways substantially contributed to MAOM, with sorption accounting for 11–96% and aggregation for 5–89% of total MAOM carbon, depending on environmental context. Sorbed MAOM was highly enriched in phenolic and carboxyl functional groups, and lignin-, tannin- and condensed aromatics-like compounds, thereby primarily plant-derived. Aggregated MAOM, however, contained abundant alkyl groups and non-aromatic materials, hence primarily microbial-derived. Sorbed MAOM exhibited Langmuir- type saturation dynamics whereas aggregated MAOM did not saturate. Despite environmental factors strongly influenced the pathway dominance, the chemical composition of each fraction remained relatively consistent across ecosystems, reflecting joint controls of microbial processing, mineral sorption, and intrinsic chemical properties of organic compounds. These findings provide pathway-specific parameters for refining soil-carbon models and offer practical guidance for management strategies targeting long-term carbon sequestration.

## ABSTRACT

Radiocarbon ($^{14}$C) measurements are widely used to constrain soil organic carbon (SOC) turnover times and assess carbon persistence in soils. However, bulk SOC $^{14}$C signatures are increasingly recognized to be biased by the presence of ancient, radiocarbon-free organic carbon (aOC). This carbon pool is not involved in contemporary soil carbon cycling but inflates apparent SOC ages, contributing to discrepancies between radiocarbon observations and modelled soil carbon dynamics. In this study, we quantify aOC at the global scale using a linear mixing model applied to $^{14}$C data from 313 soil profiles (2,204 mineral soil layers) compiled from two global databases (ISRaD and LSCE). The approach separates radiocarbon-dead aOC from biologically active SOC, allowing a reassessment of SOC radiocarbon ages commonly interpreted as turnover times.

Our results (Copard et al., 2025) show that aOC is ubiquitous in soils, with a mean concentration of 2.4 ± 3.2 mg $g^{-1}$. Its contribution increases systematically with depth, representing on average ~11% of SOC in topsoils (0–30 cm), ~27% in subsoils (30–100 cm), and >50% in deep soil horizons (>100 cm). Pedological context controls aOC abundance: high contributions occur in Andosols and Cryosols, while parent material and long-term pedogenesis explain variability across WRB soil groups. Correcting bulk $^{14}$C signatures for aOC substantially revises SOC radiocarbon age estimates. The mean corrected age of reactive SOC to 1 m depth is ~290 years, contrasting sharply with previously reported values of 3000–5000 years inferred from uncorrected bulk $^{14}$C. These revised ages are consistent with independent pedological and isotopic constraints ($^{13}$C, $^{36}$Cl) and reconcile radiocarbon observations with Earth System Model representations of soil carbon turnover.

The widespread presence of aOC necessitates its explicit consideration in the interpretation of soil radiocarbon data. Incorporating parent material, pedogenesis duration, soil depth and soil classification is critical to avoid systematic overestimation of SOC persistence and to strengthen the application of radiocarbon constraints in soil carbon modelling. This will provide a more realistic framework for assessing soil carbon turnover, sequestration potential, and potentially long-term climate mitigation strategies.

## ABSTRACT

Southern China's red soil region is confronted with soil acidification and low organic carbon stability, which constrain long-term carbon sequestration. Establishing large-diameter timber plantations is recognized as a promising approach to enhance soil carbon storage and support global climate mitigation efforts. To clarify the mechanisms of soil organic carbon stabilization in these plantations and to identify the site-specific conditions that optimize their carbon-sink function, this study was conducted in Guangdong Province, a typical area within this region.

Four major plantation species, namely *Cunninghamia lanceolata*, *Castanopsis hystrix*, *Michelia macclurei*, and *Manglietia glauca*, across fourteen state-owned forest farms were investigated. Field surveys and laboratory analyses were performed to determine soil organic carbon density as an indicator of carbon sequestration capacity, the carbon pool management index as a measure of carbon pool stability, and key soil organic carbon fractions including active components such as particulate organic carbon and permanganate-oxidizable carbon alongside the passive mineral-associated organic carbon fraction. Edaphic properties and topographic variables were integrated to develop predictive models for carbon storage through structural equation modeling and principal component analysis.Soil organic carbon density in the top one-meter layer across all four plantation types significantly exceeded the provincial forest average of ten point four four megagrams per hectare. *Castanopsis hystrix* stands achieved the highest soil organic carbon density at forty-two point four five megagrams per hectare, followed by *Michelia macclurei*, *Cunninghamia lanceolata*, and *Manglietia glauca*. All plantations exhibited obvious surface aggregation of soil organic carbon. Carbon pool management index values greater than one for both *Cunninghamia lanceolata* and *Castanopsis hystrix* indicated more stable soil carbon pools compared to forests not managed for large-diameter timber. Mineral-associated organic carbon, the dominant passive fraction accounting for over seventy percent of total soil organic carbon, served as the core of carbon stabilization. Distinct spatial heterogeneity was observed: particulate organic carbon concentrations were higher in central Guangdong than in eastern and western regions; mineral-associated organic carbon accumulation was prominent in northern and eastern Guangdong; and permanganate-oxidizable carbon, an active fraction, was elevated in western and northern regions.Structural equation modeling revealed that soil organic carbon storage was positively regulated by soil pH, soil organic carbon content, bulk density, and latitude, while being negatively affected by stand age, total potassium, available iron, and slope position. Principal component analysis identified northern Guangdong, characterized by brownish-red or brownish-yellow soils, mid-elevation, and a soil pH ranging from five point zero to five point five, as the optimal region for *Cunninghamia lanceolata*, *Michelia macclurei*, and *Manglietia glauca*. In contrast, *Castanopsis hystrix* performed best in eastern Guangdong under conditions of moderate slope, weak acidity, and high soil organic carbon content. Regarding the comprehensive performance integrating soil carbon sequestration capacity indicated by carbon density and carbon stabilization indicated by the carbon pool management index and mineral-associated organic carbon dominance, the order was *Cunninghamia lanceolata*, followed by *Castanopsis hystrix*, then *Manglietia glauca*, and finally *Michelia macclurei*.

This study elucidates the key mechanisms and spatial patterns of soil organic carbon stabilization in large-diameter timber plantations of southern China's acidic red soil region. The findings provide a scientific basis for species-specific plantation layout and sustainable management strategies, facilitating enhanced carbon sequestration and improved soil health under acidic soil conditions.

**ABSTRACT**

Wetlands play a critical role in climate change mitigation and adaptation, making their conservation and restoration essential strategies for climate action. However, research evaluating carbon storage and the mitigation value of forested wetlands remains relatively scarce. While studies on carbon stocks and fluxes in agricultural and forest soils are well-established, and research on coastal, riparian, and floodplain wetlands has progressed, the soil carbon of forested wetlands remains poorly documented. This study analyzed soil carbon stocks across six forested wetland sites in South Korea, representing different successional stages, to propose frameworks for their valuation in climate change mitigation. Ten soil cores (up to 1 m depth) were collected per site to analyze the vertical profiles of carbon, nitrogen, and their stable isotopes. Additionally, carbon stocks in aboveground biomass, including woody and herbaceous vegetation and the forest floor, were assessed through field surveys and sampling. The mean soil carbon stock was 434 Mg C $ha^{-1}$, which is approximately three times greater than typical forest soils and twice that of inland wetlands in South Korea. Soil carbon stocks ranged from 221 to 888 Mg C $ha^{-1}$ across the sites; notably, natural forested wetlands (589 Mg C $ha^{-1}$) harbored twice as much soil carbon as abandoned paddy forested wetlands (279 Mg C $ha^{-1}$). This disparity suggests significant potential for continuous carbon sequestration as abandoned paddies transition into natural forested states. Stable carbon isotope ratios ($\delta^{13}C$) ranged from –27‰ to –25‰, generally increasing with soil depth. These isotopic profiles indicated slower soil carbon turnover rates in natural forested wetlands, suggesting superior long-term carbon storage and climate mitigation capacity. Although forested wetlands occupy a small fraction of the total land area, this study confirms their high localized carbon storage potential. Therefore, we propose sustained monitoring and management of these sites as vital carbon sinks.

## ABSTRACT

Plant litter is the dominant source of organic carbon entering soils, yet the mechanisms by which litter-derived carbon is transformed into persistent soil organic matter (SOM) remain incompletely resolved. Prevailing frameworks emphasize aqueous-phase processes, either through chemical humification in solution or through the selective sorption of dissolved organic matter (DOM) onto mineral surfaces, but largely overlook the potential for a direct particulate pathway in which litter and particulate organic matter (POM) are transformed into mineral-associated organic matter (MAOM) without prior dissolution or major disruptive events. To fill this gap, we incubated model soils consisting of individual 2:1 and 1:1 clay minerals mixed with wheat (Triticum aestivum) plant litter for 180 days. Using a combination of SOM physical fractionation, FT-ICR MS, solid-state $^{13}$C NMR spectroscopy, micro-scale FTIR imaging, and causal (cross-lagged panel model, CLPM) modeling, we provide direct evidence that a particulate pathway dominates the formation and renewal of mineral-associated organic matter (MAOM). The dynamics of SOM physical fractions revealed a strong coupling between POM and MAOM accumulation with no corresponding buildup of DOM, indicating that MAOM formation does not require a dissolved intermediate. FT-ICR MS spectrum showed that MAOM is structurally distinct from DOM (Mean Jaccard, 0.38). In contrast, solid-state $^{13}$C NMR spectra spectrum showed that POM and MAOM exhibiting strong linear relationships across multiple carbon functional groups ($R^2$, 0.79~0.89). FT-IR microscopy further demonstrated intimate spatial associations between particulate litter residues and mineral surfaces, consistent with direct physical transfer. CLPM models confirmed that POM exerts a dominant and directional influence on MAOM dynamics, whereas DOM contributes weakly. Together, these results demonstrate that structural litter residues can be directly transformed into mineral-associated organic matter without prior solubilization or disruptive release events. This particulate pathway reconciles classical humification concepts with contemporary mineral-association models and reveals an overlooked mechanism governing long-term soil carbon persistence. Incorporating this pathway into soil carbon frameworks will improve predictions of carbon storage and stability across ecosystems.

## ABSTRACT

Soil organic matter (SOM) is fundamental for maintaining crop productivity and enhancing carbon (C) sequestration in agricultural soils, contributing significantly to climate change mitigation. SOM is commonly fractionated into particulate organic matter (POM) and mineral-associated organic matter (MAOM) to compare forms of potential soil C storage. However, related studies remain limited. In this study, six treatments were installed and maintained for 3 years in a red pepper cultivated field: no fertilizer (NF), only inorganic fertilizer (NPK), red pepper residue (R), compost (Com), rice hull biochar (RB), woody biochar (WB). Organic matters (OM) were annually incorporated as a basal application at 5 Mg d.w $ha^{-1}$ under the recommended inorganic fertilization level. To evaluate changes in soil C stocks in the surface soil (0-15 cm), bulk density and C content were measured separately for the 0-5 and 5-15 cm layer, and soil C stock were calculated. Then, SOM was fractionated into POM [light fraction (LF) and sand-sized fraction] and MAOM [silt- and clay-sized fraction]. Moreover, POM-C and MAOM-C contributions were calculated as the proportion of fraction-associated C relative to total SOC, indicating that these metrics reflect how soil C is partitioned between POM and MAOM pools. Soil C stocks in surface soil significantly increased with OM incorporations and showed the highest C accumulations (expressed in Mg C $ha^{-1}$) in biochar treatments (50.6 ~ 50.8) followed by Com (49.1), R (46.9) compared with the non-OM treatment (NF and NPK, 44.7). These results indicate that approximately 0.73 ~ 2.04 Mg C $ha^{-1}$ was annually accumulated with OM additions into a pepper field. OM applications altered the distribution of soil C fractions, with significant effects on the POM pools as the active C. OM applications gradually increased in the LF proportion, and notable increases were observed in the biochar treatments (2.1 ~ 3.4%) compared with the NPK treatment. C concentrations tend to increase in the LF under OM application compared with the non-OM application, while MAOM showed no significant difference among treatment. The contribution of POM-C to total SOC increased with OM incorporations and showed the highest proportions in biochar treatment (36.1 ~ 45.1%), and then followed by Com (31.8%), R (30.7%), NPK (26.1%), and NF (24.0%). Therefore, our results indicate that increases in soil C stocks under OM applications were primarily driven by enhanced POM-C accumulation. Future research is needed to evaluate whether the C accumulation under OM application contributes long-term soil C pools, considering the chemically recalcitrant characteristic of OM-derived C.

## ABSTRACT

Paddy soils represent a globally significant agroecosystem, functioning both as the primary environment for irrigated rice (*Oryza sativa* L.) production and as extensive anthropogenic wetlands with a major role in soil organic carbon (SOC) sequestration. Under climate change, increasing temperatures and reduced water availability threaten soil health, carbon (C) stability, and the long-term resilience of these systems.

This study evaluates how anaerobic digestate application influences soil organic matter (SOM) dynamics in paddy soils under simulated climate stress. A factorial field experiment tested amendment application (digestate, DS; unamended control, UN), temperature (ambient, AM; warming, +2 °C, WR), and water regime (normal flooding, NF; reduced flooding, - 30%, RF). SOM was fractionated into particulate (POM) and mineral-associated organic matter (MAOM) pools, which were characterized using Fe K-edge XANES and $k^2$-weighted EXAFS to resolve Fe speciation and coordination environments controlling SOC stabilization.

Across treatments, SOC declined under warming, with WR plots losing up to 15% more SOC than AM, while digestate under NF partially mitigated SOC losses and reduced C/N ratios, possibly indicating enhanced microbial processing.

XANES revealed strong fraction- and management-dependent shifts in Fe speciation, showing that POM was enriched in redox-sensitive Fe phases and Fe-organic complexes that responded markedly to reduced flooding and warming, whereas MAOM was dominated by illite-associated Fe and Fe (III) oxyhydroxides. Complementarily, $k^2$-weighted EXAFS resolved the short-range Fe coordination environment, indicating that POM contained mixed crystalline Fe (III) phases (hematite and lepidocrocite) embedded within a variable mineral matrix, while MAOM was systematically enriched in poorly ordered Fe (III) phases, including ferrihydrite-like and Fe (III)-organic associations, indicative of persistent mineral-protected C pools. Together, XANES and EXAFS demonstrate that climate stress primarily destabilizes SOC by disrupting redox-controlled Fe-organic associations in the labile POM fraction, whereas long-term carbon persistence under future warming scenarios depends on the maintenance of Fe (III) oxyhydroxide-mediated protection within MAOM, only weakly modulated by organic amendment and water regime.

## ABSTRACT

The high content and long-term stability of soil organic carbon (SOC) are pivotal to sustaining the ecological functions and agricultural fertility of Mollisols, whose organic matter derives predominantly from grassland vegetation. Notably, phytoliths—primarily produced by herbaceous plants—exhibit remarkable resistance to corrosion and decomposition. They act as robust proxies for reconstructing past vegetation and tracing SOC sources, while enhancing long-term SOC stability via occluded carbon (PhytOC). To elucidate the indicative significance of phytoliths for black soil organic carbon stability, we collected 30 pairs of cropland and non-cropland topsoil samples and six soil profiles across Mollisols (Phaeozems) region of Northeast China, then investigated the distribution characteristics of phytoliths and PhytOC in topsoil samples and soil profiles. In cropland, phytoliths and PhytOC contents were 13.5 ± 4.7 g·kg$^{-1}$ soil (mean ± SD) and 0.06 ± 0.02 g C·kg$^{-1}$ soil, respectively. With ~47°N as the geographical boundary, phytolith contents in the northern cropland samples were significantly higher than those in the southern region. In non-cropland, mean phytolith and PhytOC contents were 15.0 ± 3.5 g·kg$^{-1}$ soil and 0.08 ± 0.03 g C·kg$^{-1}$ soil, respectively. No significant difference was observed in their distribution along the latitudinal gradient, while PhytOC content peaked at 0.65 g C·kg$^{-1}$ soil. Moreover, soil phytolith and PhytOC contents showed no significant difference between cropland and non-cropland soils. Partial least squares structural equation modeling (PLS-SEM) reveals that soil parameters are the primary drivers of variations in phytolith and PhytOC contents in non-cropland soils. Specifically, soil pH negatively affects phytolith content, while soil nutrients significantly promote its accumulation; precipitation indirectly influences soil phytolith content by modifying soil pH and nutrient availability. Soil phytolith content was predominantly driven by long-term cultivation rather than inherent soil factors. With increasing soil depth, SOC, mineral-associated organic carbon (MAOC) and PhytOC contents decreased by 79%, 71%, and 50% on average, respectively. However, the PhytOC/SOC and PhytOC/MAOC ratios increased significantly with depth, both peaking at ~4%. Furthermore, the phytolith and PhytOC stocks in the top ~1 m soil ranged from 12.4 to 34.5 kg·m$^{-2}$ and 0.05 to 0.37 kg C·m$^{-2}$, respectively. Measured PhytOC stocks were substantially greater than values reported for other global grasslands (e.g., 0.039 kg C·m$^{-2}$ in northern grasslands and 0.033 kg C·m$^{-2}$ in temperate grasslands). Our results underscore that phytoliths are an important carbon fraction for long-term carbon sequestration in Mollisols, providing a scientific basis for optimizing land management to improve agricultural soil carbon stability.

**ABSTRACT**

Soil organic carbon (SOC) sequestration can mitigate climate change, but the development of effective management strategies is limited by a poor understanding of the factors controlling organic matter stabilization in soils. SOC sequestration occurs through interactions between organic matter and soil minerals, but the role of iron (Fe) oxides in this process is not well understood. This is particularly true in rice paddies, where waterlogging alters Fe oxide chemistry in ways that might promote SOC sequestration. For example, redox fluctuations promote the formation of amorphous Fe oxides, which have a higher surface area for sorption than crystalline Fe, and create complexes between organic matter and Fe oxides that resist decomposition. To estimate the influence of Fe compounds on SOC accumulation in rice paddies, we determined Fe and SOC pools in rice paddy and upland soils throughout South Korea. We isolated particulate organic C (POC) and mineral-associated organic C (MAOC), and quantified Fe oxides in amorphous (extracted in acid ammonium oxalate), organically associated (extracted in sodium pyrophosphate) and total pedogenic (extractable in sodium dithionite) forms. SOC is greater in paddy than in upland soils in Korea by an average of 2.0 g C $kg^{-1}$. Paddy soils also contain a greater proportion of SOC as MAOC compared to upland soils, indicating more stable SOC in rice paddies. Paddy soils contain higher concentrations of organically associated Fe than upland soils (3.2 vs 2.3 g Fe $kg^{-1}$, respectively) and a greater proportion of their pedogenic Fe is in amorphous forms (i.e., oxalate-Fe / dithionite-Fe × 100; 25% v 21% in paddy and upland soils, respectively). Overall, these results suggest that fluctuating anaerobic and aerobic conditions in rice paddies promote SOC stability through interactions with Fe oxides, predominantly via organic matter–Fe complexation. Future research should develop management practices that promote these mechanisms for effective SOC sequestration.

## ABSTRACT

The study, conducted within the EU PRIMA project ReCROP, aimed to evaluate the effectiveness of sustainable practices - including cover cropping, soil amendments, and microbial inoculants such as mycorrhizal fungi (MF) and plant growth-promoting bacteria (PGPB)- on soil carbon stocks, carbon stabilization, and soil aggregate structure in Mediterranean agroecosystems. To investigate how these treatments induce changes in soil physicochemical properties and assess their potential for soil carbon sequestration, advanced analytical techniques were employed. These included Low-Temperature Ashing (LTA), Fourier Transform Infrared (FTIR) spectroscopy combined with Photoacoustic Spectroscopy (PAS), and laser granulometry.

LTA treatments, performed using self-assembled equipment as described by D'Acqui et al. (1), allowed for the controlled removal of organic matter (OM) from soil aggregates at low temperatures. Organic carbon (C) was measured in untreated soil samples (0 hours) and in samples exposed to treatment durations of 5, 24, and 48 hours. After 48 hours, the residual carbon was considered to be physically protected within the aggregates. PAS was used to analyze the composition of soil organic matter (SOM) on the surface of both untreated and LTA-treated aggregates through FTIR-PAS spectra interpretation.

Both dry and pre-wetted aggregates gently sprayed with deionized water were immersed in distilled water, subjected to ultrasound treatment, and then analyzed with a laser granulometer to determine particle and aggregate size distribution.

The results demonstrate that treatments increasing the content of physically protected carbon enhance the stability of dry soil aggregates, which is critical for reducing erosion and conserving water. When soils are dry and subjected to rapid wetting, they are particularly vulnerable to slaking, a process where soil aggregates disintegrate due to their inability to withstand water-induced stress, resulting in the breakdown of soil structure. Additionally, the findings emphasize the importance of adopting practices that promote the transformation of organic matter into more stable, high-quality forms, such as physically protected organic matter. These improvements contribute to greater soil stability and overall soil health, promoting sustainable land management in Mediterranean agroecosystems.

## ABSTRACT

Converting organic solid wastes into functional technosols offers a promising pathway for carbon neutrality, yet the mechanisms governing mineral-associated organic carbon (MAOC) formation in such engineered soil systems remain poorly understood. Here, we present a comprehensive framework elucidating MAOC stabilization dynamics through systematic manipulation of biomass quality gradients (distiller's grains, cotton/maize/wheat straw with lignin contents of 14.6-26.8% and C/N ratios of 3.78-115.51), reactive mineral assemblages (montmorillonite, goethite, boehmite, ferrihydrite, and their combinations), and microbial inoculants across 90-day incubations at 15°C, 25°C, and 35°C.

Our results demonstrate that MAOC accumulation efficiency varies 3.2-fold across biomass types, with lignin-rich substrates (>22% lignin) yielding 47.3±4.8 g MAOC/kg compared to 14.7±2.1 g/kg for low-lignin materials after 90 days. Iron (oxyhydr)oxides exhibited superior organic carbon binding capacity, with goethite-amended technosols accumulating 156% more MAOC than montmorillonite-only treatments. Critically, we identified a synergistic mineral-microbial coupling mechanism: combining 5% ferrihydrite with microbial inoculants ($2\times10^{10}$ CFU/g including Bacillus, Trichoderma, and thermophilic bacteria) enhanced MAOC formation by 73.4% compared to single-factor treatments.

The microbial carbon pump contributed 38.6±5.2% of total MAOC through necromass deposition, with bacterial residue carbon showing stronger correlation with MAOC ($r=0.82$, $P<0.001$) than fungal residues ($r=0.54$, $P<0.01$). Extracellular polymeric substances concentration exhibited significant positive correlation with MAOC formation ($r=0.76$, $P<0.001$), while reactive oxygen species -mediated oxidation facilitated the transformation of aromatic compounds into mineral-binding carboxylated derivatives, contributing 12.3±2.8% of newly formed MAOC. Enzyme activity profiling revealed β-glucosidase ($r=0.71$, $P<0.01$) and phenol oxidase ($r=0.68$, $P<0.01$) as key regulators of MAOC-precursor generation. MAOC preferentially accumulated at mineral-organic interfaces with organic layer thicknesses of 2.8-15.6 nm on iron oxide surfaces. Temperature sensitivity analysis showed that MAOC formation was maximized at 25°C ($Q_{10}=1.42\pm0.18$), while higher temperatures (35°C) accelerated POC decomposition but reduced MAOC stabilization efficiency by 23.7%. Soil aggregate analysis demonstrated that macroaggregates (>250 μm) protected 52-68% of total MAOC, with aggregate-occluded MAOC showing 2.3-fold longer mean residence time than free MAOC. Our findings establish a mechanistic framework for engineering carbon-stabilizing technosols from organic wastes.

## ABSTRACT

Soil organic matter (SOM) represents a major carbon reservoir in forest ecosystems, yet the respective influences of tree species and site conditions on SOM molecular composition remain insufficiently resolved. To address this gap, this study examined SOM biochemical signatures across five European common gardens. Topsoil samples were collected beneath adjacent stands of broadleaf and coniferous species differing in their symbiotic microbial associations—arbuscular mycorrhizae (AM) or ectomycorrhizae (ECM)—with some species additionally forming associations with nitrogen-fixing bacteria. SOM biochemical composition was characterized using pyrolysis–gas chromatography/mass spectrometry (Py-GC/MS).

Tree species significantly shaped SOM origin and composition through their litter traits and associated microbiomes, while soil properties further modulated these effects. N-fixing ECM broadleaves enriched SOM in microbial-derived N-compounds. Topsoils under AM trees also showed higher contents of microbial-derived N-compounds compared to ECM trees, and—contrary to common expectations—AM soils were enriched in lignocellulosic residues.

Under conifers, SOM was enriched in aliphatic compounds and depleted in lignin relative to broadleaves in temperate sites, whereas the opposite trend was observed in the boreal site. Coarse-textured soils enriched in poorly crystalline oxides displayed a relative enrichment in aliphatics, while fine-textured soils rich in base cations selectively retained microbial-derived N-compounds and lignocellulosic residues.

The molecular fingerprint generated by Py-GC/MS demonstrated that lignocellulosic residues preferentially accumulate under AM- compared to ECM-associated trees in the studied soils, contrary to what is commonly inferred from forest floor observations or the use of N-related proxy analysis (such as C:N or amino-sugars). The study demonstrated that tree trait imprint on SOM composition is further modified by soil properties that determine the selective preservation of molecules. The presence of base cations, in conjunction with a finely textured phase, enhanced the mineral protection of lignocellulose and microbial-derived N compounds. It was also probable that the N-fertility inherited from a former agricultural use of the soil contributed to the non-degradation of lignin residues and microbial-derived N compounds. In soils enriched in poorly crystalline oxides, no plant or microbial preferential origin for N-compounds and polysaccharides was detected, while aliphatics were preserved due to thermodynamic limitations prevailing in such soils. Overall, the Py-GC/MS molecular fingerprint revealed the complexity of SOM formation pathways and highlighted how interactions between tree functional traits and soil mineral characteristics jointly determine the fate of plant- and microbial-derived residues in forest topsoils.

*zdb_98@163.com

**ABSTRACT**

Soil organic carbon (SOC) sequestration is essential for mitigating climate change and sustaining soil productivity in agricultural systems. Microbial necromass carbon (MNC) and plant residue-derived carbon (PRC) represent crucial stable fractions of SOC. However, it remains uncertain how fresh residues from green manure (GM) crops combined with nitrogen (N) fertilizer application influence the relative contributions and stabilization of microbial- versus plant-derived C in SOC, especially within deeper soil layers in drylands. To address this knowledge gap, a 16-year field experiment was conducted in China, comparing a rotation system of winter wheat (*Triticum aestivum* L.) with soybean [*Glycine max* (L.) Merr] versus a traditional fallow-wheat (FW) system, both subjected to two N fertilizer treatments (0 and 162 kg N $ha^{-1}$). Results demonstrated that the LGM rotation substantially enhanced SOC and mineral-associated organic C (MAOC) concentrations by 17.2-19.2% and 24.6-34.6%, respectively, in the 0-40 cm soil profile. However, particulate organic C (POC) was notably reduced at the depths of 20-40 cm. Notably, LGM crops significantly increased fungal necromass C (FNC) content by 39.7-65.1% and enhanced its contribution to SOC by 31-42%, driven by fungal-dominated microbial transformation of PRC into stable MNC via upregulated C-acquiring enzymes. Conversely, long-term N fertilization increased MAOC by 13.7-21.2%, but reduced MNC contribution to SOC. The observed reduction in POC was attributed to a shift toward alternative stabilization mechanisms, along with changes in microbial metabolism favoring rapid C turnover, thereby decreasing FNC and bacterial necromass C (BNC) at greater soil depths. Partial least squares path models (PLS-PMs) confirmed a significant positive total effect of LGM implementation on MNC, mediated through enhanced microbial biomass and C enzyme activities, whereas N fertilizer input exhibited an indirect negative influence. In summary, sustained cultivation of LGMs effectively promoted SOC stabilization through fungal-mediated MNC formation, while inorganic N fertilization impaired MNC accumulation. Optimizing LGM integration with reduced N application is beneficial for enhancing SOC sequestration and stability in the dryland agroecosystems.

**ABSTRACT**

Soil organic carbon (SOC) is the cornerstone of soil multifunctionality, underpinning plant production and the provision of food and fiber. As the largest active terrestrial carbon pool, SOC also drives negative climate feedbacks by sequestering atmospheric $CO_2$. Enhancing SOC sequestration is therefore critical for safeguarding food security and mitigating climate change. However, the capacity of soils to sequester additional SOC remains controversial, largely due to the ambiguous role of existing SOC in regulating new SOC formation. Traditional paradigms argue that existing carbon occupies vacant mineral surface sites (key for organo-mineral association formation), thereby limiting new SOC retention. In contrast, recent studies suggest existing SOC can facilitate extra carbon storage via organo-organo interactions. Resolving this contradiction is essential for accurately evaluating SOC sequestration potential and developing effective carbon-enhancing strategies.

Here, we investigated how mineral surface carbon loading (defined as the ratio of SOC to mineral specific surface area) regulates SOC formation via two key pathways: direct sorption (using $^{13}C$-labeled batch adsorption experiments) and in vivo microbial turnover (using microcosm experiments).

For both pathways, increased mineral surface carbon loading inhibited SOC formation—by reducing exogenous organic carbon retention and promoting the release/decomposition of native SOC. These results indicate that existing SOC has a limited capacity to host additional carbon, even with evidence of organo-organo interactions. Notably, in calcareous soils, exchangeable calcium exerted a more dominant regulatory role in microbial turnover-mediated SOC formation than mineral surface carbon loading. This finding reveals an unforeseen alternative mechanism of SOC formation, complementing the prevailing organo-mineral-centric framework for calcareous soils.

Our results provide novel mechanistic insights into the factors controlling SOC sequestration, offering critical implications for accurately assessing soil carbon sequestration potential and guiding targeted carbon management strategies.

## ABSTRACT

Soil organic carbon (SOC) is one of the most critical carbon pools in soil ecosystems, playing a vital role in maintaining soil fertility and ecosystem functions. The Northeast Black Soil Region is an important granary in China, however, affected by environmental and anthropogenic factors, the region is facing a series of issues such as declining soil organic matter content, reduced fertility, and soil degradation, which lead to a significant reduction in crop yields. Therefore, how to efficiently increase the SOC content and soil quality, and thereby improve crop yields, is an urgent issue to be resolved. To address this, the experiment was initiated in 2022. With straw leaving field as the control (CK), five straw returning methods were set up: straw crushing and returning to field (CR), straw crushing and returning to field + straw decomposing agent (DA), cattle manure returning to field (CM), straw composting and returning to field (SC) and straw biochar returning to field (BC) By constructing an equal-carbon-content straw returning experimental system, this study measured SOC and its active fractions, soil physical structure, biological properties, and maize growth indicators at different growth stages of maize. The study compared and analyzed the dynamic changes in SOC and its active fractions under different straw returning methods with equal carbon content and explored the synergistic relationship between soil properties and maize growth to elucidate the regulatory mechanisms of different straw returning methods on maize yield. In summary, different straw returning methods can enhance both soil active organic carbon fractions and maize yield, but each method exhibited unique characteristics. The DA treatment significantly increased soil organic carbon content and the soil carbon pool index at the jointing and maturity stages and elevated the activities of four carbon-degrading enzymes throughout the maize growth period, however, it had certain destructive effects on soil physical structure in the short term. Similarly, the CR and BC treatments also exhibited some destructive impacts on soil physical structure in the short term. The CM treatment improved soil physical structure and enhanced polyphenol oxidase (PPO) activity throughout the maize growth period, but had relatively lower efficiency in increasing SOC and the soil carbon pool index in the short term. The SC treatment also improved soil physical structure, increased the activities of four carbon-degrading enzymes, and significantly increased SOC content and the soil carbon pool index during the large trumpet and maturity stages. Overall, under short-term straw returning conditions, the SC treatment effectively improved soil physical structure, while also having the potential to enhance soil carbon sequestration capacity and promote maize growth and yield. These findings provide significant data support for optimizing straw returning methods and improving soil quality in the short term in the Northeast Black Soil Region.

# Soil Organic Carbon Fraction Dynamics Across Paddy Soil Profiles: A Critical Role of Parent Material

**C Zheng**[1*]

[1] *Affiliation of the A. C, Zheng (College of Resources, Sichuan Agricultural University, Chengdu, China)*

*2268970491@qq.com

**ABSTRACT**

Paddy soils evolve from diverse parent materials, whose legacy—particularly in terms of soil texture and elemental composition—fundamentally shapes their pedogenic trajectory and governs the accumulation of organic carbon (OC). However, the specific influence of parent material on the distribution of key functional OC pools—particulate (POC) and mineral-associated organic carbon (MAOC)—throughout soil profiles remains poorly understood. To address this knowledge gap, we investigated paddy soils derived from three major parent materials in the Chengdu Plain: Holocene alluvial deposits, Pleistocene glaciofluvial deposits, and Chengdu clay (loess deposits). Soil samples were collected from different genetic horizons down to a 1-meter depth and analyzed for total soil OC, dissolved OC, POC, MAOC, and key regulators including pH, cation exchange capacity, texture, and metal ion content.Our results revealed that the surface (hydragric horizon) and plough pan consistently exhibited higher soil OC content, dominated by the POC fraction. This dominance was negatively correlated with soil pH and positively correlated with silt+clay content. The plough pan effectively decoupled surface soil OC dynamics from those in the subsoil. Beneath the plough pan, soil OC content decreased, and the proportional contributions of soil OC functional pools diverged significantly according to parent material. Soils derived from alluvial deposits maintained relatively higher subsoil soil OC, with MAOC constituting a significantly larger fraction, a pattern strongly linked to Ca-OC complexation. In contrast, in soils derived from glaciofluvial deposits and Chengdu clay, the contribution of POC became more prominent in the subsoil, showing a negative correlation with pH but a positive correlation with free manganese oxides.Our findings reveal that the geochemical legacy of parent material dictates soil OC stabilization pathways. Accounting for this inherent control can significantly refine carbon accounting models and inform targeted.

# Effects of silicon modified biochar with different pyrolysis temperatures on carbon stabilization pathways in saline alkali soil

**ABSTRACT**

Soil organic carbon (SOC) stabilization in saline-alkali soils is constrained by poor aggregate structure. This study investigated how biochar and Si-modified biochar produced at different pyrolysis temperatures (300℃, 500℃ and 700℃) influence carbon stability in Yellow River Delta saline-alkali soils through 120-day incubation experiments. Both types of biochar significantly improved soil properties and aggregate stability. Si-modified biochars exhibited superior mineral-associated organic carbon (MAOC) accumulation, with SiBC700 achieving the highest MAOC content. Lower pyrolysis temperatures (300-500℃) proved more effective for total carbon sequestration, with SiBC300 demonstrating the most effective aggregate formation. Partial least squares path modeling revealed aggregate stability as the strongest driver of SOC stability. These findings indicate that low-temperature Si-modified biochar optimizes aggregate-mediated carbon protection, while high-temperature variants enhance long-term mineral-associated carbon stabilization in saline-alkali soils.

## ABSTRACT

Soil carbon sequestration is critical for climate change mitigation, especially in alkaline soils where inorganic carbon dominates below 1 m depth, which remains poorly understood. While straw return is known to enhance soil organic carbon, its long-term effects on deep soil inorganic carbon dynamics have been largely overlooked. This study employed a 12-year field experiment comparing straw return versus removal in a wheat-maize system, combined with carbon stock measurements across the 0-200 cm profile. We combined natural $^{13}C$ abundance analysis with laboratory incubation experiments using $^{13}C$-labeled glucose to trace carbon sources and quantify the fate of exogenous carbon in deep soil layers. Our results show that straw return significantly increased soil inorganic carbon stocks by 57.6 t $ha^{-1}$ in the 100-200 cm layers. Natural $^{13}C$ abundance data revealed that pedogenic carbon increased dramatically by 96.6% in topsoil (0-20 cm) and by 97.7% in deep soil (120-140 cm) ($P < 0.01$), whereas lithogenic carbon remained stable, indicating that soil inorganic carbon gains primarily originated from pedogenic carbonate formation. The $^{13}C$-labeled glucose incubation further demonstrated that 72.23% of the added $^{13}C$ was mineralized to $CO_2$, while 17.27% was transformed into soil inorganic carbon, suggesting that exogenous carbon entering the 120-140 cm soil layer enhances pedogenic carbonate formation. These findings reveal a previously overlooked, microbially mediated mechanism underlying deep soil inorganic carbon formation driven by straw-derived carbon inputs. Long-term straw return enhances surface organic carbon and deep soil inorganic carbon, offering a scalable, nature-based strategy to boost soil carbon storage in alkaline croplands.

**ABSTRACT**

Pyrolysis of sewage sludge into biochar has been proposed a strategy to stabilize organic carbon and mitigate environmental risks, yet the persistence of sludge-derived biochar C in soil remains poorly understood. Here we investigated the stability of biochar produced from sewage sludge collected from three wastewater treatment plants using a one-year laboratory incubation in soil. Sludge biochars retained 95–96% of added C after one year and were approximately seven times more recalcitrant than their feedstock. However, based on our conservative estimates, the median mean residence time (MRT, 27 years) was roughly an order of magnitude lower than that of plant-derived biochars recalculated from published datasets under comparable conditions (median 210 years). In addition, sludge biochar usually contains a large ash fraction and the abiotic CO2 release at the early stage of incubation may lead to underestimation of biochar persistence in soil. Carbonate removal had only a marginal effect on MRT estimates, likely because carbonate-derived CO2 was released slowly and carbonates were chemically protected within the biochar matrix. The reduction of biomass during pyrolysis led to an increase in concentrations of most trace elements with an exception for Hg. Overall, these results indicates that, relative to plant-derived biochars, the potential of using sewage sludge biochars for long-term soil C sequestration may be limited. Nonetheless, sludge biochar may still provide benefits for waste management and nutrient recycling, which requires further evaluation through life-cycle assessments and agronomic studies.

# Application of Clay and Iron Oxide-Amended Compost: Linking Emission Reductions to Enhanced Soil Aggregation, Necromass, and Plant Performance

**Benedikt J. Boppré*[,1,2], Eiko Kuramae[1,2], George Kowalchuk[2]**

[1] *NIOO-KNAW (Microbial Ecology, Wageningen, Netherlands)*

[2] *Utrecht University (Ecology and Biodiversity, Utrecht, Netherlands)*

*b.boppre@uu.nl

**ABSTRACT**

Background: Farmers use composting since millennia to process organic waste into valuable organic soil amendments. During the composting process, more than 50 % of the carbon (C) is mineralized to $CO_2$ and more than 30 % of the nitrogen (N) is lost as $NH_3$ and $N_2O$. This C and N is thereby no longer available to form mineral associate organic matter (MAOM). The composting process is therefore the ideal starting point to mitigate these emissions to improve the sustainability of agricultural practices.

In our approach, we seek to decrease these losses by adding minerals directly to the start ofthe composting process, thereby providing both organic matter and reactive mineral surfaces upon application to promote microbial necromass build-up and C protection through organo- mineral associations and aggregation.

Objective: We compare abundant clay-rich waste with clay minerals and iron oxides, and linking gaseous emissions during the composting process to gaseous emission during the incubation with soil. At the same time, we research the effects of our engineered compost on plant performance and soil quality.

We hypothesize that mineral compost amendments decrease the C and N loss during the composting process , and compost amended with minerals increases soil aggregation, necromass build-up and stimulates plant performance.

Methods: For our mesocosm experiment, we mixed compost feedstock with 25 % (w/w) minerals (i.e., synthetic Goethite, volcanic Bentonite and natural clay) at the beginning of the composting process. 5 L mesocosms (n = 6 per treatment) were incubated for 40 days, with daily measurements of gaseous emissions ($CO_2$, $N_2O$, $CH_4$, $NH_3$). Additionally, every week, we monitored compost quality and maturity.

The resulting compost is transferred to a soil incubation experiment, during which gas measurements, soil quality and plant performance are assessed over period of 90 days.

Results: In preliminary experiments, we measured 20 % lower $CO_2$ emissions and 50 % higher $N_2O$ emissions in treatments with Bentonite compared to unamended compost. We will validate these results with our ongoing experiment where we test more treatments and different mineral amendments over a longer time.

Additionally, our set up allows us to examine if lower emissions during composting also translate to lower emissions over 90 d soil incubation and track their effects on soil quality and plant performance.

Conclusions: Our engineered compost approach seeks to demonstrate a strategy for increases C stabilization and decreased greenhouse gas emissions at the mesocosm scale. We show the potential to reduce C and N losses and at the same time maintain a productive soil that transforms organic matter into MAOM.

**ABSTRACT**

Soil minerals, particularly high-surface-area secondary minerals like iron oxides, stabilize soil organic carbon (SOC). However, as these minerals transform into more crystalline forms over time, their ability to protect mineral-associated organic matter (MAOM) may also change, which is a dynamic feedback that is still not well understood. This study examines how ferrihydrite, a short-range-ordered iron oxide, protects polygalacturonic acid (PGA) under varying carbon loadings (C/Fe ratios) and Fe(II)-induced redox conditions.

We show that ferrihydrite transforms into goethite in pure mineral systems, diminishing its carbon protection potential due to reduced surface area. However, in mineral-PGA complexes, protection is maintained across different carbon saturation levels via distinct mechanisms. Under high carbon loading, PGA inhibits mineral transformation, forming stable complexes that in turn protect the PGA from degradation. Under low carbon loading, transformation proceeds but protection is maintained through relatively sufficient residual surface area. Notably, the degradation product galacturonic acid (GA) more effectively inhibits mineral transformation than PGA itself, creating a negative feedback that further stabilizes remaining organic matter.

Our findings demonstrate that carbon saturation governs two functional pathways in mineral–organic systems: a transformation-resistant pathway under high saturation and a surface-mediated protective pathway under low saturation. This updated conceptual model explains how MAOM can remain stable despite dynamic soil environment, and identifies soil carbon saturation as a key predictor of the stabilization mechanism. This work also presents SOC acts not as a passive substrate, but as an active regulator of mineral evolution and its own long-term persistence, offering insights for predicting SOC stability under environmental change.

**ABSTRACT**

Increasing soil organic carbon (SOC) levels is essential for sustainable agricultural productivity and climate change mitigation, particularly in alkaline soils with inherently low SOC. While amorphous Al hydroxide (Am-Al) significantly influences SOC stabilization in volcanic and humid-region soils, and biochar enhances SOC in temperate and tropical regions, their effectiveness and stabilization mechanisms in alkaline soils require further exploration. We conducted a 1-year incubation of low SOC alkaline soils (5.2 g $kg^{-1}$) amended with $^{13}C$-labeled maize residue (1 g $kg^{-1}$), with or without Am-Al or rice-husk biochar (each 10 g $kg^{-1}$); residue mineralization/retention was quantified and molecular composition profiled by solid-state $^{13}C$ NMR and Py-GC/MS. Rapid decomposition of plant residue ceased around 12 weeks, while plant residue-derived C and native SOC decomposition continued throughout the incubation period. Am-Al significantly reduced maize mineralization within the initial two weeks and retained 30% more residue-derived C than the control soil with maize addition after one year. $^{13}C$ NMR and pyrolysis–GC/MS showed smaller decreases in carbohydrate-C and saccharides and a higher carbon pReferences index and odd-even predominance of alkanes, indicating that Am-Al better preserved carbohydrate- and cuticular-wax-derived components, proxies for less-degraded residues. Respiration dynamics and molecular fingerprints indicate Am-Al rapidly stabilizes labile plant compounds, possibly through non-electrostatic sorption and ligand-exchange. Biochar increased residue-derived C retention by ~17%, but its effects on mineralization emerged later in the incubation (>6 months). We attribute this lag to surface degradation/activation of the biochar that then more efficiently stabilizes microbially processed compounds. Overall, adding Am-Al or biochar with plant residues significantly increased residue-derived C retention through immediate and delayed mechanisms, respectively. Treatments combining Am-Al or biochar with plant residue yielded a net positive C balance over the incubation, whereas residue alone did not. Thus, the application of Am-Al and biochar with plant residues represents a promising strategy for sustained C stabilization, thereby improving SOC in degraded alkaline soils.

# Soil Erosion and Organic Matter Stabilization Mechanisms

**Xiang Wang**[1*]

[1] *College of Land Science and Technology, China Agricultural University, Beijing, China*

*E-mail: wangxiang@cau.edu.cn

**ABSTRACT**

Erosion induces the transport and spatial redistribution of soil organic matter (SOM). The erosion-driven lateral transport of carbon-rich topsoil facilitates the movement of organic carbon along hillslopes, resulting in the exposure of subsurface soils and the effective burial of soil, sediments, and their associated protected organic carbon at depositional sites. Erosion processes influence the stability of SOM across various landscape positions along slopes. Currently, the three primary mechanisms by which erosion governs SOM stabilization include: (1) physical protection of soil organic carbon (SOC), involving the physical occlusion of SOC within aggregates or the spatial isolation of SOC from decomposers; (2) chemical interactions between organic carbon molecules and soil mineral surfaces; and (3) the chemical composition and molecular structure of SOM. Investigating the impact of soil erosion on the spatial heterogeneity of SOC is crucial for deepening our understanding of the interactions between geomorphic and biogeochemical processes.

# Iron-Mediated Carbon Dynamics in Coastal Wetlands under Seawater Intrusion

**Chunmei Chen[1*], Yanqi Xiao[1], Yilin Lan[1], Jingxuan Chen[1] and Cong-Qiang Liu[1]**

[1] *School of Earth System Science, Tianjin University, Tianjin, China*

*E-mail Address of Presenting Author: cmchen88@tju.edu.edu

**ABSTRACT**

Coastal wetlands are critical global carbon reservoirs. Under climate change, seawater intrusion driven by sea-level rise poses a major threat to these ecosystems by increasing inundation frequency and duration and introducing large quantities of saline ions, thereby altering mineral–organic carbon (OC) interactions. However, the response of mineral-mediated OC preservation to seawater intrusion remains poorly understood.

To address this knowledge gap, we conducted a one-year laboratory incubation experiment using soils collected from 32 coastal wetlands across China. A simulation system encompassing a wide range of redox conditions and salinity gradients was established. The results showed that under prolonged anaerobic conditions, most reactive iron oxides were vulnerable to rapid reductive dissolution, resulting in an approximately 50% decline in iron-bound OC. This substantially weakened the capacity of iron minerals to stabilize OC and consequently enhanced the leaching loss of dissolved organic carbon (DOC). In addition, iron reduction accounted for 57% of anaerobic $CO_2$ production, representing the dominant pathway of anaerobic OC mineralization and partially offsetting the suppressive effect of anoxic conditions on OC decomposition. These findings indicate a functional shift of iron in coastal wetlands from a “rusty carbon sink” to a net carbon source.

With increasing salinity, the iron-reducing bacterial community exhibited a successional transition from *Clostridium* toward salt-tolerant genera, such as *Geothermobacter*. Even at salinities up to 30‰, iron reduction and associated $CO_2$ emissions were only marginally inhibited (<10%). In contrast, $CH_4$ emissions and the abundance of key methanogens declined sharply, primarily due to sulfate inhibition. Additionally, DOC leaching losses were substantially reduced under high-salinity conditions. Together, these results provide a mechanistic foundation for predicting the dynamic evolution of carbon pools in coastal wetlands under increasing seawater intrusion.

**ABSTRACT**

Soil organic carbon (SOC) plays a vital role in climate change mitigation, global food security, and soil health sustainability. While conservation tillage, particularly no-tillage (NT), has been empirically proven to enhance SOC, the temporal dynamics of SOC formation pathways remain poorly quantified across different cropping systems. Samples were collected from the surface layer in a long-term NT experiment (since 2001) that included two treatments: a) NT with continuous maize (NTMM); b) NT with maize-soybean rotation (NTMS). Plant- and microbial-derived C were quantified using lignin phenols and amino sugars as biomarkers to assess SOC formation pathway. Rock-Eval (RE) thermal analysis was used to assess SOC stability. SOC reached a steady-state after 12 years under both NTMS and NTMM. Although cropping systems influenced the fungal/bacterial ratio, they did not significantly alter the total microbial-derived C contribution to SOC in the steady-state (since 2014). Plant-derived C increased substantially, reaching 4.68 times (NTMS) and 5.97 times (NTMM) initial levels after 15 years. Microbial-derived C dominated SOC formation, but plant-derived C contributed more to SOC accumulation. The increase of hydrogen index and residual C calculated from RE indicated that NT increased both the labile C pool that promoted crop growth and the stable C pool which benefited the long-term SOC sequestration. These findings shed light on the SOC formation and stabilization change in time series in no-tillage and provide a stepping stone for SOC sequestration mechanism under different cropping systems.

## ABSTRACT

Soil organic carbon (SOC) stocks vary through time and across land use, climate, and soil type, making large-scale modeling of current SOC (SOCcs) challenging. The attainable steady-state stock (SOCat), the practically achievable SOC level under optimal soil, climate, and management conditions, is also dynamic because several soil loss pathways impact biophysical factors that control maximum storage capacity and can shift SOCat. Robust methods are therefore needed to model and extrapolate both SOCcs and SOCat so that current deficits (SOCdef = SOCat – SOCcs) can be quantified as unrealized sequestration capacity. Most existing theoretical and data-driven approaches are limited by lack of empirical evidence and temporally rich datasets, making them less reliable for dynamic estimation of SOC References states from legacy data alone.

To overcome these limitations, we combined legacy SOC observations, time adjustment, and data-driven modeling to generate spatially explicit 2024 SOCcs projections at 250 m resolution for the contiguous United States. We then estimated SOCat by identifying the maximum SOC stock within a spatially constrained similarity matrix of projected SOCcs and, using both References layers, calculated location-specific SOCdef. The resulting maps reveal pronounced heterogeneity, with mean deficits average 3.46 kg $m^{-2}$ in croplands versus 3.1 kg $m^{-2}$ in grasslands and forests. Larger deficits cluster on historically cultivated Mollisols and Alfisols in the Midwest, although they are lower than anticipated, indicating that decades of cultivation have depleted both SOCcs and SOCat. Degraded grasslands show similarly reduced storage capacity, underscoring the need to recalibrate sequestration targets to today's lower steady states. By providing empirically based, regionally calibrated SOCcs-SOCat-SOCdef benchmarks, our framework offers actionable References points to align management incentives, climate-smart policy, and site-specific restoration efforts.

## ABSTRACT

Despite wide acceptance of the potential of soils to store carbon, the effectiveness of formal schemes for soil carbon sequestration such as emission trading schemes remains uncertain. Concerns include the non-permanence of sequestered carbon, high costs of verification and inconsistent information on attainable soil organic carbon (SOC) under differing land management. The concept of SOC equilibrium, where soils achieve new higher equilibrium levels of carbon under more sustainable land management, can promote confidence in projected long-term carbon stocks. We demonstrate broad soil SOC equilibrium levels across Australia under 48 unique environmental - land management regimes, comprising three climate classes, four soil groups and four vegetation cover classes. The dataset comprised 4325 points across Australia with SOC stocks to 30 cm, sourced from the Australia-wide SCaRP monitoring project, supplemented with further state government soil data.

Random forest machine learning modelling using only key variables (annual precipitation, annual maximum daily temperature, soil-lithology and MODIS total fractional vegetation cover) revealed moderate performance with 68% of variation explained and a Lin's concordance value of 0.77 in independent validation. Plotting of median SOC stocks for the 48 regimes (Figure 1) demonstrates broadly consistent trends with varying climatic, soil type and vegetation cover conditions, although some regimes lack data or have apparent anomalies. The lowest stocks (20 t/ha) are demonstrated for dry - highly siliceous soil - low vegetation cover (<60%) conditions; whilst the highest stocks (110 t/ha) are demonstrated for wet - mafic soils (fertile clay rich) - high vegetation cover (>88%) conditions. A broadly consistent and predictable pattern exists between these two end-points.

The plot demonstrates the increase in stocks that are expected when transitioning to a higher vegetation cover class in the same climate and soil class, i.e., at the same site. We propose that the SOC stocks demonstrated for each of the 48 environmental – vegetation cover regimes represent broad equilibrium conditions for these regimes over Australia. Landholders and policy makers can have confidence in the reliability of these long-term equilibrium trends and thus confidence in decisions to participate in carbon trading schemes based upon them.

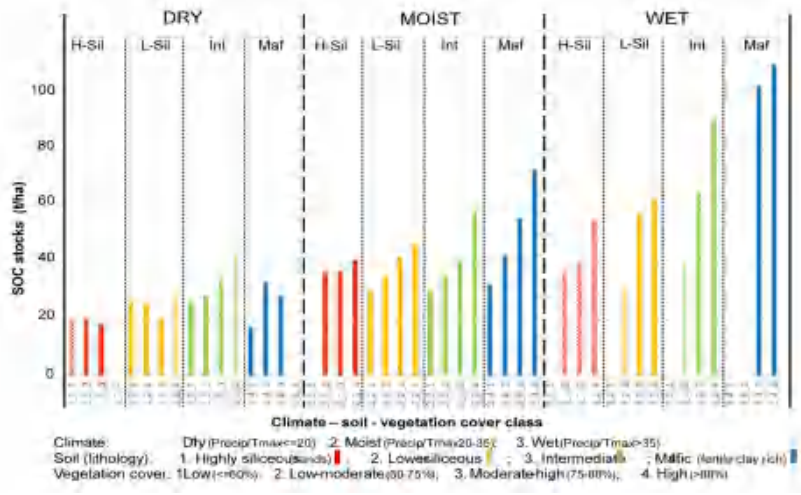

*Figure 1: Median SOC stocks by environmental – vegetation cover regime, Australia (0-30 cm, t/ha)*

# Microscale soil organic matter patches shaped by carbon- and nitrogen-rich microdomains

**ABSTRACT**

Enhancing soil carbon storage through mineral-associated organic matter (OM) is widely advocated, yet the underlying storage mechanisms remain poorly understood. In soil systems, OM has been observed to be distributed heterogeneously in patches at the microbially relevant microscale. Due to the high spatial complexity of heterogeneous soil structures, data-driven approaches are required to quantify the spatial arrangement of OM. We elucidate patchy OM distribution patterns based on 450 measurements by nanoscale secondary ion mass spectrometry (NanoSIMS) with a field of view of 30x30 µm and 120 nm spatial resolution. To investigate general patterns of microspatial OM, we build a large dataset consisting of fine fractions (<20 µm) covering soils with diverse textures. The spatial patterns of OM distribution were analyzed at three different scales, each step zooming in more and more: the average coverage of OM patches was determined across several measurements per soil sample, the clustering of OM patches for each individual soil aggregate or particle, and the variation of C and N within the OM patches. Across various soil samples, microscale OM coverage on mineral surfaces was linearly correlated with the soil organic carbon content up to a coverage of 74% of the particle surface covered with OM at an OC content of 380 mg C g-1. When zooming into individual soil particles, the connectivity and clustering of OM patches revealed that higher OM coverage was related with a more clustered and connected pattern of OM patches. To evaluate the heterogeneity of C and N distribution within OM patches, we applied an advanced lacunarity analysis that incorporated a variance-driven h value and lacunarity curves derived from mean and variance metrics. Maximum change points in the lacunarity curve indicated pronounced spatial variation within OM patches. Patches were classified as heterogeneous when exhibiting both a second maximum change point on lacunarity curves and the detection of C-rich and N-rich microdomains, otherwise as homogeneous. The heterogeneous OM patches were significantly larger than the homogeneous OM patches, with a median size of 0.23 µm², regardless of the C or N composition. Heterogeneous OM patches size depends on the composite microdomains, large as C-rich microdomain (0.16 µm²) in C-dominated OM patches (7 µm²), or small as N-rich microdomain (0.08 µm²) in N dominated OM patches (1.10 µm²). These identified spatial C-rich and N-rich microdomains, which derived from distinct plant and microbial sources, form these mosaic-like OM patches over mineral surfaces. Micro spatial heterogeneity of OM determines microbial accessibility, mineral-organic protection mechanisms, and the formation of distinct biogeochemical microenvironments, providing essential insights for predicting soil carbon dynamics across scales.

## ABSTRACT

Coastal wetlands represent a key reservoir of organic carbon (OC) at the land-ocean boundary, where interactions between iron (Fe) minerals and OC may influence long-term burial (Lalonde et al., 2012; Chen et al., 2024; Moore et al., 2023). Reactive, poorly crystalline and short-range-ordered Fe oxides are often proposed to protect OC, yet their expected vulnerability to reductive dissolution under anoxic conditions leaves their persistence and role in wetland soils uncertain. To evaluate these uncertainties, we integrated a global dataset of ~23,000 observations with a nationwide survey along China's coastline. Relative to uplands, coastal wetlands are enriched preferentially in poorly crystalline or short-range-ordered iron minerals over well-crystalline phases. Mössbauer spectroscopy confirms that ferrihydrite, nanogoethite, and highly disordered oxides dominate the Fe oxide pool in coastal wetland soils, while crystalline phases are minor, challenging the notion that reactive metastable minerals are removed preferentially under anoxic conditions. The abundance of reactive metastable Fe was most abundant in tropical wetlands, contrasting with tropical uplands where crystalline oxides are more prevalent. However, the proportion of total OC associated with Fe oxides is comparable between coastal wetlands (~13%) and uplands, despite the higher reactive Fe inventory in coastal wetlands. Furthermore, these widespread metastable iron minerals show no evidence of organic carbon saturation in coastal wetlands, highlighting potential for boosting this rusty carbon sink through management practices.

**ABSTRACT**

Nature-based solutions (NBS) involving soil organic carbon (SOC) sequestration may be funded through the voluntary carbon market. However, such credits are issued upon verification procedure relating the sequestration achieved against the baseline assessment. Here we examine two project areas in South Africa and a virtual experiment:

1.Introduction of innovative soil cultivation methods and crop rotation into existing wheat production in the Western Cape province within a field trial conducted by the WC government department of agriculture from 2015 till 2025. The focus was on 0-5cm depth interval, where the most significant changes were expected in the no-till wheat production system. Here, the analysis was conducted using the statistical power of the baseline assessment, continuous yield monitoring and repeated soil sampling.

2. Restoration of degraded coastal thicket in the goat farming area of the Eastern Cape province. Here, the assessment was made for a 30cm fixed depth in stony soils. The method was based on the T-test of baseline sampling (degraded land) against the target values (closed canopy thicket) to optimize the cost/benefit function, where soil sampling and analysis are a significant part of the project implementation cost considering the study area of 10 000 ha with a view of expansion to 200 000 ha. The competing projects are aimed at restoration of 1 million ha of coastal thicket, and all the participants require a robust methodology for baseline assessment, monitoring and audit of SOC credits to compliment the credits generated by restoration of the vegetation.

3. In addition, virtual data sets were created and analyzed to optimize soil sampling and analysis depending on the basic statistics of the baseline and target values taking into consideration the magnitude of the expected intervention effect.

Recommendations are made regarding the calculation of the carbon credits, risk distribution between project participants as well as baseline establishment and adjustment of SOC monitoring time scales and audit frequency depending on the baseline and target statistics.

## ABSTRACT

Straw return is widely regarded as a promising management strategy to enhance soil organic carbon (SOC) stocks; however, the contents and stability of SOC fractions are jointly regulated by straw incorporation methods and tillage intensity. In this study, Fourier-transform infrared spectroscopy (FTIR), metabolomics, and biomarker analyses of amino sugars and lignin phenols were employed to characterize soil carbon fractions and their stability. Combined with microbial community profiling and metagenomic analysis, we further elucidated the dominant pathways of organic carbon turnover in rhizosphere and bulk soils. Specifically, compared with IT, the ST treatment significantly increased POC content and CBH activity in bulk soil and rhizosphere soil by 29.17% and 54.19%, respectively, while significantly decreasing the MAOC/POC ratio by 29.66%. Across all treatments, O-Alkyl C and Aromatic C=C/Alkyl-C in bulk soil showed a potential increasing trend. Relative to ST, IT significantly reduced the NOSC of bulk soil by 1.92% and increased the standard Gibbs free energy (ΔG°Cox) by 0.79%, suggesting that IT enhanced the stability of DOC in bulk soil. Furthermore, compared with IT, ST significantly upregulated the abundance of GH51, GH30, and GH26 genes in bulk and rhizosphere soils; these glycoside hydrolases are involved in the degradation of cellulose and hemicellulose. Collectively, low-disturbance ST rapidly increased POC accumulation, whereas IT was more conducive to enhancing organic carbon stability. Overall, this study provides theoretical support for sustainable agricultural management aimed at strengthening soil carbon sequestration through improved retention of carbon fractions.

evgenia.blagodatskaya@ufz.de

**ABSTRACT**

Realistic estimation of carbon storage in agricultural soils requires long-term field experiments, as the stability of soil organic carbon (SOC) under climate change is strongly influenced by fertilization strategies. We evaluated SOC dynamics in a long-term fertilization trial established in 1902 in central Germany. Over 120 years, combined mineral and organic fertilization increased SOC by 11–34% relative to the unfertilized control. Carbon accumulation slowed down and even turned to C losses after 80–95 years depending on fertilization strategy. We will discuss a potential of mineral and organic fertilization to mitigate the consequences of global warming and maintain long-term SOC stocks.

# Coupling of microbial carbon and energy fluxes in soil

**ABSTRACT**

Microorganisms acquire both carbon (C) and energy required for growth and maintenance from the decomposition of organic substrates in soil. These matter and energy fluxes are tightly coupled according to stoichiometric relationships and the laws of thermodynamics, and unraveling the details of this coupling is essential for our understanding of soil functions mediated by microbes such as nutrient cycling and carbon storage. Recently, the ratio of heat release to $CO_2$ release during the microbial decomposition of organic compounds, the so-called Calorespirometric Ratio (CR), has received renewed attention as a useful tool for study of the bioenergetics of microbial growth in soils (Endress et al., 2024a, b). However, due to the complex and obscure nature of the soil system, measured CR values always require mechanistic models of the underlying processes for proper interpretation. In our study we show how with the help of simple dynamic bioenergetic models the linkage between apparent carbon use efficiency (CUE) and calorespirometric ratio (CR) can be formulated. Maintenance metabolism reduces apparent CUE, while its effects on CR depends on the energy content of the soil organic matter (SOM) or biomass compounds consumed to fuel maintenance. In arable soils, we find a close linear relationship between maintenance CR and average SOM energy content, while there is no clear pattern in forest soils.

# Enhancing soil carbon sequestration and straw utilization through optimized microbial decomposition strategies

**Shuaimin Chen*, Haiyan Wu, Hongguang Cai**

*Institute of Agricultural Resource and Environment, Jilin Academy of Agricultural Sciences,Changchun, China*

*E-mail: shmchen1991@126.com

**ABSTRACT**

Straw retention—through direct incorporation or composting—has emerged as a promising agricultural practice to enhance soil productivity and optimize straw resource utilization. To address the challenge of slow straw degradation, this study constructed high-efficiency microbial consortia for rapid straw decomposition and investigated their functional mechanisms.Straw-degrading strains were isolated from straw, soil, and compost samples, followed by evaluation of their carboxymethyl cellulase activity, filter paper disintegration capacity, and straw degradation efficiency. Two specialized microbial consortia were constructed based on temperature adaptation: a low-temperature resistant consortium (LRC) for direct straw incorporation and a high-temperature composting consortium (HCC) for enhanced decomposition under thermophilic conditions. For the LRC, a field experiment was designed with two tillage methods (straw mulching and deep tillage), and three treatments (non-microbial consortium, with microbial consortium, and without straw retention). Deep tillage with straw returning enhanced subsoil carbon sequestration and facilitated homogenization of microbial functions and communities across soil depths, potentially enhancing soil carbon capture and storage. In addition, applying the decomposition microbial consortium could improve the straw decomposition rate and increase SOC storage. For the HCC, three composting treatments were designed, including the treatment using only cattle manure (CK), the treatment mixing cattle manure and maize straw (CS), the treatment involving cattle manure, straw, and microbial consortium (CSM). The results showed that straw additives improved the formation of a diverse aerobic bacterial community and a unitary thermophilic fungal community, and promoted a stronger relationship between the bacterial and fungal communities.Furthermore, the CSM treatment could effectively increase the composting temperature, and improve the quality of the composting products. This study aimed to provide a critical basis and References for optimizing straw retention techniques and enhancing soil carbon sequestration capacity, thereby promoting sustainable agricultural development.

# Latitude-dependent temperature thresholds reverse soil organic carbon losses in global Mollisol croplands

**Xiangtian Meng**[1*]

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun 130012, China*

*mengxiangtian@iga.ac.cn

**ABSTRACT**

Soil organic carbon (SOC) in Mollisol croplands plays a crucial role in sustaining agricultural yields and combating climate change. Nevertheless, its spatial and temporal variations in these areas are still not well characterized, especially in the context of global warming. We integrated 5,535 field soil samples with over 1 million Landsat images using a hybrid probability deep learning framework to produce high-resolution SOC stock maps for global Mollisol croplands from 1990 to 2020. Our results show a 5.59% decline in SOC stocks over the past three decades, characterized by pronounced spatial heterogeneity and clear latitudinal gradients. Climate—especially temperature—emerges as the primary driver of SOC variability and change, even in intensively managed agricultural systems. Notably, we identify a nonlinear threshold response: while warming initially accelerates SOC losses, gains emerge when the rate of temperature change exceeds 0.034 °C/yr. This threshold increases from high to low latitudes, consistent with the theory of ecosystem thermal adaptation. By 2050, more than 60% of Mollisol cropland is expected to exceed this threshold, indicating the emergence of warming-enabled carbon reversal zones. These findings challenge linear assumptions in soil–climate feedbacks and offer a spatially explicit basis for climate-resilient soil carbon management under future warming.

*rgtang@zafu.edu.cn

**ABSTRACT**

Earthworms play crucial roles in regulating soil organic carbon (SOC) and greenhouse gas emissions in forest soils. Laboratory studies have proven that they promote soil carbon dioxide ($CO_2$) emissions. However, the effects of earthworm activity on forest soil $CO_2$ emissions and organic carbon (C) have not yet been quantified in situ, and the impact of different earthworm densities remain unclear. In this study, we investigated how earthworm (*Pheretima guillelmi*) activity at three densities (no earthworms, original density, and double the original density) affected SOC, its labile fractions, C-related enzyme activities, and soil $CO_2$ emissions in a Moso bamboo (*Phyllostachys edulis*) forest ecosystem over a six-month field experiment. Our results showed that the original earthworm density resulted in a 23.4% increase in soil $CO_2$ emissions, while double the original earthworm density resulted in a 9.6% reduction in emissions compared to the original density. Additionally, earthworms at both densities significantly increased the concentration of SOC and its labile fractions. Notably, the increase in SOC density (SOCD, SOC stock per unit land area, kg C $ha^{-1}$) induced by earthworm activity far exceeded the increase in $CO_2$-C emissions. Specifically, the earthworms at double the original density led to an 8.8-fold increase in SOCD, while the original density resulted in a 3.7-fold increase. Furthermore, our findings identified dissolved organic C (DOC) as the most critical labile organic C fraction influencing soil $CO_2$ emissions associated with earthworm activity, while β-glucosidase (BG) was the most significant C-related enzyme affecting soil $CO_2$ emissions driven by earthworm activity. These results provide important insights into the role of earthworms in both $CO_2$ emissions and SOC accumulation in subtropical forests.

# Impact of long-term tillage on the soil organic carbon storage and its composition in black soil

**Pengxiang SUI, Yang Luo, Hao WANG, Ying REN, Xiaodan LIU, Ye Yuan, Jinyu ZHENG***

*(Institute of Agricultural Resources and Environment, Jilin Academy of Agricultural Sciences (Northeast Agricultural Research Center of China)/Northeast Key Laboratory of Crop Physiology, Ecology and Cultivation, Ministry of Agriculture and Rural Affairs, Changchun 130033, Jilin, China)*

*E-mail Address of Presenting Author: 15844052867@163.com

**ABSTRACT**

Soil organic carbon (SOC) is essential for maintaining soil fertility and promoting sustainable agricultural development. This study investigates the impact of long-term tillage practices on soil organic carbon storage (SOCS) and its components in dryland farming areas of the thin black soil region, based on a 40-year tillage practices experiment. It compares the effects of different tillage practices (Conventional rotary and ridge tillage, CT; no-tillage, NT; subsoiling tillage, ST; moldboard plowing, MP) on SOCS, active organic carbon components, and microbial necromass carbon (MNC) content in the 0~40 cm soil layer. The results showed that, compared to CT, NT significantly increased SOCS, SOC, dissolved organic carbon (DOC), microbial biomass carbon (MBC), easily oxidizable organic carbon (EOC), and MNC content in the 0-20 cm soil layer. Both ST and MP significantly improved SOCS, SOC, and EOC content in 0-20 and 20-40 cm soil layers compared to CT and increased MBC content in the 20-40 cm soil layer. Additionally, MP treatment significantly improved DOC, particulate organic carbon, and MNC content in the 20-40 cm soil layer compared to other treatments. ST and MP significantly reduced the contribution rate of MNC to SOC in both soil layers compared to CT and NT treatments. Structural equation modeling revealed that enhancing the mean weight diameter of soil aggregates, field capacity, and total phosphorus content, along with increasing $\beta$-glucosidase, amylase, and lignin peroxidase activities, could promote MNC accumulation. MP treatment facilitates the uniform distribution of SOC, active organic carbon, and MNC in the 0-40 cm soil layer, which is more conducive to the fixation of SOC in farmland in the thin black soil region.

## ABSTRACT

Soil biogeochemical models are widely used to simulate and predict soil organic carbon (SOC) dynamics, incorporating physical, chemical, and biological processes. These models vary significantly in structure, input parameters, and initial conditions, leading to considerable uncertainty in predictive outcomes.

SOC models are broadly categorized into process-based models (e.g., RothC, CENTURY, DNDC, EPIC) and statistical regression models. Process-based models simulate soil property changes by representing specific processes, making them suitable for small- to medium-scale simulations. However, they require regional calibration, and some parameters are difficult to obtain, limiting their performance at larger scales.Recent advancements increasingly integrate microbial processes, such as microbial enzyme activities, dormancy, and necromass production, to enhance SOC turnover simulations.

Machine-learning models, a key example of statistical models, autonomously learn from complex nonlinear relationships without empirical parameters. With the evolution from traditional machine learning to deep learning, their capabilities have significantly improved. Neural networks and random forests are widely applied in agriculture, studying the impacts of management measures on soil environments and crop yields across spatial and temporal scales.

This report, based on the reporter's studies, provides an in-depth exploration of the performance and application methodologies of mainstream SOC prediction models in agricultural environments. It systematically analyzes and compares the advantages and limitations of three distinct model categories—simple process-based models, complex mechanistic models, and statistical models—across varying spatial and temporal scales. The analysis highlights how these models differ in their ability to capture SOC dynamics, from field-scale processes to broader regional patterns, while addressing challenges such as parameterization, data requirements, and computational efficiency.

Looking ahead, the report also examines the future trajectory of biogeochemical models, emphasizing emerging trends such as integration of microbial processes, advancements in machine learning for model calibration, and enhanced coupling with other technologies. Furthermore, it discusses the pivotal role these models are expected to play in agricultural production practices, including precision farming, carbon sequestration strategies, and climate-smart agriculture initiatives, ultimately contributing to more sustainable and resilient food systems.

# Stover incorporation enhances soil carbon sequestration by improving the hydrophobicity of humic acid and soil water repellency

**Boyan Zhang[1], Sen Dou[1*], Song Guan[1], and Dan Guo[1]**

[1] *College of Resource and Environmental Science, Jilin Agricultural University, Changchun 130118, China*

* dousen1959@126.com

**ABSTRACT**

The hydrophobicity of humic acid (HA) refers to the repulsive ability between HA, a component of soil humus, and water molecules, as well as its tendency to bind to non-polar substances. The core of the HA molecule is a polycyclic aromatic hydrocarbon skeleton, to which a large number of long-chain alkyl and aliphatic carbon groups are attached, and these groups are the main source of hydrophobicity. Soil water repellency (SWR) is a property that reduces soil's affinity for water and keeps water on the soil surface, which is mainly induced by hydrophobic organic matter covering the surface of soil particles. The two most common methods for characterizing SWR are contact angle and water drop penetration time. Stover incorporation is a core measure to increase soil carbon input, but it has problems such as rapid carbon decomposition and loss after incorporation. Traditional studies on soil carbon sequestration have mostly focused on macro aspects such as soil organic carbon (SOC) content and physical protection of aggregates, or micro mechanisms such as individual microbial decomposition, lacking systematic correlation analysis of "micro molecules-soil functions-carbon sequestration". HA molecules with strong hydrophobicity are difficult for microorganisms to contact and degrade, and can remain in the soil for a long time in the form of recalcitrant organic carbon; moderate SWR slows down water infiltration, maintains the air-water balance in soil pores, promotes the slow decomposition of SOC, and reduces carbon loss. This study takes HA hydrophobicity and SWR as the entry points to study soil carbon sequestration, because the two can multi-dimensionally reveal the intrinsic mechanism of soil carbon sequestration after stover incorporation from the perspectives of soil chemical and physical properties, as well as micro molecular structure and soil functions. The results showed that compared with the no-stover treatment, continuous full-rate stover incorporation for 5 years promoted HA formation and increased HA hydrophobicity by 21%; SOC content increased by 9.8%, and maize yield increased by 23%. A further experiment on one-time stover incorporation for 10 years showed that compared with conventional tillage, in the 3rd year after incorporation, HA hydrophobicity and SWR increased by 10% and 122% respectively, and SOC content increased by 24.1%. However, this effect began to weaken after 3 years and completely disappeared after 7 years. Stover incorporation enhances soil carbon sequestration capacity by regulating HA hydrophobicity and SWR, which is a suitable measure that balances carbon sequestration and crop yield increase. By demonstrating the relationship between HA hydrophobicity, SWR and SOC under specific conditions, this study provides a new perspective for observing soil carbon sequestration capacity.

# Crop diversity enhances soil total carbon via increasing inorganic carbon concentration

**Chuanlin Xiao[1*], Naihao Ji[1], and Long Li[1]**

[1](*College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*)

*E-mail Address: xiaocl4804@163.com

**ABSTRACT**

Numerous studies have demonstrated that increasing crop diversity can significantly enhance soil organic carbon (SOC) sequestration; however, its effects on soil inorganic carbon (SIC) remain poorly understood. At present, we evaluated the effects of maize/faba bean intercropping, N application rates, and inoculation rhizobia of faba bean on SIC in the top 20 cm of soil depth using a 13-year crop diversity field experiment.

The results showed that long-term faba bean/maize intercropping significantly increased soil total carbon (TC) concentration by 5.9 % and 7.0 % compared to faba bean monoculture and maize monoculture, respectively. Intercropping increased pedogenic carbonates (PIC) by 36.7%, thereby increasing SIC by 8.9% compared with faba bean monoculture. In addition, intercropping alleviated lithogenic carbonates (LIC) dissolution by 17.5%, which contributed to a 7.6% higher SIC content relative to maize monoculture. The formation of PIC was closely associated with increased concentrations of exchangeable $Ca^{2+}$ in soil, whereas the preservation of LIC was related to changes in SOC derived from $C_4$ crops and exchangeable $Mg^{2+}$ concentrations. In addition, inoculation of faba bean with rhizobia led to a decrease in soil pH, which consequently resulted in a reduction in soil inorganic carbon content.

Overall, our findings indicate that increasing crop diversity not only enhances SOC sequestration but also promotes total soil carbon sequestration by increasing SIC concentration. Our study highlights the importance of considering changes in inorganic carbon in the soil for accurately assessing the carbon sequestration potential of agricultural management practices. This study provides a theoretical basis for improving soil carbon sequestration and promoting sustainable agricultural development.

**ABSTRACT**

Black soils (Chernozem, WRB) in China, very fertile due to its high SOC content and crop productivity, are distributed primarily in the northeast region of China, which is one of the three largest black soils area in the world. It is the most important soil resources and plays a critical role in ensuring food security in China. Carbon (C) sequestration on farmland ecosystem is of great importance in the terrestrial C cycle. Increasing soil organic C (SOC) sequestration not only will helpfully mitigate atmospheric $CO_2$, but also improve soil quality and ensure regional food security. It is well known that high soil fertility in agriculture is the improvement target pursued for the medium and low fertility soils in that it has the higher nutrients and the greater sequestration potentials of soil organic carbon (SOC). Based on this, we put forward that the cropland SOC content of high soil fertility would be the greatest and relative stable at the current conditions of agricultural management, soil properties and natural environment in the continuous cropping system, which was regarded as the SOC balance point (SOCb). The SOC sequestration potential (SOCsp) was the amount of SOC at the SOCb state. Afterwards, a SOCb statistical model ($R^2$=0.85) in the Chinese black soil dryland region was built using 52 topsoil samples (0-20cm) of high soil fertility with a model verification by other 23 high fertility samples, driven by the factors of annual mean temperature, annual precipitation, annual effective accumulative temperature, the ratio of precipitation and temperature, soil clay content and pH. The regional mean SOCb was estimated by 39.98 g/kg, and the regional mean SOCsp and the regional largest SOC storage would be 8.97 kg/m$^2$ and 522.92 Tg, respectively. The sensitivity analysis of this model showed that the high SOCb area distributed in the areas with low temperature, dry, high clay content and low pH, while the low SOCb area distributed in the areas with high temperature, wet, low soil clay content and high pH. Moreover, the means of regional SOC content in medium and low soil fertility levels could be increased by 13.17 g/kg and 23.98 g/kg between SOCb and them, respectively. As well, the means of increased regional SOC density in medium and low soil fertility levels could be 2.30 kg/m$^2$ and 4.57 kg/m$^2$ between SOCsp and them, respectively. Furthermore, the means of increased regional SOC storage in medium and low soil fertility levels could be 153.07 kg/m$^2$ and 252.35 kg/m$^2$ between the regional largest SOC storage and them, respectively. The study would give an important support to estimating regional SOC sequestration potential from the view of the differences of cropland soil fertility levels in order to more reasonably guide the current soil fertility improvement.

# How Spatial Resolution Shapes Soil Carbon Estimates

**Bradley A. Miller[1*] and Michael L. Thompson[1]**

[1] *Agronomy Department, Iowa State University, Ames, Iowa 50011, USA*

*E-mail Address of Presenting Author: millerba@iastate.edu

**ABSTRACT**

Understanding the influence of spatial resolution on geographical calculations is critical for accurately interpreting soil data and optimizing sampling strategies in agronomic and environmental studies, such as estimating field-scale carbon stocks. This study examines the impact of variations in data resolution, achieved through adjustments in observation density and spatial modeling of unsampled locations, on both the estimated field-scale organic carbon and its associated uncertainties. We utilized a synthetic spatial dataset, derived from 143 real-world observations, to serve as a geographic field with known values for all locations. This hypothetical field with known organic carbon stock values at each point (0–30 cm depth) served as the "ground truth." From this baseline, we applied multiple sampling designs and densities to compare calculated carbon stocks and their uncertainties with one another. Additionally, we tested the effect of spatial modeling to generate finer-resolution estimates with fewer direct observations. Results indicate that coarser resolutions consistently reduce apparent spatial variability while inflating uncertainty. Conversely, finer resolutions capture small-scale heterogeneity but require sufficient sampling density to avoid high prediction uncertainty. These findings demonstrate that variability in estimating field-level soil properties is influenced not only by measurement error but also by the choice of spatial resolution. Both estimated values and their uncertainties are resolution-dependent, raising the question of what level of certainty is necessary – in the context of measurement error - for confident carbon stock assessments in practical applications. This work provides a framework for identifying thresholds beyond which additional sampling yields diminishing returns under both direct measurement and spatial interpolation scenarios, offering guidance for researchers, practitioners, and policymakers who rely on spatial data analysis.

## ABSTRACT

Soil carbon sequestration is a key strategy for mitigating climate change, as soil is the largest terrestrial carbon sink. Quantifying Soil Organic Carbon (SOC) stocks requires accurate data on carbon concentration, bulk density, and gravel content. However, conventional bulk density measurement methods rely on destructive sampling, which is labor-intensive and time-consuming, especially given soil's high spatial heterogeneity. While hyperspectral imaging has advanced non-destructive carbon concentration estimation, non-destructive bulk density measurement methods remain limited. The thermal conductivity method, based on the simplified de-Vries model, offers a promising non-destructive alternative. However, models validated in laboratory settings often neglect in-situ heterogeneity, particularly gravel presence. This study aims to quantify the impact of gravel content on thermal conductivity-based bulk density estimation and refines the model for better field application. Experiments used 20 mL conical tubes to measure thermal conductivity under controlled conditions. Soil samples included three grassland soils (Sandy Loam, Silty Clay Loam, Loam) and one paddy soil (Sandy Loam). Gravel content was varied using 2–4 mm granite at weight ratios of 0, 0.1, and 0.2, and water content adjusted to 0, 0.1, and 0.2. A total of 108 measurements were taken with a TEMPOS thermal properties analyzer and SH-3 sensor. Results showed gravel significantly reduced the conventional model's accuracy. The model fit gravel-free soils reasonably well ($R^2$=0.735) but dropped sharply with gravel ($R^2$ : 0.488–0.530). To improve this, parameters ($\lambda_{soil}$ and $g_a$ (soil)) of the simplified de-Vries model were modified to include gravel as part of the soil matrix. The enhanced model showed better performance: $R^2$ increased from 0.571 to 0.602, and Standard Error (SE) decreased from 0.127 to 0.121. A rigorous 95% Confidence Interval (CI) evaluation confirmed robustness. Both models met the 1:1 correspondence condition, but the improved model had narrower CI widths for slope (0.316 to 0.301) and intercept (0.455 to 0.434), indicating greater precision and less uncertainty. This study quantified gravel's confounding effects and proposed a refined, more accurate model. Future work will extend to various lithogenic materials and consider in-situ factors like root biomass. This advancement is vital for integrating soil sensing with Physical AI, enabling real-time, high-resolution monitoring of soil carbon stocks to support global carbon management.

# Parameters Optimization of RothC Model for Simulating Soil Organic Carbon Dynamics: A Case Study of Rice Straw and Soybean Residue Inputs

**Chien-Kai Liao[1] and Kai-Wei Juang[1]***

[1] Department of Agronomy, National Chung Hsing University, Taichung, Taiwan

*E-mail: kwjuang@dragon.nchu.edu.tw

**ABSTRACT**

Soil is one of the most potential carbon sinks globally, and accurate estimation of its organic carbon stock is crucial for enhancing carbon sequestration and developing effective climate change mitigation strategies. The Rothamsted Carbon Model (RothC) is a widely used tool for simulating soil carbon dynamics. It conceptualizes soil organic carbon (SOC) as five compartments: decomposable plant material (DPM), resistant plant material (RPM), microbial biomass (BIO), humified organic matter (HUM), and inert organic matter (IOM). The SOC variation is modeled through transfer rates among these compartments. Key input parameters, including climate data, plant residue carbon inputs, and the DPM/RPM ratio, strongly influence the model's performance and prediction accuracy. This study aimed to optimize the parameters related to plant carbon input and the DPM/RPM ratio in the RothC model to improve simulation accuracy. A long-term incubation experiment was conducted using three representative soil types (Lugang, Pingzhen, and Dapaisha), three temperature regimes (15, 25, and 35 °C), three moisture conditions (flooded, field capacity, and 60% of field capacity), three residue treatments (no residue, rice straw, or soybean residue at 1%, 2%, and 5%), and eight incubation periods (0.5, 1.5, 3, 6, 9, 12, 15, and 18 months). The estimation of the DPM/RPM ratio was based on SOC changes per unit time obtained from the incubation experiment. First, the decomposition rate of fresh organic matter ($k_1$) was derived from the initial carbon loss curves of each residue treatment. During the incubation process, when $k_1$ gradually reached a stable state, this stable phase was used to estimate the decomposition rate of the RPM fraction. The DPM and RPM proportions were then adjusted to control the relative contributions of the fast and slow decomposing pools. The optimal DPM/RPM ratios for soybean and rice residues were 1.44 and 0.75, respectively. The ratio for soybean was close to the default value for general crops in RothC. Adjusting the DPM/RPM ratio for rice residue to 0.75 reduced both the root mean square error (RMSE) and coefficient of variation (CV%), demonstrating that this adjustment effectively improved RothC's ability to simulate SOC dynamics in paddy soils. These findings provide essential parameterization References for future modeling of carbon sequestration in rice-based systems.

# An Integrated Framework Combining Spatial Soil Carbon Information and a Calibrated RothC Model for Improving Cropland SOC Estimation

**Kyeongyeong kim[1*], Sang Ho Jeon[1], Ahnsung Roh[1], Seon Ah Hwang[1], and Seong Heon Kim[1]**

*[1] Soil and Water Environment Division, National Institute of Agricultural Sciences, RDA, Wanju, Korea*

*kky0808@korea.kr

**ABSTRACT**

Cropland soil organic carbon (SOC) is recognized as an important carbon sink in national greenhouse gas inventories under the Land Use, Land-Use Change and Forestry (LULUCF) sector. However, the current IPCC Tier 1–2 soil carbon estimation methods are based on static coefficients and simplified equations, which limits their ability to adequately capture gradual soil carbon accumulation resulting from changes in soil management practices. In contrast, the results from Monitoring project on agri-environmental quality in Korea indicate a gradual increase in soil organic matter in croplands, highlighting the need for an advanced methodological framework that incorporates observation-based SOC dynamics into inventory estimation.

This study aims to improve cropland SOC sequestration estimation by proposing an integrated methodological approach that combines nationwide spatial SOC information with the Roth C model calibrated for domestic conditions. Nationwide cropland SOC maps were developed by integrating national soil testing program data with national soil survey data to establish spatial SOC baseline conditions. In addition, long-term organic matter amendment experiments were comprehensively analyzed to calibrate key Roth C model parameters for Korean cropland soils. This framework enables a more realistic simulation of SOC dynamics in response to soil management and organic matter inputs.

Overall, this study presents the applicability of a cropland SOC estimation methodology that reflects site-specific soil characteristics and long-term observational data, thereby providing an alternative to conventional coefficient-based approaches. The proposed framework is expected to serve as a methodological foundation for quantifying management-induced SOC sequestration in croplands and for advancing national greenhouse gas inventories toward IPCC Tier 3-level reporting.

## ABSTRACT

Long-term application of straw and composted manure has received considerable attention for its enhancement of soil fertility and carbon sequestration. However, their combined application may provide even greater potential for soil organic carbon (SOC) formation and accrual. To elucidate the mechanisms underlying SOC accumulation under this practice and to inform nutrient management strategies, we collected paddy soils with low (10 g $kg^{-1}$) and high (20 g $kg^{-1}$) initial SOC levels. These soils were subjected to unfertilized control (CK), 10 t $ha^{-1}$ $^{13}C$-labeled straw returning (SS), composted manure with the same C content as 10 t $ha^{-1}$ straw returning (MM), 5 t $ha^{-1}$ $^{13}C$-labeled straw with composted manure with the same C content as 5 t $ha^{-1}$ straw returning (SM), and 10 t $ha^{-1}$ $^{13}C$-labeled straw with composted manure with the same C content as 10 t $ha^{-1}$ straw (SSMM), followed by indoor incubation for 30 and 150 d. Microbial metabolism and SOC contribution were assessed using $^{18}O$-$H_2O$ incubation and $^{13}C$ biomarker tracing techniques. Our results demonstrate that SOC accumulation was significantly enhanced under both low and high-C conditions with SSMM practice, and more effective in promoting straw-derived C contribution. Particulate OC contributed more to SOC accumulation than mineral-associated OC, significantly increased microbial diversity and the elevated of necromass C was primarily from bacterial necromass. Furthermore, microbial survival strategies shifted from K to r-strategists under combined treatment. Mechanistic modeling indicated that under low-C condition, SOC accumulation at SM was primarily driven by nutrient availability and microbial pathways, whereas at SSMM microbial community and metabolism became dominant roles. In contrast, under high-C condition, soil nutrient availability and microbial community structure directly promoted SOC accrual, while microbial metabolism exerted a negative effect—likely due to elevated microbial respiration and reduced C use efficiency, resulting in shorter C turnover times. In conclusion, the study highlights the critical role of composted manure in enhancing SOC contribution through its regulatory effects on nutrient availability and microbial metabolism functioning in paddy soils. These findings suggest that the optimal rates of combined organic amendments can significantly improve nutrient supply and straw-derived C sequestration in rice-based agro-ecosystems.

## ABSTRACT

Considering the pivotal influence soil organic carbon (SOC) on soil physical, chemical, and biological properties, it is considered a key indicator of soil health. Agriculture has globally reduced SOC, trough processes that are important to understand and reverse. This means that it is important to determine SOC variations over a timeframe that allows managers to adjust agricultural practices according to their actual impact. However, detecting SOC changes over short timeframes remains challenging, due to its characteristically slow rate of variation. Depending on the geographic location and the magnitude of SOC fluctuation, minimum sampling intervals of 10 to 20 years can be required to accurately detect changes.

Labile C fractions exhibit greater sensitivity to management practices, compared to total SOC, making them valuable early indicators of soil carbon dynamics. On the other hand, SOC plays a fundamental role in soil structure, by acting as a binding agent for stable aggregate development, which in turn protects SOC from microbial decomposition. Consequently, soil structure indicators have been recognized as effective short-term proxies for detecting SOC variations. In addition, SOC models can enhance the accuracy of SOC change estimates by incorporating critical variables, such as soil type, climate conditions, management practices, and baseline SOC concentrations.

In Portugal, the absence of a comprehensive soil health monitoring system and long-term experimental fields has constrained the investigation of SOC and other soil properties dynamics. Nevertheless, significant progress has been achieved through the development of INFOSOLO, a geoReferencesd open-access database containing nationwide soil property data collected since 1966. Furthermore, few studies have examined variations in SOC and labile SOC fractions under different management practices. no

The main objective of this work is to comprehensively assess SOC, SOC fractions, soil structure, and management practices, to develop a framework for detecting short-term SOC variations and projecting long-term changes, resulting from different management practices. To achieve this goal, a two-phase approach is necessary: (1) to identify sites with historical soil properties data (via INFOSOLO), where agricultural practices can be tracked, enabling analysis of long-term variations (>10 years) in SOC, SOC fractions, and soil structure across different management practices and pedo-climatic regions; and (2) to analyse correlations among SOC fractions, soil structure indicators, and management practices, combined with SOC modelling, to develop a robust framework for detecting short-term variations and inferring long-term trends. Preliminary results from a selected case study will be presented herein.

## ABSTRACT

Engineering waste soils known as Anthrosols derived from subsoil typically possess an undeveloped structure and extremely low organic matter content. Rapid restoration via co-composting with organic wastes such as seafood sludge, manure, and straw has been demonstrated as an effective engineering approach for soil reconstruction. However, the dynamic evolution of soil organic carbon (SOC) fractions and their underlying stabilization mechanisms during this intensive process remain poorly understood. This study investigated the transformation processes of both labile and stable carbon pools, specifically focusing on the pivotal role of microbial necromass carbon (MNC) in driving carbon accumulation and stabilization.

A 17-day intensive amendment experiment was conducted using waste soils from a coastal engineering project in Yuhuan, China. By integrating physical fractionation of particulate organic carbon (POC) and mineral-associated organic carbon (MAOC) with amino sugar biomarkers, we tracked the transition of sequestered carbon through three distinct evolutionary stages.

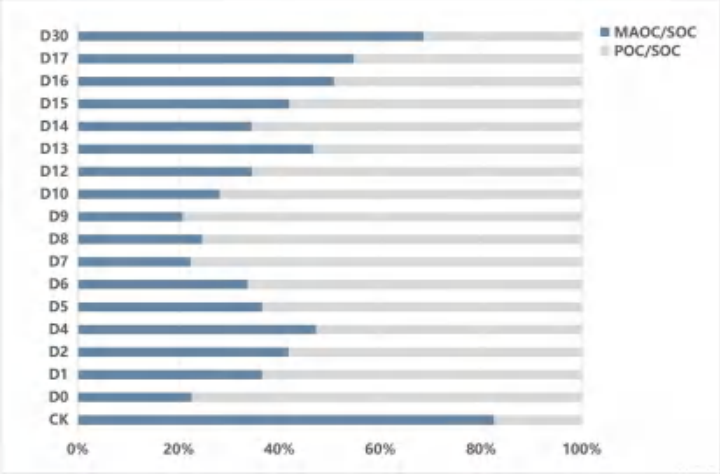

**Figure 1 Dynamics of the ratio of Mineral-associated Organic Carbon to Particulate Organic Carbon (MAOC/POC) during the 17-day co-composting process of engineering waste soil. CK represents the control group of raw waste soil without any organic amendments.**

The results revealed that the MAOC to POC ratio followed a characteristic decrease-increase-decrease trend, reflecting the complex biochemical responses of the soil system. In the initial stage from day 0 to day 4, the input of labile organic matter triggered a bacterial bloom. The rapid accumulation of unstable POC significantly outpaced the formation of MAOC. This led to a sharp decline in the MAOC to POC ratio and represented a state of carbon pool imbalance. In the second stage from day 4 to day 10, a successional shift toward fungal dominance was observed as indicated by the recovery of the fungal to bacterial residue ratio. This shift activated the microbial carbon pump (MCP), which facilitated the efficient conversion of exogenous carbon into MNC. Consequently, the MAOC to POC ratio rose significantly as MNC became the primary driver for MAOC accumulation. In the final stage from day 10 to the maturation of the nutrient soil, the ratio exhibited a slight decline as the system reached a state of re-equilibrium. This indicates that the carbon pool transitioned from violent fluctuation to a relatively stable dynamic balance during the maturation of the artificial soil.

In conclusion, this study demonstrates that microbial necromass plays a crucial role in the early-stage accumulation and stabilization of organic carbon in reconstructed engineering soils. The three-stage evolution of carbon fractions provides a mechanistic framework for optimizing waste soil formulations. These findings suggest that engineering waste soils can be transformed into stable carbon sinks within a remarkably short timeframe through microbial-mediated pathways.

## ABSTRACT

Carbon sequestration by arable soils is a key element of low-carbon development strategies. Improving the accuracy of assessing this potential is important for fulfilling Russia's climate policy objectives and transitioning to the third level of the IPCC methodology, which requires the use of national monitoring data.

Based on simulation modeling, the possibility of controlling carbon sequestration and the expected dynamics of organic C stocks in the arable layer of chernozems and sod-podzolic soils were assessed through the implementation of a set of carbon-saving technologies based on the RothC carbon model.

To increasing the detail of modeling a methodology for calculating net primary products based on national statistical data from the Russian Federation was developed and tested. Using data on crop yields and cultivated areas obtained at the municipal level, the biomass of plant residues and carbon input into the soil were calculated.

Refinement of estimates of carbon sequestration compared to the FAO GSOCseq project methodology shows an increase in the rate of sequestration by arable soils. Thus, for the Rostov Region, estimates based on global models that characterized the region as a weak carbon emitter (-0.007 t C·ha$^{-1}$·year$^{-1}$) changed when statistical data was used to show a small but steady accumulation (0.032 t C·ha$^{-1}$·year$^{-1}$) even with business as usual scenario. With the implementation of sustainable soil management scenarios, the sequestration potential could increase to 0.161 t C·ha$^{-1}$·year$^{-1}$, which makes the region one of the most promising ones for the introduction of carbon farming.

The possibility of achieving a carbon accumulation rate of 4 ppm in arable soils is demonstrated. Dynamic modeling of sequestration processes has significantly expanded the value of databases from long-term field experiments with fertilizers as sources of local data on the prospects for managing $CO_2$ sequestration and emissions in order to avoid possible losses of soil carbon and maximize the benefits provided by expected climate change. With high initial carbon stocks in arable chernozems, the role of organic fertilizer forms and rates in sequestration management increases. Under future climate conditions, the non-Chernozem zone is quite promising in terms of both the absolute values of soil carbon sequestration and the duration of this process.

**Acknowledgments**

The research was carried out as part of the most important innovative project of national importance "Development of a system for ground-based and remote monitoring of carbon pools and greenhouse gas fluxes in the territory of the Russian Federation, ensuring the creation of recording data systems on the fluxes of climate-active substances and the carbon budget in forests and other terrestrial ecological systems" (Registration number: 123030300031-6)."

# Soil Carbon Sequestration: Realism versus Potential

**William R. Horwath**[1*]

[1] *Department of Land, Air and Water Resources, Universality of California, Davis, USA*
wrhorwath@ucdavis.edu

**ABSTRACT**

Climate change and food insecurity are the two major threats to humankind and both are linked to global cycling of C. Soil acts as a sink for both natural and anthropogenic $CO_2$ in short and long-term global C cycles. The main question is "Can soils act as a short and long-term sink to remove ever increasing amounts of $CO_2$ due to anthropogenic release of fossil C into the atmosphere". The short-term C cycle is dominated by biological processes of net primary production (NPP) and net secondary production (NSP). The long-term Cycle represents more permanent storage such as sedimentary rock. Soil organic carbon (SOC) is one of the most important characteristics of soils that result from the interplay of net primary producers, soil biomass and mineralogy. Decomposers particularly the soil microbial biomass are the main players of the NSP but are dependent NPP as a source of autotrophic C that they degrade into products that eventually stabilize into the soil matrix. The resulting soil organic matter is the foundation of ecosystems, providing the necessary resources to drive NPP. The stabilization of SOC with reactive minerals, particularly clays and short-range order and metal oxide minerals, provide a matrix that supports soil structure and function, increases moisture holding capacity and contains nutrients that allows net primary producers such as crops to thrive. The importance of SOC to support food and fiber production cannot be understated. Recent studies and in particular predictive efforts have supported the 4 per mil initiative (COP21) that suggests an increase in global SOC stocks by 4 per mille (or 0.4 %) per year or 3.6 to 4.3 Gt C is possible and could consume up to 40% of annual fossil C emissions. To meet this lofty goal, global soils on average would need to sequester 1.5Gt annually. Yields for major world grain crops (e.g., wheat, rice, maize) typically range from 4 to 8 metric tons per hectare (t/ha) with an equivalent amount of crop residue return. This means that 19 to 38% conversion of crop residue and root inputs into SOC. Some productive temperate climate areas may be able to achieve these yields goals, however lower producing areas such as arid climates will be lower requiring higher yielding areas to be more productive. These issues including cost and societal benefit will be covered to help in understanding the limits of C-sequestration in soils.

*E-mail Address: *lilujun@iga.ac.cn*

**ABSTRACT**

Black soils in Northeast China, classified as Isohumisols in Chinese Soil Taxonomy, are critical for national food security, contributing 25% of China's total grain output (64% soybean, 42% corn, 19% rice in 2022) and covering 18.53 million hectares across Heilongjiang, Jilin, Liaoning, and Inner Mongolia. Characterized by high soil organic carbon (SOC), total nitrogen, and clay content, these soils face severe threats of SOC loss and degradation. The study synthesizes dynamics of SOC and its mineralization processes, along with driving factors and mitigation strategies. Long-term monitoring (1980–2011) shows that Northeast China's black soils are the only region with declining SOC nationally: average loss of -0.41 Mg C $ha^{-1}$, compared to a national increase of 4.34 Mg C $ha^{-1}$. In Heilongjiang Province, ~85% of black soil areas exhibit SOC reduction, with Hailun (-19.1%), Baoqing (-11.2%), and Liandian (-0.49 Mg C $ha^{-1}$ $yr^{-1}$) being severely affected. Key drivers of SOC decline include intensive tillage, straw removal/burning, and climate warming. Across the geographic gradient of Northeast China's black soil region, fungal diversity and mineral protection enhance SOC accumulation via microbial necromass and mineral-associated organic carbon. Long-term full straw return with NPK fertilizer increases SOC by 14.2% (9.5‰ $yr^{-1}$) over 15 years, with maize-derived C contributing more than soybean. Regarding SOC mineralization, straw return induces a positive priming effect but reduces temperature sensitivity. Microbial biomass and nutrient availability regulate priming effect: higher microbial biomass promotes SOM-derived DOC/MBC production, while N addition suppresses priming effect. Environmental conditions (temperature/moisture) interact with SOC content, with the highest PE at 45% water-holding capacity and 22°C; drought dampens $Q_{10}$, supporting the carbon quality-temperature hypothesis. China has implemented national actions, including the National Black Soil Protection Project (2021–2025) and conservation tillage. Optimized agricultural management (organic input, conservation tillage, crop rotation) is vital to reverse SOC loss and sustain black soil fertility.

## ABSTRACT

Soil organic carbon (SOC) plays a critical role in ensuring food security and addressing climate change. This study, based on a regional-scale soil quality geochemical monitoring network established by the China Geological Survey (covering approximately 2.6×10$^5$ km$^2$), systematically analyzed the spatiotemporal evolution characteristics and driving mechanisms of SOC in the Northeast China Plain. A total of 1910 and 1920 topsoil samples were collected in 2005 and 2018, respectively, and analyzed using empirical Bayesian kriging interpolation and random forest methods. The results indicate that: (1) SOC density ranged from 0.83 to 8.79 kg·C·m$^{-2}$ (median: 3.25 kg·C·m$^{-2}$). The spatial distribution of SOC exhibited significant zonal characteristics, with concentrations gradually increasing from the southwest to the northeast. Soil SiO2 content, Fe2O3 content, and mean annual precipitation were identified as the primary driving factors, explaining 38.2%, 18.8%, and 13.3% of the spatial variability, respectively, while other factors such as topography, NPP, and NDVI showed relatively weaker explanatory power. (2) From 2005 to 2018, SOC density and SOC stock increased by 0.16 kg·C·m$^{-2}$ and 49.79 Tg, respectively, representing growth rates of 5.18% and 5.84%. Spatially, 57.91% of the study area exhibited an increase in SOC, with 18.07% of the area showing a growth rate exceeding 20.00%. (3) Land use change had a limited contribution to SOC stock variation, as regions with unchanged land use types accounted for 73.03% of the total SOC stock increase. This study reveals the spatiotemporal evolution patterns of SOC in the Northeast China Plain, providing scientific insights for regional soil carbon management and offering important guidance for formulating effective soil conservation strategies.

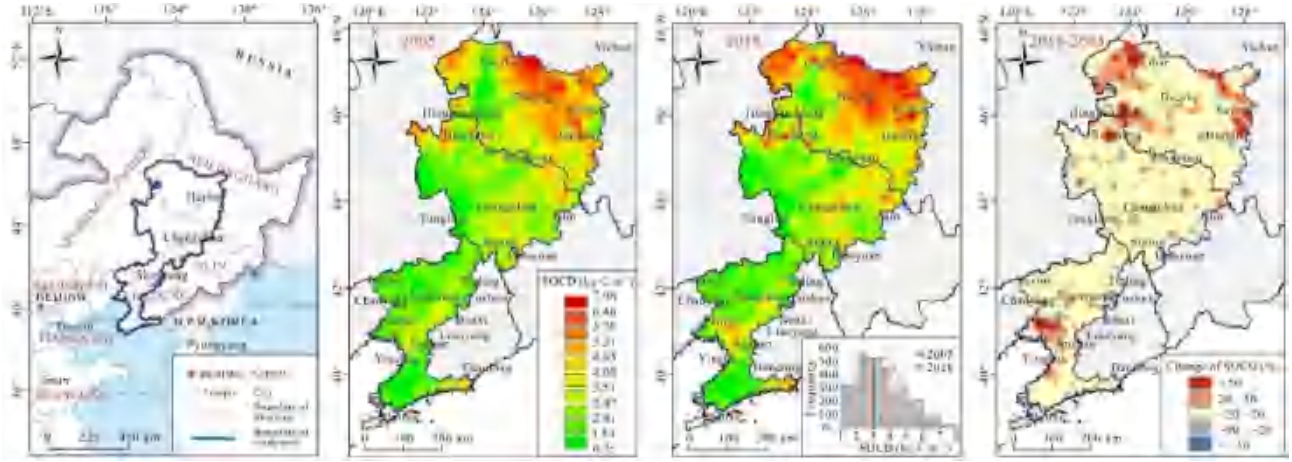

Fig 1. Spatial distribution of soil organic carbon density (SOCD) in 2005 and 2018, and SOCD changes (2018–

## ABSTRACT

Long-term human cultivation activities are the key factors of the vertical distribution and storage dynamics of soil organic carbon (SOC) in cropland. Based on a 45-year long-term field experiment, this study systematically compared SOC dynamics and carbon storage characteristics in soil profiles (0–200 cm) between cultivated land and adjacent natural forest. The findings reveal the hierarchical regulatory effects of tillage management on the soil carbon pool.

The results show that: (1) Under both land use types, SOC content decreased exponentially with depth, but values in cultivated soils were 0.35–1.54% lower than in forest soils at each layer. SOC content in surface soil (0–78 cm) was significantly higher than in the subsoil (78–158 cm) and substratum layers (158–200 cm) ($p < 0.01$). At equivalent depths, SOC in cultivated land was significantly lower than in forest land ($p < 0.01$). Over 45 years, the SOC accumulation rate in the surface soil of cropland (0.07 $g \cdot kg^{-1} \cdot yr^{-1}$) was only half that of forest land (0.14 $g \cdot kg^{-1} \cdot yr^{-1}$). (2) The controls of soil physicochemical properties on SOC differed with land use: in forest soils, SOC correlated positively with clay content ($r = 0.63$, $p < 0.01$), whereas in cultivated soils, SOC was primarily regulated by total nitrogen ($r = 0.94$, $p < 0.01$) and sand content ($r = 0.60$, $p < 0.01$) and negatively correlated with bulk density ($r = -0.55$, $p < 0.01$) and pH value ($r = -0.45$, $p < 0.05$). (3) Long-term tillage significantly reshaped soil profile structure, thickening the plough layer from 20 cm to 78 cm. Surface carbon storage reached 20.76 $t \cdot ha^{-2}$, an increase of 11.13 $t \cdot ha^{-2}$ compared with forest soil ($p < 0.01$). However, storage decreased by 4.99 $t \cdot ha^{-2}$ and 7.60 $t \cdot ha^{-2}$ in the subsoil and substratum layers, respectively ($p < 0.01$). The SOC storage increment rate was 50.95 $t \cdot ha^{-2} \cdot yr^{-1}$ higher than that of forest soil in the surface layer but 46.81 $t \cdot ha^{-2} \cdot yr^{-1}$ and 11.12 $t \cdot ha^{-2} \cdot yr^{-1}$ lower in deeper layers. These results confirm that cultivation alters soil structure and material cycling, enhancing carbon enrichment in surface soils while accelerating depletion of deeper carbon pools. This provides new insights into the vertical differentiation mechanisms of SOC under long-term agricultural management.

## ABSTRACT

Human-induced soil erosion significantly impacts soil organic carbon (SOC) dynamics, particularly in rangelands, where land degradation and overgrazing exacerbate SOC loss. This study investigates whether sediments from small farm reservoirs in South Africa's Karoo rangelands can serve as archives to reconstruct the temporal pattern of SOC changes during the 20$^{th}$-century. Sediments from three dams, accumulated during different time periods, were analysed for radionuclide markers (e.g. $^{137}$Cs), organic carbon (OC) content, sediment yield and OC flux. The results illustrate the suitability of the farm dam sediments to reconstruct soil erosion history in the Karoo and reveal distinct temporal patterns of SOC erosion for each catchment. For all dams, increases in sediment input into the reservoirs did not correspond to a proportional increase in OC accumulation, highlighting the influence of land degradation on SOC depletion over time. Dam-specific variations underscore the role of land use and local heterogeneity in shaping erosion and carbon fluxes. These findings suggest that lateral SOC transfer has been dynamic during the 20$^{th}$ century, challenging models that assume constant sediment OC concentrations over time. Therefore, this study illustrates the importance of reconstructing past SOC dynamics and gain a correct understanding of the carbon fluxes in degraded rangelands and their broader implications for the global carbon cycle during the 20$^{th}$ century.

## ABSTRACT

Conservation tillage improves soil organic carbon (SOC) management by balancing microbial decomposition and physico-chemical protection. Minerals stabilize SOC, but how tillage practices affect calcium (Ca) speciation and its role in microbial–mineral–organic matter interactions in calcareous soils remains unclear. Thus, a 22-year tillage experiment and soil incubation were conducted to investigate Ca-mediated SOC sequestration and mineralization. Conservation tillage, including no-tillage with straw mulch (NTS) and subsoil tillage with straw mulch (STS), increased SOC storage by 9.9-14.3 % at 0-20 cm soil depth by promoting organo-Ca associations, compared to conventional tillage without straw return (CTN) and reduced tillage without straw return (RTN). Moreover, NTS and STS increased aggregate stability and macroaggregate proportion, reducing total SOC mineralization, as macroaggregates had lower SOC mineralization than microaggregates. In aggregates, increased exchangeable Ca was linked to higher particle- and mineral-associated SOC and lower SOC mineralization, showing positive ($p < 0.01$) and negative ($p < 0.001$) relationships, respectively. Compared to CTN and RTN, long-term NTS and STS not only promoted the transformation of $CaCO_3$ to exchangeable Ca, but also increased microbial biomass, especially the proportion of Gram-negative and arbuscular mycorrhizal fungi. Mechanistically, higher $Ca^{2+}$ reshaped bacterial communities and promoted the microbial by-product binding to the minerals to form stable organo-Ca complexes, which was supported by the positive correlations between $Ca^{2+}$, microbial composition and SOC content (PLS-PM, $p < 0.01$). Overall, conservation tillage increased Ca availability for carbon binding by mediating microbial structures, thereby promoting aggregate protection and SOC stability in Calcaric Cambisols.

# Evaluating the Applicability of the RothC Model for Soil Organic Carbon Dynamics in Canadian Prairie Grasslands Using Physical Fractionation

**Ruitian Chen[1*], Moazame Mesgar[1], and Adam W. Gillespie[1]**

[1] *School of Environmental Sciences, University of Guelph, Guelph, Canada*

*ruitian@uoguelph.ca

**ABSTRACT**

This project aims to validate and calibrate the Rothamsted Carbon Model (RothC) for Canadian prairie soils by integrating empirical data from physical fractionation with model-based simulations, following the framework of Zimmermann et al. (2007) and Jebari et al. (2021). 74 air-dried soil samples from Saskatchewan grasslands will undergo Zimmermann's multi-step fractionation to separate SOC into five identified pools and be connected to RothC simulation.

The empirical pool data will initialize three RothC configurations: (1) $RothC_0$—a baseline model using default initialization; (2) $RothC_2$—integrating plant residue and rhizodeposition and (3) $RothC_3$—a water-modified version incorporating decomposition constraints under saturated conditions. Monthly climatic data—temperature, precipitation, and potential evapotranspiration—from Environment and Climate Change Canada will be calculated.

In March 2026, follow-up soil sampling at the same sites will provide SOC data for short-term validation. Modeled SOC values from the three configurations will be compared to measured changes using Root Mean Square Error (RMSE) and Coefficient of Determination ($R^2$). Correlation analysis between measured SOC fractions and modeled pools, following Zimmermann's approach, will identify the most effective configuration for simulating short-term SOC dynamics in Canadian Prairie soils.

**ABSTRACT**

Soil organic carbon (SOC) plays a pivotal role in agricultural productivity, climate mitigation, and ecosystem stability. However, traditional chemical analysis methods for SOC quantification are costly, time-consuming, and environmentally intensive. This study employs mid-infrared (MIR) spectroscopy as a rapid, low-cost, and sustainable alternative for SOC estimation. A comprehensive meta-analysis of 176 peer-reviewed studies was conducted to assess the influence of soil sample preparation, spectral pretreatment, and chemometric modeling on MIR-based SOC prediction accuracy. The results reveal that finely ground samples and specific pretreatments such as multiplicative scatter correction (MSC*) and Savitzky–Golay derivative (SGD) significantly enhance model performance ($R^2$ up to 0.91, RMSE < 1.0). Optimal spectral parameters include the 4000–600 $cm^{-1}$ range, 4–8 $cm^{-1}$ resolution, and ≥64 scans per sample. Among chemometric techniques, partial least squares regression (PLSR) remains the most robust, though emerging methods like Cubist and machine learning models show promise. Validation using datasets from China, Kenya, Indonesia, and Australia confirms the model's adaptability and scalability. The Australian case study—covering 430 farms and 15,480 samples—demonstrates that MIR reduces analytical costs by more than half while maintaining high accuracy ($R^2$ = 0.87, RMSE = 16.9 t $ha^{-1}$). Overall, MIR spectroscopy offers a transformative pathway for efficient SOC monitoring, enabling climate-smart soil management and supporting national carbon accounting frameworks.

**ABSTRACT**

Accurate monitoring of soil organic carbon (SOC) content, a core indicator of soil quality and ecosystem health, is important for sustainable agricultural development. Visible-near infrared (Vis-NIR) spectroscopy has become an important monitoring method owing to its fast, non-destructive, and cost-effective advantages. Regional soil data is difficult to cover soil attribute variations in complex environments. Soil spectral library (SSL) significantly enhances the comprehensiveness of data by integrating spectral and attribute data from multiple areas and types of soils. However, SSL has strong heterogeneity, and its soil samples may differ significantly in their attributes from the soil samples of the target area, which may lower the model accuracy. In this study, 210 soil samples were collected from three irrigated agricultural areas in Xinjiang, China, to construct a regional soil spectral library, and spectral preprocessing was combined with regression algorithms for modeling. Stratification modeling and covariate modeling strategies based on geographic region, soil type, clay content, and spectral type were proposed and evaluated. The results showed that the modeling based on first-order differential combined with random forest (FD-RF) showed optimal performance in all modeling strategies. Stratification modeling strategies and covariate modeling strategies significantly increased the SOC estimation accuracy compared with the entire dataset-based modeling. The geographic region-based stratification model ($R^2_v$ = 0.788) had a higher estimation accuracy than soil type-, clay content-, and spectral type-based stratification models ($R^2_v$ = 0.521–0.717), and the model synergizing spectral data with geographic region and clay content had optimal SOC estimation performance, with an $R^2_v$ of 0.871, which was 44.21 % higher than the entire dataset-based model. This study demonstrates that using geographic region and clay content as covariates for modeling can reduce the influence of soil spatial heterogeneity on SOC estimation accuracy, and provides a new strategy for spectral estimation of soil properties.

**ABSTRACT**

Accurate assessment of soil organic carbon (SOC) is crucial for sustainable agriculture and climate change mitigation; however, conventional laboratory methods remain expensive and time-consuming, particularly for smallholder farmers in developing countries. This study evaluated five machine learning models (Random Forest (RF), Artificial Neural Network (ANN), Support Vector Machine (SVM), Boosted Regression Tree (BRT), and eXtreme Gradient Boosting (XGBoost)) for SOC prediction across the Indo-Gangetic Plains using smartphone imagery and topographic parameters. Two hundred soil samples were collected from agricultural fields spanning Karnal and Kaithal districts of Haryana, IARI farm of Delhi, Varanasi district of Uttar Pradesh, and Nadia district of West Bengal, representing diverse agroecological conditions. Three modelling approaches were tested: Model-1 used smartphone images as sole predictors, showing poor performance with testing $R^2$ values of 0.005-0.06 and normalized root mean square error (nRMSE) of 0.31-0.34. SVM achieved best performance ($R^2$ = 0.06, nRMSE = 0.31). Model-2 employed topographic parameters derived from digital elevation models, including slope, aspect, openness measures, terrain ruggedness index, and total curvature. This approach outperformed Model-1, with RF achieving $R^2$ = 0.147 and nRMSE = 0.29. Model-3 integrated smartphone imagery with topographic features, producing exceptional results. XGBoost achieved optimal performance ($R^2$ = 0.717, nRMSE = 0.16, Nash-Sutcliffe efficiency = 0.710, concordance correlation coefficient = 0.82, d-index = 0.906), representing significant improvement over individual approaches. The integrated framework enables real-time soil assessment, eliminating expensive laboratory requirements and supporting resource-limited farmers in making informed management decisions.

## ABSTRACT

Straw-derived biochar has a greater potential for carbon (C) sequestration than straw that is directly returned into the soils. An incubation experiment was carried out to explore the impact of different straw returning modes (straw and biochar) on soil organic C (SOC) sequestration and their underlying physical protection mechanisms. The $^{13}C$-labeled straw and biochar were applied at rates of 0.5% and 1% (w/w) to three typical upland soils collected from Yuzhong, Yangling, and Changwu (labeled as YZ, YL, and CW, respectively) on the Loess Plateau in China. Soil C fractions and isotopic C were measured, and the pore structure of macroaggregates was quantified using X-ray computed tomography (CT) and verified by 3D visualization images. Compared to the control (CK), the addition of straw biochar increased SOC contents more than straw in three soils, especially at higher rates. Only biochar improved particulate organic C (POC) contents, and the changes of mineral-associated organic C (MOC) contents differed with soil types. Soil potential C mineralization (PCM) and microbial biomass C (MBC) increased with the addition of straw rather than biochar, except for MBC in YZ soil. The contribution percentages and contents of $^{13}C$ in SOC, POC, and MOC were higher with biochar addition than with straw addition, especially in YZ and YL soils. The total porosity and pore connectivity increased with straw addition in YL soil and with the 1% biochar application in CW soil. However, only isolated porosity increased in YZ soil. Meanwhile, the macropores increased while the mesopores and micropores showed decreasing trends in both YL and CW soils. Additionally, YL soil exhibited more pronounced positive correlations between pore structure and C fractions compared to the other two soils. These findings suggested that the sequestration of SOC was attributed to the improvements of POC and MOC by affecting soil pore structure in straw- and biochar-amended soils, respectively. Therefore, both the form of imported C and soil properties, such as the fertility and pore structure, should be comprehensively considered to fully optimize the potential for C sequestration in farmland soils.

## ABSTRACT

Soil organic matter (SOM) mapping in salinized areas is crucial for scientific guidance on soil salinization. However, accurately mapping SOM is challenging due to the intricate interplay between soil moisture content (SMC) and soil salt content (SSC), which significantly influences soil spectra. Unlike prior research that has separately examined the impacts of moisture or salinity, this study delves into the combined effects of these factors on SOM spectra. The objective of this study is to develop and validate several spectral optimization algorithms at both the laboratory and satellite levels. In October 2020, a study was conducted using 291 ground-truth data to examine the impact of various moisture-salt stages (seven moisture stages, five salt stages) on hyperspectral data. Spectrum mechanism responsive for soil moisture and salinity were analyzed through spectral curves, correlation, and analysis of variance (Anova, AOV), and spectrum mechanism responsive for soil moisture and salinity model were built. Following that, the spectra were optimized using piecewise direct normalization (PDS)-AOV, non-negative matrix factorization (NMF)-AOV, and orthogonal signal correction (OSC)-AOV. The SOM prediction models were then built by integrating these optimized spectra with Stacking ensemble machine learning algorithms (RF, GBM, ANN). Eventually, the lab-optimized spectra were merged with satellite multispectral images to create new image (named REC) for SOM mapping. The results indicated varying impacts of SMC and SSC on spectra, particularly between 1400 nm to 2000 nm, revealing the influence of moisture-salt interaction; the best optimization algorithm (OSC-AOV) with Stacking mitigated the effect of moisture-salt coexistence on spectra (the R2 and RPD of the best models elevated by 0.005-0.267, 0.020-0.374 respectively, RMSE reduced by 0.137-1.817 g/kg); implementing this algorithm on REC significantly improved the accuracy of SOM mapping (R2 elevated by 0.185-0.259, RMSE reduced by 2.615-3.203 g/kg). This study extensively investigated the effects of moisture and salinity on spectra, spanning from laboratory to satellite, offering a novel approach to understanding and addressing the complexities in SOM mapping in salinized environments.

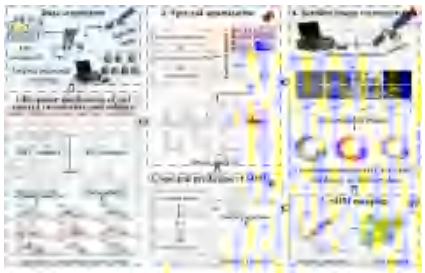

Fig.1. The workflow of this study (SR: Soil reflectance; SOM: soil organic matter; SMC: soil moisture content; SSC: soil salt content; R: original data; PDS: piecewise direct normalization; NMF: non-negative matrix factorization; OSC: orthogonal signal correction).

*E-mail dymov@ib.komisc.ru

**ABSTRACT**

The soils of Northern regions of Eurasia contain significant carbon stocks. One of the factors influencing the qualitative and quantitative composition of soil carbon is fires. Forest and swamp landscapes are subject of pyrogenic impacts. Low-intensity fires predominate in the study area, which result in complete or partial combustion of forest litter and, in rare cases, the upper organic soil horizons. Partial combustion products of biomass, which are usually represented by aromatic compounds, can enrich the composition of soil organic matter. Moreover, the consequences of the influence of fires on the composition of soil organic matter can be traced back thousands of years, both in the content of benzene polycarboxylic acids (BPCAs) and polycyclic aromatic compounds (PAHs), and in the increase in the content of aromatic fragments in the composition of soil organic matter estimated by $^{13}$ C-NMR. At the same time, swampy forests, which are subject to more frequent fires, despite the smaller thickness of the peat deposit, can contain larger carbon reserves compared to less fire-prone areas with a higher thickness of the peat deposit. In addition, the use of fire during settlement, development of the use of slash-and-burn agriculture, preparation of coal-burning production facilities near the centers of bog ore metallurgy in the 18-20$^{th}$ centuries led to a significant increase in soil carbon stocks of Northern landscapes (5-7 times higher than background values). Thus, given the ubiquity of the pyrogenic factor and the frequency of fires in northern latitudes, fires should be considered as one of the main factors of long-term carbon stabilization in semi-hydromorphic, swamp and anthropogenic soils.

**ABSTRACT**

The radiocarbon content of soil organic carbon (C) is assumed to reflect the carbon's biological reactivity. Large soil radiocarbon ages deep in the soil are interpreted to mean that the C will have a slow response to environmental perturbations such as the effects of warming on the soil microbial C decomposition rate. Here we show that downward advective transport of soil C is an important process affecting soil C ages, leading to an inevitable increase in radiocarbon age with depth even if the decomposition rates remain constant. Thus, the increasing radiocarbon ages of C with depth do not directly imply a corresponding decrease in C reactivity as a function of depth, and instead suggest this C may be as biologically reactive as that nearer the surface. Based on theory and an independent assessment of soil C decomposition rates, the radiocarbon profiles (and content for a given depth) were calculated for over 3000 soils in the USA, and were compared to observational results based on measured soil radiocarbon. The first-order coherence between the two entirely differing approaches suggests the fundamental importance of transport, and the implication that the soil C decomposition rate constant may be relatively invariant with depth. This has significant implications for the soil C response to the changing climate system. These insights may also help serve to reduce biases in Earth System Models which presently do not match the observed depth patterns in soil C or its radiocarbon content.

# A long-term global Mollisols SOC content prediction framework: integrating prior knowledge, geographical partitioning, and deep learning models with spatio-temporal validation

**Xiangtian Meng**[1*]

[1] *Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun 130012, China*

*mengxiangtian@iga.ac.cn

**ABSTRACT**

Recently, Soil Organic Carbon (SOC) content has declined across global Mollisols region due to erosion, intensive agriculture, and other factors, weakening the soil's capacity to buffer climate change and necessitating urgent monitoring of SOC dynamics. Large-scale SOC content monitoring using remote sensing technology faces challenges in extracting advanced features from remote sensing data and mitigating the negative impact of high spatial heterogeneity in SOC content on prediction accuracy. To address these challenges, we collected 8,984 samples, 956,423 Landsat TM/OLI images, shuttle radar topography mission-digital elevation model data, and meteorological data. We developed a Geographic Knowledge Dataset (GEKD) incorporating prior knowledge of soil formation and erosion processes. We then input the GEKD into a Probability Hybrid Model (PHM). In the PHM, we applied a fuzzy Gaussian mixture model to cluster the global Mollisols region and calculate corresponding probabilities. We then built a high-accuracy SOC content prediction model by integrating the Attention mechanism, Convolutional Neural Networks, and Convolutional Long Short-Term Memory Networks (A-CNN-ConvLSTM). Finally, we generated spatial maps of SOC content at a 30 m resolution for 8 periods since 1984 and verified the accuracy of its spatial distribution and temporal variation patterns. The results showed that (1) the highest SOC content prediction accuracy (RMSE=7.17 g/kg, R2=0.72, and RPIQ=1.92) was achieved when GEKD was input into PHM using the A-CNN-ConvLSTM algorithm. (2) PHM effectively reduces the negative impact of high SOC spatial heterogeneity on prediction accuracy, resulting in smoother spatial distribution at cluster boundaries. Compared to the global model, PHM reduced RMSE by 1.66 g/kg and improved R2 and RPIQ by 0.06 and 0.15, respectively. (3) Compared to the commonly used random forest algorithm, A-CNN-ConvLSTM reduced RMSE by 1.50 g/kg and improved R2 and RPIQ by 0.13 and 0.47, respectively. The spatial context features extracted by the CNN structure in the A-CNN-ConvLSTM algorithm are the most effective in improving SOC content prediction accuracy. (4) Currently, the SOC content across continents in the global Mollisols region is ranked as follows: Siberia (27.21 g/kg) > Europe (26.78 g/kg) > Asia (20.48 g/kg) > North America (20.43 g/kg) > South America (16.49 g/kg). Since 1984, SOC content has shown a decreasing trend, with the global Mollisols region losing 1.91 g/kg overall. The Asian Mollisols region experienced the largest decline (2.93 g/kg), while Siberia saw the smallest decrease (1.45 g/kg).

# Field NIR Spectroscopy for Soil Carbon Monitoring in Hazelnut Orchards

**Leonardo Pace[1*], Sara Caccia[1], Valerio Cristofori[1] and Simone Priori[1]**

[1] *University of Tuscia (Department of Agriculture and Forest Science, Viterbo, Italy)*

*Leonardo.pace@unitus.it

**ABSTRACT**

Monitoring organic carbon stocks in soil is increasingly in demand to support policies on greenhouse gas emissions control, soil quality and carbon farming. This study investigates the application of a rapid and field method based on Near-Infrared (NIR) spectroscopy, in hazelnut orchards in central Italy. Three different plantation ages of hazelnut orchards (<10 years, 20-30 years, > 40 years) were selected within four different farms in Viterbo province.

For each age class, three field replicates were sampled, resulting in 36 soil cores. Depth profiles were not uniform across orchards: while some sites were sampled at standard layers (0–15, 15–30, 30–45 cm), others extended down to 75 cm or were subdivided into uneven intervals according to local soil conditions. In total, these cores produced 108 soil samples. NIR spectra were acquired using the NeoSpectra Scanner both in situ, on moist field samples, and in the laboratory after drying at 40 °C. Because the number of horizons varied among cores, the number of NIR scans per soil augerings was not constant. Overall, the NIR dataset includes approximately 370 spectra, capturing both field and dry conditions and allowing the evaluation of moisture effects across heterogeneous depth profiles.

Given the strong influence of water on NIR measurements, the External Parameter Orthogonalization (EPO) method will be applied to correct moisture-induced spectral distortions and improve SOC prediction accuracy. The aims of the study are: (i) comparing the performance of NIR spectroscopy for SOC stock prediction under field and laboratory conditions; ii) analyzing SOC stock variations with the age of the hazelnut orchards, to determine the role of this crop in the carbon sequestration.

The results will support the development of rapid and cost-effective soil carbon monitoring strategies, providing a structured methodological framework also for carbon credits certification.

# Supporting environmental sustainability by increasing soil carbon sink through biowaste recycling and remote sensing integrated with machine learning

**C.Y. Wu[1*] and Z.Y. Hseu[2]**

[1] *Department of Environmental Science and Engineering, Tunghai University, Taichung City 407224, ROC*

[2] *Department of Agricultural Chemistry, National Taiwan University, Taipei 106319, ROC*

*cywu@thu.edu.tw

**ABSTRACT**

Expanding soil carbon sinks through biowaste recycling and fertilization management is a land use strategy with potential for achieving net-zero carbon emissions. Nevertheless, the key of this approach relies on the transformation of exogenous carbon into decomposition-resistant forms and a practical and sensitive technique that can identify the change in soil organic carbon (SOC) contents. Thus, in this study, different plots in a Napier grass (*Pennisetum alopecuroides*; a potential bioenergy crop) field in northern Taiwan were treated with a manure compost, a chemical fertilizer, or manure compost plus chemical fertilizer for 40 weeks. Then, the topsoil (0–15 cm) was physiochemically fractionated into a plant-residue forming light fraction, an aggregate-bound heavy fraction, and silt/clay-bound oxidizable and non-oxidizable fractions, with varying SOC contents. The results showed that in the combined treatment group, the tillage-induced soil disturbance and nutrient-driven bacterial activity, indicated by reduced aggregate stability and elevated 16S ribosomal DNA counts, likely facilitated the shift of SOC from an aggregate occluded form (heavy fraction) to organo-mineral complexes (oxidizable fraction), which led to a 5 to 15% enrichment in the stable soil carbon sink. Additionally, grass shoot biomass was 20% higher in the combined treatment group than in the control. On the other hand, this study assessed the robustness of a visible and near-infrared (VIS-NIR) spectrum-based Cubist model trained with Walkley-Black (WB) method measured SOC data (n = 400) from diverse land uses and soil types in Taiwan. Additionally, SOC contents by other wet chemistry approaches—including total organic carbon (TOC) analyzer, elemental analyzer (EA), and loss-on-ignition (LOI) methods—from an independent sample set (n = 46) were introduced to test model's practical applicability across References methods. The model achieved a R2=0.72, RMSE=1.09, RPD=1.88, RPIQ=1.46, and LCCC=0.82. The major model predictors indicated the occurrence of SOC with different stabilities, where degradation was promoted by soil weathering and stabilization was associated with iron oxides. Model-predicted SOC contents also aligned closely with TOC (LCCC = 0.81) and EA (LCCC = 0.76) methods, but less with LOI method (LCCC = 0.48), due to its overestimation from loss of structural water in clay. Overall, this study constructed a practical scheme for soil carbon sink enhancement using biowaste recycling and nondestructive measurement using Vis-NIR-based machine learning model, may be a promising strategy for achieving environmentally sustainable development.

# Engineered biochar amendments to address multiple soil constraints: Results from 12 field studies

**Lukas Van Zwieten[1*], Murray Hart[1], Rick Graham[1], Tendo Mukasa Mugerwa[1], Kattie Weigh[1], Neroli Graham[1], Sean Murphy[1], Ashlea Webster[1], Nicole Rice[1]**

## ABSTRACT

Soil constraints resulting from sodicity or acidity significantly limit production across Australian cropping systems, with losses in productivity estimated at around A$2B annually. Internationally, these same soil constraints impact food security and sustainability, especially under increasingly variable rainfall. A partnership between the Grains Research and Development Corporation and the New South Wales Department of Primary Industries and Regional Development aims to address these constraints through the development and evaluation of Next Generation Soil Technologies (NGSTs), evaluated in diverse agro-climatic zones across the state of New South Wales, Australia. This presentation will focus on data from 6 field trial sites in 2024, and 12 field sites in 2025; where engineered biochar-mineral composites, multi-functional organic amendments and nano-structured biochar/ lime and gypsum formulations were deployed. These novel amendments have been designed to address potential shortcomings with traditional amendments, including the slow dissolution rate of agricultural lime and the challenges faced in addressing constraints that occur in the sub-soil.

Results from the 2024 field trials indicate that NGST efficacy varies considerably across soil types and agro-climatic zones. Biochar-mineral composites and multi-functional organic amendments demonstrated greatest efficacy at some sites with sodic, dispersive soils, achieving yield responses which exceeded conventional gypsum amelioration. Site-specific factors including soil type, constraint severity, and seasonal rainfall appear critical determinants of treatment response. Ongoing multi-year evaluation will assess persistence of amelioration effects and improvements to sub-soil extraction of water and nutrients. Statistical analysis of 2024 yield and biomass data was conducted using linear mixed models and showed that significant treatment effects were detected at several sites. For example, in a sodic dispersive subsoil, the control was no different to gypsum (2t/ha) incorporation (traditional amendment) resulting in 4.30 t grain/ha ($p<0.01$), while the deep placement of a stoichiometrically balanced organic amendment or an engineered biochar containing soluble Ca resulted in yield exceeding 5.1 t grain/ha ($p<0.01$). Results from these field evaluations will begin to elucidate mechanisms of action of engineered biochar products.

The presentation will cover some of the logistical challenges of amending soils to address sub-soil constraints, and how this was overcome through optimizing pellet formulations and dimensions. For these products to be practically applied, it needs to flow freely through agricultural equipment and be structurally stable for transport and handling. Insights will be provided for commercialization of NGSTs to facilitate enhanced agricultural productivity.

## ABSTRACT

Future lunar exploration requires self-sufficient food production. However, lunar regolith provides a hostile environment that lacks the biological and physical properties necessary for cultivation. Developing functional soil from regolith requires engineering three core components: biological, chemical, and physical properties.

Here, we evaluated the foundational requirements to grow lettuce on The Lunar Highlands Simulant (LHS-1), a high-fidelity mineral analogue that closely resembles Apollo-collected samples (Easter *et al.* 2022). Continuous $^{13}C$-$CO_2$ labelling at 500 ppm with $^{13}C$ endmember at 15atom% was used to trace carbon (C) cycling pathways. A fully factorial design was evaluated against an unamended control: 1) Earth microbiome transplant, 2) biosolids biochar (HTT 500ºC, 5% w/w), and 3) synthetic root exudates (0.22% C w/w soil). Transplanting microbial communities – achieved by placing donor soil on filter paper above tubes of receiver soil and washing through with water for two weeks – has proven effective for establishing beneficial microbiomes and restoring essential soil functions in novel environments (Howard *et al.* 2017). Biochar, a C-rich pyrolysis product, provides an organic matrix that supports microbial function while simultaneously improving water retention, reducing bulk density, and mitigating metal toxicity. In addition, it will be technically feasible to pyrolyze biosolids generated during lunar exploration into biochar, recycling nutrients in a closed-loop system while eliminating biosecurity risks. With plants delivering up to 40% of their photosynthetically fixed C to microbes at the root surface in established systems, a cocktail of various C substrates was incorporated as immediate food for the microbial community. After 68 days, lettuce growth, soil chemistry and microbial community composition were assessed as indicators of regolith transformation. Source partitioning using $^{13}C$ isotopic signatures was used to trace C cycling pathways and determine the fate of C allocation in amended lunar regolith.

Preliminary results demonstrated that the addition of biosolids biochar increased lettuce production more than 5-fold compared to treatments without char. Microbiome transplantation was the dominant driver of community structure, explaining about 13% of variance in bulk-soil bacteria and 22% in root bacteria, compared with 3–10% for biochar and synthetic root exudate addition. Microbiome transplantation explained 7–9% of variance in fungal community composition, with modest additional effects from interactive explanatory variables. Through recycled biosolids and engineered microbiomes, this study transforms regolith into a living soil that is capable of supporting plant growth, establishing the biological foundation for sustained human habitation on the lunar surface.

## ABSTRACT

Biochar is a potential regenerative viticulture (RV) tool to increase vineyard soil carbon (C) and restore vineyard soil health, improve ecosystem services and mitigate against extreme climatic events, yet its impact on subtropical vineyard soils remains limited. This study used a dual stable isotope analysis approach to evaluate the short-term impacts of pine biochar on soil total C and total nitrogen (N) and their isotope compositions ($\delta^{13}C$ and $\delta^{15}N$) in the top 0 – 30 cm of two Southeast Queensland vineyards in subtropical Australia.

Pine biochar (650°C pyrolysis) was applied at 0, 5.0, 10.0 and 20.0 t $ha^{-1}$ to the vine rows (VR) soil at two vineyards, Nuova Scuola (NS, clay-loam soil) and Ballandean Estate (BE, sandy soil) in August 2023. Soil samples were collected at sample depths of 0 – 10 cm, 10 – 20 cm, and 20 – 30 cm of the VR and mid row (MR) soils in Spring 2023 and Summer 2024, one day before Harvest. Soil total C, total N and their stable isotope compositions ($\delta^{13}C$ and $\delta^{15}N$) were measured. Biochar had muted effects on the clay–loam soil of NS with little mobility through the soil depths. In contrast, the sandy soil of BE was more responsive, with increased total C, total N and enriched $\delta^{15}N$, and biochar movement down the soil profile. Differences in VR and MR were associated with vegetation inputs, soil microbial activity and chemical use (fungicides and herbicides).

The $\delta^{13}C$ enrichment in the sandy soils indicated clear incorporation of biochar-derived C into the soil matrix, consistent with improved soil water retention and microbial accessibility. In contrast, $\delta^{13}C$ shifts at the clay-loam soils were smaller, reflecting dominant organo-mineral associations and stronger buffering capacity. Patterns in $\delta^{15}N$ revealed divergent N cycling pathways: MR soils showed $^{15}N$ enrichment indicative of intensified microbial N processing and potential N loss, while VR soils at the clay-loam site maintained a more closed N cycle.

The dual stable isotope analysis ($\delta^{13}C$ and $\delta^{15}N$) approach provided a sensitive diagnostic framework for fingerprinting soil C and N transformations in biochar-amended vineyard soils. These findings demonstrate that pine biochar can meaningfully alter soil biochemical processes within 6 months, with outcomes strongly influenced by soil texture. This work supports site-specific biochar management strategies aimed at enhancing vineyard soil health and advancing climate-smart regenerative viticulture.

**ABSTRACT**

Soil Organic carbon (SOC) is fundamental to sustaining soil health and moderating climate, yet conventional laboratory analyses and advanced sensing can be prohibitive and logistically demanding at fine spatial scales. We evaluated a low-tech, gravimetry-based proxy that leverages the coupling between organic matter and water retention to estimate SOC using only an oven and a balance. We assessed 11 subtropical Australian soils across a range of contrasting textures, subject to varied disturbance regimes. As a single predictor, the proxy provided a modest relationship with laboratory SOC methods ($R^2 \approx 0.2$-$0.4$; $p=0.001$). However, introducing minimal profile context substantially improved performance to $R^2 \approx 0.7$-$0.9$ ($p<0.001$) while preserving very low cost and operational simplicity. The procedure is inexpensive, fast, and easily adopted by practitioners without spectroscopic or remote-sensing infrastructure, though has potential to complement existing methods. While broader validation beyond the initial 11 soils is required, the approach shows promise for scalable SOC identification and monitoring. It may be used for identifying hotspots/coldspots, guiding sampling intensity, and complementing higher-end methods, without dependence on instrument-specific libraries. Overall, this work demonstrates that simple gravimetric measurements can deliver actionable SOC insights at scale and at low cost.

## ABSTRACT

Pyrogenic carbon (PyC), represented by biochar in agricultural application, is increasingly recognized as a critical lever for climate mitigation and soil sustainability. However, pyrogenic carbon has historically been framed as a passive, physiochemically stable carbon pool, whereas the microbial mechanisms that actively govern its role in soil carbon stabilization and transformation remain largely unresolved. Here, we synthesize mechanistic insights, incubation experiments, and field-scale functional analyses to demonstrate that biochar operates as a dynamic microbial interface that restructures soil carbon cycling through both heterotrophic and autotrophic pathways. Biochar–microbe interactions are governed by coupled physical, chemical, and electrochemical mechanisms [1]. Biochar modifies microbial habitats via pore-mediated colonization, nutrient retention, and pH buffering, while simultaneously participating in extracellular and interspecific electron transfer, altering redox-sensitive metabolic pathways. These mechanisms regulate microbial activity, community assembly, and signaling processes, positioning biochar as an active mediator of soil biogeochemical reactions rather than an inert carbon reservoir. Biochar-induced priming effects on native soil organic carbon (SOC) are driven by shifts in microbial community structure and metabolic functions rather than by carbon recalcitrance alone [2]. High-temperature biochar enhances SOC stability by maintaining physicochemical homeostasis and selectively favoring microbial consortia associated with reduced heterotrophic disturbance, enhanced electron transfer capacity, and secondary metabolite turnover. These results identify microbial accessibility and functional redundancy as key controls on carbon persistence in biochar-amended soil. Additionally, biochar activates an often-overlooked autotrophic carbon sequestration pathway. Biochar significantly restructures Calvin cycle–driven $CO_2$ fixation by regulating the abundance, activity, and community composition of *cbbL*- and *cbbM*-harboring autotrophic microbes [3]. The rhizosphere emerges as a hotspot of autotrophic $CO_2$ assimilation, with biochar effects mediated by soil pH, redox potential, nitrogen availability, and labile carbon pools. Importantly, autotrophic $CO_2$ fixation is functionally coupled with nitrogen, iron, methane, and arsenic cycling, linking PyC systems to broader biogeochemical cycles. By integrating heterotrophic carbon protection with autotrophic carbon input, future research is expected to move beyond passive representations of pyrogenic carbon and incorporate microbially mediated regulation to better constrain long-term soil carbon sequestration.

# Biochar at scale needs long-term proof: LTE field trials supporting the green transition of Danish agriculture

**L. Elsgaard[1*] and L. Busk Holm[1]**

[1]*Department of Agroecology, Aarhus University, Tjele, Denmark*

*Lars.Elsgaard@agro.au.dk

**ABSTRACT**

Pyrogenic carbon (biochar) is increasingly positioned as a climate-smart soil amendment, yet robust long-term evidence under cool-temperate, high-yield farming systems remains scarce. Denmark is now moving toward large-scale biochar deployment as part of national climate policy, creating an urgent need for practice-near data on agronomic performance, carbon persistence, and potential risks to soil–water systems. Here we present the Danish Biochar LTE (Long-Term Experiment), a coordinated platform designed to generate the empirical foundation required for regulation, greenhouse-gas accounting, and sustainable implementation. The platform is supported by a 10 Mio. € grant from the Ministry of Green Transition.

A key novelty is the Danish focus on producing biochar from biogas residue fibers (BRF), a widely available, circular-economy feedstock from anaerobic digestion, pelletized and pyrolyzed under controlled, industrial conditions (600°C, >1 h residence time). This next-generation pyrogenic-C pathway links waste-stream valorisation to soil carbon sequestration and creates a distinct biochar type with properties and co-benefits that remain poorly documented in field settings. The LTE in addition includes biochars from straw, wood, and sewage sludge, produced at established full-scale plants, enabling traceable, reproducible product batches.

Field trials are established at four research-managed sites spanning Danish soil and climate gradients. Treatments compare annual low-dose inputs (1 t biochar-C/ha/yr) versus a single high-dose application (10 t biochar-C/ha). Biochar is incorporated into the upper 20-25 cm and a comprehensive monitoring program targets crop yield and nutrient use, soil physical functioning, carbon stabilization, microbial and biogeochemical responses, and environmental safeguards, including nitrate and contaminant leaching measured via suction cups at 1 m depth and complementary worst-case leaching tests performed with lysimeters.

By integrating industrially produced BRF-biochar with replicated, multi-site long-term field experimentation, Danish Biochar LTE provides a timely testbed to connect to inform on climate mitigation outcomes and risk-informed governance of pyrogenic-C in agriculture.

**Acknowledgments**

The Danish Biochar LTE is a collaborative project led by scientists from Aarhus University and the University of Copenhagen, and we thank all participants for their contributions. The skilled support of technical staff in the field has been instrumental to the successful establishment and operation of the experiments, as has the assistance of laboratory staff in sample processing and analysis.

# Resolving Organic-Inorganic Carbon Overlap: Comparing Soil Organic Carbon (SOC) Measurement Methods to Improve Accuracy in Calcareous Soils

**Nastaran Chalabianlou V. [1*], Paul R. Voroney [2], Adam Gillespie [3]**

[1] Postdoctoral Researcher, School of Environmental Sciences, University of Guelph, Guelph, Canada

## ABSTRACT

Accurate quantification of soil organic carbon (SOC) is essential for evaluating soil quality, modeling carbon cycling, and supporting soil carbon accounting frameworks. However, SOC estimates can vary substantially among analytical methods, particularly in soils containing measurable soil inorganic carbon (SIC), where incomplete carbonate removal or thermal overlap can bias results. This study evaluated the accuracy and applicability of commonly used SOC measurement methods across soil layers differing in SIC content under two land uses: cultivated land and adjacent deciduous forest.

Forty-five soil profiles were sampled to 100 cm depth, each with five depth increments (0–5, 5–15, 15–30, 30–60, and 60–100 cm). SOC was quantified using (i) dry combustion following acid fumigation and (ii) an indirect method based on total carbon (TC) minus SIC after muffle furnace treatment. Loss-on-ignition (LOI) was also evaluated as an estimate of soil organic matter. Soil inorganic carbon was also independently measured using a digital manometer–based Calcimetry method to determine SIC thresholds affecting method accuracy.

SOC values obtained by acid fumigation and the indirect method were comparable in soil layers where SIC was low (~ 3%), particularly within the upper 60 cm of the soil profile. However, method divergence increased markedly in carbonate-rich subsoils (60–100 cm), where SIC exceeded ~5%. In these horizons, acid fumigation did not completely remove inorganic carbon, resulting in systematically inflated SOC estimates, whereas SOC derived from TC–SIC subtraction remained consistent with expected subsoil carbon levels. LOI showed strong correlations with SOC in surface horizons but exhibited depth-specific conversion factors, indicating that a single SOM-to-SOC conversion factor is unsuitable across the soil profile.

These findings demonstrate that SOC method accuracy is strongly controlled by measured SIC content. Acid fumigation is appropriate only when SIC is low, whereas the indirect method provides more reliable SOC estimates in carbonate-rich subsoils. The integration of digital calcimetry allows identification of practical SIC thresholds and highlights the critical need to quantify SIC when selecting or interpreting SOC analytical methods in soils containing carbonate-bearing horizons.

# Life Cycle Assessment of Traditional Japanese Thatched Roofs with Biochar End-of-Life Integration: Implications for Carbon Mitigation

**Tawiah Joseph Kotey[1*], Mitsuru Hirota[2], and Asano Maki[2]**

**ABSTRACT**

Traditional Japanese thatched roofs constructed from locally sourced grasses such as *Miscanthus sinensis* and *Phragmites australis*, represent a renewable building material with cultural heritage value. Beyond their historical significance, these biomass-based materials offer untapped potential for climate mitigation. This study evaluates their potential as a climate mitigation strategy through a cradle-to-grave life cycle assessment that incorporates biochar production at end-of-life. The objective is to determine whether coupling traditional roofing systems with carbon-sequestering processes can transform them into carbon-negative solutions. The assessment was conducted using Brightway2 in Python, modeling cultivation, transport, installation, and end-of-life conversion to biochar under a functional unit of one square meter of roof area over a 30-year service life. Inventory data included fertilizer and diesel inputs, transport distances, and pyrolysis energy requirements. Environmental flows accounted for biogenic carbon dioxide uptake during plant growth, nitrous oxide emissions, nitrate leaching, and permanent carbon storage in biochar with stability exceeding one thousand years. Contribution analysis was used to identify the most influential life cycle stages, and sensitivity tests examined the impact of parameters such as electricity carbon intensity and biomass yield. Comparative benchmarking against conventional roofing materials, including ceramic tiles, metal sheets, and asphalt shingles, was also performed to contextualize potential climate benefits. The findings indicate that integrating biochar production into traditional thatch systems can significantly enhance their environmental performance by leveraging long-term carbon sequestration. Preliminary modeling suggests that end-of-life strategies and cultivation practices are critical drivers of overall climate impact, while sensitivity analysis highlights energy-related processes as the most influential factor, underscoring the importance of low-carbon electricity in pyrolysis operations. This research demonstrates a pathway for linking heritage architecture with modern carbon management strategies, offering a scalable approach to low-carbon construction.

**Acknowledgments**

We thank the Japanese Thatcher Association for generously sharing their aged thatch, the students who worked tirelessly to prepare it as biochar, and the University of Tsukuba for funding and supporting this research. The old thatch used in this study was obtained during reroofing work with the cooperation of Earth Building Co., Ltd. (Representative Director: Mr. Okimoto Taichi).

# Methodological insights in the determination of soil SOC:clay ratio at farm level in Southern Belgium

**G. Colinet*[1]**

[1] *Water Soil Plant Exchanges Department, TERRA, University ofLiège, Belgium*

*Gilles.Colinet@uliege.be

## ABSTRACT

Soil organic matter is a key soil property of soil functioning and its capacity to deliver major ecosystem services. But it has undergone a substantial decline in cultivated soils worldwide, urging the needs for preservation and restoration practices for sustainable agricultural land management.

The SOC-to-clay ratio has been proposed by some authors as a metric of soil quality as it correlates with aggregate structural stability. Despite scientific debates about the relevance of this indicator, it has been the central point of an agri-environmental scheme in Wallonia (MAEC Sol).

This study evaluates the methodological basis for implementing the SOC/clay indicator within the MAEC Sol Assessing soil organic carbon (SOC) at farm scale requires robust indicators and sampling strategies capable of capturing spatial and pedological heterogeneity.

Using detailed soil maps and geostatistical simulations of SOC spatial variability, we assessed the performance of multiple sampling designs across homogeneous soil zones. Results show that pedological units derived from high-resolution soil maps are highly relevant for predicting clay content, whereas SOC variability is primarily driven by management. Comparison with measured granulometry revealed substantial uncertainties in clay estimates from existing soil texture maps (mean absolute error ≈ 4.6%), emphasizing the need for improved cartographic products. Geostatistical modelling demonstrated that ≥20 subsamples collected in a zig-zag pattern provide robust estimates of zone-level SOC means.

The assessment scheme at farm level is based on (i) the characterization of a selection of homogeneous zones defined by soil type, land use and levels of organic restitutions, and (ii) the extrapolation of measurements to the similar unsampled plots. A specific web-application was developed within the REQUASUD structure allowing farmers to delineate limits of parcels and laboratory operators to identify the selection of sampling zones. In a feasibility study, we compared the diagnosis made at farm level based on measurement of soc:clay ratio on every plot to the diagnosis made upon the selection of plots. Results for a selection of 15 farms show that the both approaches do not differ significantly.

Together, our findings confirm the scientific validity of the approach implemented to use the SOC/clay ratio as a soil quality metric at farm level and highlight the essential role of detailed soil mapping and geostatistical approaches for its reliable implementation at operational scales.

**ABSTRACT**

Global food security is increasingly threatened by the adverse consequences of interrelated environmental problems, including climate change, biodiversity loss, and pollution, also referred to as the triple planetary crisis. In response to these challenges, comprehensive strategies for designing sustainable agri-food systems, such as agroecology, have recently gained significant interest. It is therefore important to optimize good agricultural practices by turning to methods such as intercropping.

These can increase crop yields, effectively control pests, and optimize carbon sequestration in the soil, thereby contributing to the dynamics of soil carbon stocks, which have a significant impact on atmospheric chemistry and the global carbon cycle.

Carbon sequestration in the soil is an essential process in combating climate change, as it allows carbon present in the atmosphere to be stored in the form of stable organic matter. This storage also contributes to improving soil structure, fertility, and water retention capacity. In addition, carbon-rich soil promotes biological activity and improves the resilience of agricultural systems. Therefore, carbon capture is both an environmental strategy and a driver of sustainability in agriculture. This study aimed to assess the impact of intercropping on soil carbon sequestration.

# Uncertainty of Vis–NIR–based models for predicting soil organic carbon using Monte Carlo simulation

**Po-Hui Wu[1*] and Zeng-Yei Hseu[1]**

[1] *Department of Agricultural Chemistry, National Taiwan University, Taipei 10617, Taiwan*

*f11623001@ntu.edu.tw

**ABSTRACT**

Soil is regarded as the largest and most promising carbon sink. Therefore, the rapid and efficient measurement of soil organic carbon (SOC) is crucial for estimating soil carbon sequestration capacity. Conventional destructive wet chemical methods for determining SOC are time-consuming, labor-intensive, and generate chemical waste. Visible and near infrared (Vis–NIR) spectroscopy can detect the molecular vibration spectra of organic matter, and when combined with machine learning algorithms (e.g., Cubist), it enables rapid and non-destructive SOC prediction. However, uncertainty still exists in the models of SOC measurement. This dry chemistry approach represents a promising tool for carbon sink assessment. The study aimed to integrate soil Vis–NIR spectral data with the Cubist algorithm and Monte Carlo uncertainty analysis to develop an SOC prediction model calibrated with the total organic carbon (TOC) analyzer method. Additionally, the predictive performance of in-situ Vis–NIR spectral data using the TOC-based SOC model was evaluated. A total of 1,600 soil samples were collected in Taiwan, including both Vis–NIR spectra and SOC data measured by the TOC method. After confirming the absence of outliers in the spectral dataset using Mahalanobis distance, 200 samples were randomly selected as the validation set, while the remaining 1,400 samples were further divided into calibration sets of 200, 400, 600, 800, 1,000, 1,200, and 1,400 samples to compare model performance across different sample sizes. The results indicated that the model calibrated with 1,000 samples achieved the best predictive performance ($R^2$ = 0.64, RMSE = 0.18, RPD = 1.67, and LCCC = 0.80). Furthermore, to assess the applicability of the in-situ Vis–NIR SOC model, 19 field sites were selected as demonstration areas. The evaluation results showed an overall RMSE of 0.83% between the model-predicted and TOC-measured SOC values, with the best fit observed when SOC contents were below 3%. Based on the analysis of model variable importance, the key spectral bands influencing SOC prediction were identified. These wavelengths can serve as References for developing portable narrow-band Vis–NIR spectrometers, thereby enhancing the potential of in-situ Vis–NIR non-destructive SOC monitoring and measurement for field-scale carbon sink assessment.

# Innovation and Application of Targeted Humification of Agricultural Wastes and Targeted Soil Improvement Technologies

**Wei Dan[1*], Ding Jianli[1], Cai Shanshan[2], Li Yan[2], Wang Shuang[2], Hu Yu[1], Lv Qilin[1], Feng Xiaojie[1], Qiu Yanhua[1], Wang Yanrun[1], Xu Yonghui[1], Feng Qianzi[1]**

*[1] Beijing Academy of Agriculture and Forestry Sciences, Beijing, China*

*[2] Heilongjiang Academy of Agricultural Sciences, Haribn, China*

*wd2087@163.com

**ABSTRACT**

Agricultural development in China faces the dual constraints of increasing organic waste accumulation and declining soil fertility. Large quantities of crop residues and livestock manure remain inefficiently utilized due to low humification efficiency and slow lignocellulose degradation, particularly under low-temperature and oxygen-limited conditions. This study developed and evaluated a targeted humification and soil amelioration framework to enhance organic waste transformation and soil functional restoration.

We established a theory of directed humification based on targeted microbial consortium assembly and microenvironmental regulation. A composite microbial system consisting of psychrophilic bacteria, phosphate-solubilizing bacteria, *Pseudomonas*, *Bacillus*, *Streptomyces*, and *Clostridium* was constructed to enable low-temperature initiation, sequential lignocellulose degradation, and carbon stabilization. The initiation temperature for decomposition was reduced to 0-5 °C, and over 90% straw degradation was achieved within 7 days. Compared with conventional composting, humification efficiency increased by 20%-24%, fulvic acid content increased by 6%, soluble organic carbon by 11%, and total organic carbon retention by 22%, while humic acid content was maintained.

A microenvironment-regulated humification technology was developed to couple lignocellulose decomposition with the directed synthesis of soil functional amendments. The decomposition period was shortened to 7-15 days, and active humic fractions increased by 12.8%. Using humified organic matter as a carrier, a suite of soil functional materials was formulated, including organic-mineral composite aggregate stabilizers, carbon-based pH conditioners, nutrient activators, growth-promoting biofertilizers, and disease-suppressive microbial conditioners. The microbe-material interface regulation strategy integrating biological driving, interface construction, nutrient regulation, and environmental control was proposed to enhance soil structural, chemical, and biological functions.

A targeted soil improvement and land-use integration model was established, combining crop rotation, residue return, biological constraint mitigation, pH regulation, and water-nutrient conservation with precision fertilization and intelligent fertigation. Field implementation from 2022 to 2024 treated 1.8 million tons of agricultural waste and improved 6 million mu of farmland. Soil fertility increased by 0.5-1 grade, soil organic carbon increased by 3-8%, carbon emissions were reduced by 0.8-19 t $CO_2$ eq $ha^{-1}$, and soil carbon sequestration increased by 0.14-4.2 t $CO_2$ eq $ha^{-1}$. Crop yields increased by more than 8%, demonstrating that directed humification provides an effective pathway for agricultural waste valorization, soil functional restoration, and climate-smart agriculture.

**Key Words: Targeted humification, Agricultural Wastes, Soil functional amendment, Carbon sequestration**

# Challenges and Coping Strategies for the Journals of Soil Science in China

**Ren-kou Xu**[1,2*]

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China*

[2] *University of Chinese Academy of Sciences, Beijing 100049, China*

*rkxu@issas.ac.cn

**ABSTRACT**

The high-quality development of academic journals is of common concern to journal editors, editorial board members, paper authors, and readers. High quality journals require the support of excellent manuscripts, and high-quality academic papers drive the high-quality development of journals. In the past 20 years, the number of papers written by Chinese scholars and published in various academic journals has significantly increased, but most journals published in China are facing the challenge of insufficient high-quality manuscript sources. This article provides a brief analysis of the specific problems and possible solutions in soil science journals published domestically in China.

There are three main challenges:

1. The number of journals and the number of publications per journal are limited

At present, the number of Chinese and English journals that mainly publish research papers in the field of soil science in China is very limited, and the number of publications in each journal is also not high. Due to the limited publication capacity of journals, the publication period of papers is relatively long. It usually takes 1-2 years from paper submission to formal publication.

2. The quantity of scientific achievements has significantly increased, and the publishing capacity of journals is unable to meet the demand

Chinese government attaches great importance to agriculture and environmental issues, and the government's investment in research activities related to soil science has been increasing year by year; On the other hand, the number of researchers engaged in soil science investigation is also constantly increasing. Therefore, in the past 20 years, the number of scientific achievements related to soil science has been continuously increasing. However, due to the limited ability of domestic soil science journals to publish papers, most of the relevant research results have been published in English in international journals.

3. The quantity of high-quality articles is insufficient, and the quality of soil science journals needs to be improved

Similar to other disciplines, due to the fact that most of the research papers in the field of soil science written by Chinese authors are submitted and published in international journals, the number of high-quality articles in domestic journals in China is insufficient, and the quality of journals needs to be improved.

Coping strategies are as follow”

1. Increase the number of journals in the field of soil science

Chinese government is encouraging the establishment of new academic journals to publish more scientific research results. In recent years, some new academic journals, including soil science journals, have been launched.

2. Increase the number of articles published in soil science journals and shorten the publication period

Chinese government is encouraging existing academic journals to increase the number of published papers in response to the increasing demands for publishing scientific achievements.

3. Enhance the influence of soil science journals both internationally and domestically, and attract high-quality manuscript sources

By improving the quality of soil science journals and strengthening publicity and promotion activities, the journal's influence will be enhanced both internationally and domestically, and more excellent articles will submit to the journals. The publication of high-quality papers will further enhance the quality and influence of soil science journals.

# The Role of Scientific Societies and Their Journals to Foster Trust in Science

**Michael L. Thompson[1*] and Markus Flury[2]**

[1] *Agronomy Department, Iowa State University, Ames, Iowa, USA*

[2] *Department of Crop and Soil Sciences, Washington State University, Pullman, Washington, USA*

*E-mail Address of Presenting Author: mlthomps@iastate.edu

**ABSTRACT**

Public trust and support for science are essential to successfully address the global challenges of climate change, ecological sustainability, human health, and resource use. To serve the public good at the highest level, scientists adhere to values and practices that must be understood, maintained, and improved as societal needs and technology change. What can scientific societies such as SSSA and IUSS do to help maintain and modernize the highest standards for science in the coming years, especially as artificial intelligence (AI) revolutionizes key steps in the scientific process? Here we propose to expand the service and educational platforms for students, early career scientists, and scientists in general.

In this presentation, we discuss how scientific societies can provide educational resources like online short courses, webinars, in-person workshops, and mentoring opportunities for students. These programs would focus on general topics like preparation of manuscripts, experimental design, considerations of scale in sample collection and data interpretation, data management, interpretations and assumptions of all statistical procedures, how to embrace uncertainty in scientific research, ethical use and reporting of data, use of AI – its dangers and appropriate uses, patterns of logical inference – with or without statistics, and other relevant topics. Such guidelines need to be continuously adapted as AI tools further develop. In addition, scientific societies play an important role in providing a platform for publication of scientific results, reviews and discussions, and comprehensive surveys of methodology. Journals, books, and newsletters published by scientific societies are important for the dissemination of scientific ideas, results, and impacts. In contrast to commercial publishers, scientific societies keep their ownership and responsibilities over the editorial process and quality control, and so can foster trust in science.

June 7-12, 2026
Nanjing, China

# Evolution of Global Soil Science Collaboration Networks and Its Implications for Journal Development

**Ping Lu* and Xiang Chen**

(*Periodical Publishing and Literature Information Center*, *Institute of Soil Science*, *Chinese Academy of Sciences*, *Nanjing*, *China*)
*E-mail: luping@issas.ac.cn

**ABSTRACT**

Soil science plays a critical role in addressing global challenges such as climate change, food security. Advancing this field therefore requires research that integrates cross-regional data and leverages multinational expertise. For academic journals, understanding how global scientific collaboration evolves is not only about improving citation metrics, but also about fostering a more integrated and inclusive research ecosystem. Based on soil science publications from the Web of Science Core Collection (1995–2025), this study employed Social Network Analysis and bibliometric indicators to examine co-authorship networks at national and institutional levels, aiming to quantify the interplay between collaborative structures and research quality. Results show that the global soil science network has evolved from a more fragmented state toward a denser, more connected system with a pronounced small-world tendency, implying more efficient reachability for knowledge exchange. The network has shifted from early single core dominance toward a polycentric, multi hub configuration in which emerging hubs, most notably institutions in China, have increasingly strengthened their bridging role alongside established centers. International collaboration is positively associated with publication quality. Internationally coauthored papers are more likely to be published in Q1 journals, with an odds ratio of 1.44 to 1.94 for international versus domestic papers across the six time slices. Furthermore, a clear collaboration gradient is observed. When collaboration involves five or more countries, the share of papers entering the within year top 10% most cited group reaches 26.6%, compared with 9.2% for single country papers. This suggests that broad global connectivity significantly enhances the scientific robustness of soil research. Thus, journals should play an active role in connecting the global scientific community. First, aligning with the trend towards polycentricity, journals should foster inclusive editorial networks involving scientists from diverse regions. Second, recognizing that high-quality research relies on cross-regional validation, editorial strategies should prioritize curating themes focused on transnational comparative studies and global-scale synthesis, thereby facilitating the integration of fragmented local knowledge into generalized theories. Finally, in the era of Open Science, journals must champion data standardization and the FAIR principles. By removing technical barriers to collaboration through transparent data policies, journals can help build a cumulative, reproducible, and highly collaborative knowledge base for the future of soil science.

# Soil as Component of Ancient Adobe, Mudbricks, Mortar, and Plaster: Investigation of Engineering Structures of The Past in Oman

**Khoula Al-Toubi and Said Al-Ismaily***

*Department of Soils, Water and Agricultural Engineering, College of Agricultural and Marine Sciences, Sultan Qaboos University, Muscat, Oman,*

*E-mail: esmaily@squ.edu.om

**ABSTRACT**

Soil is a vital material of old structures (buildings, aqueducts, liners of irrigation channels, etc.) that form the architecture and cultural heritage of Oman, enduring for millennia. his research investigates soil cultural ecosystem services, sustainable construction materials, and ancient engineering techniques in Al-Dakhiliyah Governorate, focusing on monuments and ruins in Izki, Nizwa, and Bahla. This research explores how ancient Omanis used local soil to build durable structures. We assess the physicochemical, mechanical, mineralogical and elemental characteristics of the soil used in the old structures and evaluate the cultural and economic values of soil-based heritage sites among local communities and visitors. A mixed method approach was employed by integrating field observations, interviews, laboratory analysis and perception-based questionnaire. Soil samples were collected from different old engineering structures and examined through physical, chemical, mechanical and elemental lab analysis. Simultaneously, a structured survey was conducted to evaluate public perception of the cultural and economic importance of soil-based heritage. The results show that soil used in ancient structures predominantly fall within loam, silt loam and sandy loam textures. Izki soil materials revealed higher clay (25.6%), whereas Bahla ones contained finer silt rich soils (59.7%). The inclusion of plant fibres, straws and shell fragments was found to enhance the durability and improve hydrothermal performance of adobe, mudbricks and other engineered parts of the structures. Elemental analysis confirmed calcite, quartz and dolomite as dominant minerals, which reflect the adaptive use of locally available geological resources and the deep knowledge of traditional builders. Mechanical tests indicated compressive stress ranging between 0.35-20 MPa and bulk densities from 1.38-1.78 g/cm3. The public perception survey highlighted that over 70% of respondents strongly agreed that these sites contribute to Omani cultural identity. Heritage tourism also arisen as an important economic driver: 63.5% of visitors reported spending between 10-50 OMR (26-130 US$) per visit, while 97.1% agreed that improving facilities like guided tours, explaining the value of soil as vital construction materials, and recreational areas, which educate about soil resources, would increase visitation. However, 80% of respondents indicated limited awareness of the role of soil and traditional materials in construction, suggesting the need for enhanced education and interpretive programs. This work demonstrates that ancient Omani builders owned sophisticated knowledge of soil properties in old engineering projects, enabling the creation of structures that remain environmentally and culturally meaningful.

# Engaging Youth with Soil Science through an Original Picture Book

**Shunhua Yang[1*], Yongxiang Han[2], Yanning Zhang[3], Jie Zhang[4]**

*[1]State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*

*[2]Xugou Central Primary School, Lianyungang, China*

*[3]Nature Watching Science Center, Nanjing, China*

*[4]Jiangsu Science Communication Center, Nanjing, China*

*E-mail Address of Presenting Author

**ABSTRACT**

Soil, as the foundation of terrestrial ecosystems, is indispensable for sustainable development. However, effective communication of soil science remains a challenge, particularly among younger audiences. While general soil science resources exist, there is a noticeable lack of high-quality, original picture books that are both scientifically accurate and culturally relevant for school students.

To address this gap, we developed an original picture book specifically designed for primary and secondary students. This interdisciplinary project integrates expertise from soil scientists, educators, and artists to ensure the content is engaging and pedagogically sound. The book systematically introduces key concepts such as soil formation, material composition, and the science behind soil colors. It builds relatable connections by linking soil types to common foods and introduces cultural context through China's iconic "Five-Colored Soil" tradition. The narrative also addresses pressing environmental issues like soil degradation in China and suggests practical, everyday actions that students can take to protect soil resources.

This presentation will elaborate on the creative strategy and co-development process used to transform ABSTRACT ideas—such as soil profiles, composition, and biogeochemical processes—into visually compelling, story-driven illustrations. We will demonstrate how the book's design fosters curiosity and encourages a sense of responsibility among young readers.

This project shows that a well-designed picture book, grounded in local context and scientific rigor, can serve as an effective bridge between soil science and the public. It offers a meaningful model for enhancing soil literacy and cultivating ecological awareness from an early age, contributing to long-term sustainability education.

**Keywords:** Soil Science Communication; Science Picture Book; Interdisciplinary Collaboration; Public Understanding of Science; Environmental Education

# Analysis and Exploration on the Paths of Experiential Soil Science Popularization towards Primary School Students

**ABSTRACT**

Soil lies at the center of the terrestrial and ecological environment of the Earth. It is the foundation for agricultural and forestry production and plays a crucial role as an environmental buffer. However, the overall level of public scientific literacy in soil science remains low, and there are marked regional imbalances in soil science popularization efforts. Primary school students are one of the key target groups for science popularization in China in the new era, and experiential science communication can not only help them acquire scientific knowledge, but also deepen their emotional resonance with soil and agricultural sciences. In this study, we first investigate the soil- and agriculture-related knowledge points included in primary school science education. On this basis, we classify the knowledge system of soil science, design and develop experiential soil science popularization courses for primary school students, and carry out science popularization practice activities in university laboratories and soil museums. Finally, we disseminate the courses and typical case videos through online media. The project outcomes have enhanced primary and secondary school students' and the general public's understanding of soil, stimulated their curiosity about and interest in agricultural science, and contributed to leveraging science popularization to support all-round human development and the building of an innovative nation.

**Key words:** Soil science popularization; Primary school students; Experiential learning; Science education;

# Multidimensional Sustainability Assessment of Heavy Metal-Contaminated Farmland Remediation: An Environment-Policy-Economy Synergistic Framework and Long-Term Roadmap (2005–2040)

**Lin Dasong[1*], Chen Nengchang[2], Min Qifeng[1], Wang Yajun[1], Jiao Weixiong[1], Wang Xinyi[1]**

*E-mail Address: lindasong608@126.com

**ABSTRACT**

Heavy metal contamination in arable soil has escalated into a planetary crisis, severely compromising global food security and posing chronic carcinogenic risks to human health through dietary accumulation. Given the scale of this hazard, the governance of contaminated land is shifting from emergency pollution control to a Green and Sustainable Remediation (GSR) paradigm, which prioritizes minimizing secondary environmental footprints and resource consumption. Against this backdrop, China is undergoing a critical transition from government-centric intervention to market-driven management; however, existing evaluations predominantly focus on short-term technical efficacy, lacking a systemic understanding of the long-term trade-offs between environmental burdens, economic viability, and policy incentives. To address this gap, this study constructs an Environment-Policy-Economy (EPE) ternary synergistic analysis framework. Methodologically, we first diagnose the spatiotemporal evolution of pollution trends from 2005 to 2025, quantitatively isolating the net contribution of landmark policy interventions, such as *the Soil Pollution Prevention and Control Law.* Subsequently, an integrated Life Cycle Sustainability Assessment (LCSA) and Cost-Benefit Analysis (CBA) system is established over a prospective 20-year cycle (2021–2040) to rigorously benchmark diverse remediation technologies, ranging from physicochemical engineering to nature-based solutions. Results indicate a distinct trade-off: while physicochemical measures offer rapid risk reduction, they incur disproportionately high Life Cycle Costs (LCC) and carbon emissions. Conversely, agronomic and biological strategies, though slower, yield superior long-term ecosystem service values and alignment with GSR principles. Furthermore, the economic analysis highlights that the diminishing marginal utility of fiscal subsidies renders the current model financially unsustainable, suggesting that a structural shift toward market-based instruments is essential. By revealing these multidimensional interaction mechanisms, this study provides empirical evidence for optimizing the technological roadmap, ultimately informing the strategic development of China's soil governance towards the 2035 and 2040 sustainability horizons.

# Optimal Organic Amendment Strategies for Safe Utilization of Heavy Metal-Contaminated Soils via Interpretable Machine Learning and Multi-Objective Optimization

**Min Qifeng[1], Lin Dasong[1*], Chen Nengchang[2], Wang Yajun[1], Jiao Weixiong[1], Wang Xinyi[1]**

**ABSTRACT**

Anthropogenic heavy metal accumulation in arable soils constitutes a critical bottleneck for global food security and the "One Health" framework, necessitating sustainable remediation strategies that reconcile pollution control with agricultural productivity. Within the paradigm of safe utilization, organic amendments (OAs) are widely advocated for their dual capacity to sequester carbon and restore fertility; however, their deployment remains fraught with uncertainty due to the "double-edged" behavior of dissolved organic matter, which can inadvertently mobilize toxic metals under specific edaphic conditions. Conventional heuristic approaches, limited by linear assumptions, are insufficient to navigate the complex, non-linear trade-offs between remediation efficacy, yield enhancement, and secondary environmental risks across heterogeneous landscapes. To bridge this gap, this study develops a precision decision-support framework by synthesizing multi-decadal bibliometric data (1995–2025) into an optimized ensemble machine learning architecture. We successfully modeled the dynamic heterogeneity governing soil-OA interactions, employing SHAP (SHapley Additive exPlanations) to quantitatively decouple the mechanistic tipping points between metal immobilization and activation. Furthermore, the NSGA-III algorithm was deployed to resolve high-dimensional conflicts, generating a Pareto-optimal frontier of non-dominated solutions. These generalized results identify site-specific OA regimes that strictly constrain mobilization risks while maximizing ecological benefits, effectively advancing remediation strategies from empirical trial-and-error to data-driven precision management. Ultimately, this framework provides scientific leverage for digital soil governance, enabling policymakers to design spatially explicit incentive mechanisms that harmonize soil carbon sequestration goals with stringent food safety standards in sustainable agroecosystems.

# An Integrated Practice and Model Building Based on the "Bio-Vitality Cultivation Method"

**Li Miaoxian,zhong Haiying, Wu Jiaqiang,**

## ABSTRACT

Soil health is the cornerstone of sustainable agricultural development. Addressing the degradation of soil ecological functions in China caused by high-input farming models requires the effective translation and widespread dissemination of soil science knowledge into practical technologies. This paper takes the "Bio-Vitality Cultivation Method" implemented by Just Agrotech Co., Ltd. as a case study. It systematically analyzes how this method transforms principles of soil microbiology and ecology into a core technological system for "targeted activation" of indigenous functional microbial communities. The study focuses on how this system is applied to soil ecological restoration through a closed-loop "diagnosis-activation-management" pathway and constructs a three-dimensional knowledge dissemination and agricultural technology extension model integrating "R&D, service, and science popularization." Practical data indicate that this system can reduce chemical fertilizer and pesticide use by 10%-50% while enhancing soil biological activity, improving crop quality, and significantly increasing farmers' income. This research provides a practical model for the application and effective dissemination of soil health knowledge, combining technological innovation, service empowerment, and educational outreach, offering valuable insights for promoting the green transformation of agriculture.

Keywords: Soil health; Knowledge translation; Microbial ecology; Technology dissemination; Input reduction and efficiency increase; Agricultural extension

Introduction

Soil degradation has become a core obstacle to global sustainable agricultural development, often rooted in the neglect of soil ecosystem complexity and the disconnection between soil management knowledge and its application. While ensuring food security, Chinese agriculture faces severe challenges such as soil compaction, loss of biodiversity, and disruption of nutrient cycling due to long-term reliance on chemical inputs. Addressing this dilemma requires not only advanced soil science knowledge but, more critically, the systematic translation of this knowledge into practical technologies that farmers can "understand, use, and see results from," and the achievement of large-scale, efficient dissemination and adoption.

The "Bio-Vitality Cultivation Method" is an integrated practical system developed in this context. It is not merely the application of a single technology but a comprehensive process that applies theories of soil microbial ecology and plant nutrition throughout problem diagnosis, technological product development, field service, and agricultural extension. This paper aims to systematically review and academically evaluate this system from the two dimensions of knowledge application and dissemination practice, to provide a replicable pathway for the scientification and popularization of soil health management.

1. Application and Translation of Soil Science Knowledge: From Theory to Targeted Technology

Effective knowledge application begins with accurately grasping core scientific issues and technological innovation. The application logic of the "Bio-Vitality Cultivation Method" reflects a deep understanding and engineering translation of the ecological concept that "soil is a living system."

(1). Scientific Basis of Application: A Paradigm Shift from "Addition" to "Activation"

This system departs from conventional approaches that simply add exogenous microbial agents or inert organic matter to soil. Instead, it is based on the principles of "resource regulation" and "competitive exclusion" in microbial ecology. Its core scientific understanding is that healthy soil itself harbors a rich gene pool of beneficial microorganisms (indigenous microbes), whose activity is constrained by the supply of energy (carbon sources) and nutrients. Therefore, the focus of technological application is not on "introducing external aid" but on targeted activation of existing, locally adapted beneficial functional microbial communities (e.g., phosphate-solubilizing bacteria, nitrogen-fixing bacteria, biocontrol agents) by providing readily available, high-quality organic carbon sources and metabolic stimulants (such as specific oligosaccharides and peptides). This aims to restore the soil's inherent functions of nutrient transformation, disease suppression, and structural stability.

(2). Development of Technological Products: The Vehicle for Materializing Knowledge

To realize the "activation" concept, two key products have been developed as the vehicle for materializing knowledge.

- Stronggreen®: Focuses on providing basic carbon sources and nutrition. Its highly active organic matter and small-molecule organic compounds provide the "food" foundation for the proliferation of indigenous microorganisms, aligning with the principle in soil biochemistry that energy drives microbial community succession.
- Enzyaetiver®: Focuses on providing metabolic signals and stimulation. Rich in various microbial metabolites, it aims to mimic root-microbe dialogue in natural ecosystems, targeting the awakening of specific beneficial microbial communities in the rhizosphere. This reflects the deep application of knowledge concerning microbial quorum sensing and the ecological functions of root exudates.

The iteration from the first to the second-generation product reflects the deepening of applied knowledge from "improving the soil environment" to "precisely regulating microbial functions."

2. Technology Dissemination and Agricultural Service Practice: Building Bridges for Knowledge Implementation

The value of advanced knowledge and applied technology cannot be realized unless effectively communicated to end-users. The Just system constructs a multi-level, interactive knowledge dissemination and agricultural service system.

(1). Closed-loop Technical Service: Embedding Knowledge into Management Decisions

The system establishes a standardized agricultural service closed-loop of "detection-diagnosis-prescription-tracking-filing." This is not merely service provision but a continuous process of knowledge infusion and feedback learning.

- Scientific Diagnosis First: Relies on professional laboratories for soil health assessments, translating the ABSTRACT notion of "poor soil" into quantifiable indicator problems—the first step in scientific understanding.
- Customized Solutions and Explanation: Crop therapists develop personalized plans based on diagnostic results, considering local crop and climatic conditions, and explain the underlying principles to farmers (e.g., "why activate bacteria rather than fungi at this stage"). This foster understanding of both the "how" and the "why."
- Visualization of Effects and Data Feedback: Field demonstrations and sensor data displays make results "visible." Simultaneously, collected application data feeds back into technology optimization, forming an iterative cycle of "practice-data-knowledge."

(2). Multi-dimensional Science Popularization and Extension: Reaching, Educating, and Influencing

Employing differentiated communication strategies for different audiences, a three-dimensional science popularization network is built.

- For Growers: Experiential and Participatory Communication. Offline experience stations, field observation meetings, and on-site training create immersive learning environments, using local success stories to change entrenched mindsets and shift from "passive acceptance" to "active inquiry."
- For Industry Channels: Empowerment-based Co-construction Communication. Empowers distributors and retailers with technical knowledge, transforming them from mere product sellers into localized technical service nodes, expanding the coverage radius and trustworthiness of knowledge dissemination.
- For the Public and Academia: Authoritative and Digital Communication. Collaborations with experts and media enhance the system's credibility. Digital tools like short videos, live streams, and agricultural service apps break through spatial and temporal constraints, making knowledge dissemination more dynamic and accessible.

3. Evaluation of Practical Outcomes: Demonstrating the Value of Knowledge Application and Dissemination

The effectiveness of this integrated system is the ultimate test of the success of knowledge translation and dissemination.

- Improvement in Soil Ecological Indicators: Post-application increases in soil available calcium/phosphorus (32%-50%) demonstrate the restoration of nutrient cycling functions. The alleviation of continuous cropping obstacles and reduction in soil-borne diseases confirm the beneficial regulation of microbial community structure.
- Enhancement of Agricultural Production Benefits: Data such as 10%-50% reduction in chemical fertilizers and pesticides, average crop yield increase of 25%, and income increase of 500-15,000 RMB per mu directly reflect the economic feasibility of the technology application. This serves as the most potent driver for the widespread dissemination of the knowledge.
- Expansion of Knowledge Dissemination Scope: Annual training exceeding 15,000 person-times, coverage of over 30 million mu of crops, and the establishment of hundreds of service terminals and demonstration sites signify that this knowledge system and technical solution have gained extensive market validation and user acceptance.

4. Discussion and Implications: Rethinking the Dissemination System for Soil Health Knowledge

The practice of the "Bio-Vitality Cultivation Method" offers the following insights for the application and dissemination of soil health knowledge:

1. Knowledge Translation Requires Systems Thinking: Effective technology is not an isolated point but a complete chain from scientific principle to product to usage protocol. The soil must be treated as a system, requiring systemic solutions.
2. Technical Service is the Core Dissemination Channel: In agriculture, face-to-face, problem-solving technical service is far more effective than one-way information delivery. Agricultural technicians (therapists) are crucial "knowledge translators" and trust bridges.
3. Economic Benefit is the Foundation of Dissemination: All scientific knowledge and technological dissemination must ultimately create perceptible value (especially economic returns) for the user. Successful dissemination models inherently incorporate a clear path to helping farmers improve quality and efficiency.
4. Digital Tools Amplify Dissemination Efficacy: Combining traditional offline services with digital tools (digitized detection data, online solutions, multimedia communication) can significantly enhance the precision, efficiency, and reach of knowledge transfer.

Conclusion

This study, through the analysis of the "Bio-Vitality Cultivation Method" case, demonstrates that promoting soil health management hinges on the organic integration of effective translation of scientific knowledge into application and widespread dissemination through innovative models**. This system, with "targeted activation of soil biological vitality" as its core scientific application, successfully translates specialized knowledge like soil microbial ecology into actionable management practices for farmers by constructing a complementary dissemination network of "closed-loop agricultural service" and "multi-dimensional science popularization." It has achieved significant ecological and economic benefits. This integrated paradigm of "knowledge-technology-service-dissemination" provides a scientifically grounded and practical References for the current agricultural green transformation centered on soil health.

# From Soil Healing to System Thinking: Repositioning Sustainability through Nature's Logic

**Enheng Wang[1*] and Richard M. Cruse[2]**

**ABSTRACT**

Modern sustainability frameworks often rely on comparisons with degraded environmental baselines to assess progress. While such benchmarks offer visible signs of improvement, they may obscure a deeper truth: we are still measuring success against broken systems. This presentation argues that truly regenerative sustainability cannot emerge from anthropocentric metrics, but must instead align with the self-organizing, cyclical logic of nature. Soil should be understood not merely as a medium for productivity, but as a living entity whose vitality depends on systemic balance, energy flow, and feedback loops. We propose three key shifts: from intervention to alignment, from symptoms to systems, and from static goals to dynamic coherence. We also highlight early efforts to construct AI-assisted ecological References models capable of simulating nature-based baselines. These models help quantify how far current land-use practices deviate from ecological resilience, offering a more accurate compass for long-term sustainability.

Black soil (Mollisol), with its high fertility and rapid degradation under pressure, offers a symbolic and practical case. Through this lens, the report invites the global soil and water conservation community to expand sustainability science: not only as a technological challenge, but as a cross-cultural and philosophical undertaking rooted in our relationship with land. By listening to the land—not just acting upon it—we may rediscover a regenerative path for both ecosystems and the scientific paradigms that guide us.

**ABSTRACT**

Soil serves as the foundation of Earth's life-support systems, underpinning ecosystem functions while profoundly influencing the sustainable development of human civilizations and cultural identity. We will introduce the geographical and ecological context, soil formation factors, microbial diversity, ecosystem services functions, and patterns revealed through our scientific research regarding the Bayinbuluk alpine grassland (wetland) ecosystem in Xinjiang, China. Furthermore, we explore the critical role of soil science in revealing ecological resilience, supporting environmental conservation, and fostering cross-cultural understanding. In 2013, Bayinbuluk alpine wetland was inscribed as part of the "Xinjiang Tianshan" serial World Heritage property and listed as a UNESCO World Natural Heritage site.

The alpine meadow soil of Bayinbuluk is the product of long-term interactions between climate, topography, and living organisms. Its unique grass felt layer structure, rich microbial communities, and diverse plant-animal networks collectively form an efficient system for water conservation and carbon storage. Soil not only provides the habitat for local rare species such as the black-necked crane and swan but also carries the material heritage of herder cultures and ecological wisdom.

Globally, however, soils face multiple threats including degradation, desertification, and loss of organic matter. The Bayinbuluk case demonstrates that overgrazing and climate change pose severe challenges to its soil health. Through conservation practices such as scientific rotational grazing, soil restoration techniques, and public education, we can not only restore the land's vitality but also preserve place-based knowledge systems intertwined with the land, promoting both ecological and cultural sustainability.

From dirt to destiny—indeed, from the dirt of Bayanbuluk to the intertwined fates they sustain, supporting the lives of plants, animals, and human communities alike. Communicating soil science means recognizing soil as a living bridge between nature and civilization. Across regions, soil embodies place-based memory, ecological wisdom, and cultural heritage. Through science outreach, data sharing, and cross-cultural dialogue, we can deepen public understanding, and advance "Global Community of Shared Future" that healthy soil sustains all destinies—ecological, social, and cultural.

## ABSTRACT

Heavy metal contamination in soil is a major environmental issue of great concern to society, and its coping mechanism is also a significant national strategic requirement. The public, especially primary school students, urgently need an accurate understanding of the causes, impacts, and control measures of soil heavy metal pollution. However, current geoscience-related popular science activities seldom cover this topic. Based on the organic integration of geoscientific knowledge and primary school science education, this study uses the primary school as a practice platform. Drawing on the experience in geoscience popularization, the study sets three research dimensions at different levels: "Cognitive Construction: Establishing a Scientific Thinking Paradigm," "Practical Innovation: Building New Forms of Science Popularization," and "Value Shaping: Cultivating an Ecological Civilization Mindset." It guides students to deeply understand the relevant knowledge and objective realities of soil heavy metal pollution, learn about the specific implementation paths and operational methods for remediation, and enhance the awareness of soil environmental protection as well as the depth and breadth of popularizing dialectical views on development in primary schools. The study's implementation will help strengthen the connection between the scientific community and the public and enhance society's understanding of basic research.

# From Soil to Screen: Storytelling and Digital Media to Boost Soil Literacy

**S. Mantel**[1*]

[1] *ISRIC World Soil Information, Wageningen, the Netherlands*

*Stephan.mantel@isric.org

**ABSTRACT**

From Soil to Screen: Storytelling and Digital Media to Boost Soil Literacy

Soils are fundamental to life on Earth, yet they remain largely invisible and poorly understood by the general public. Since not many schools include soil in their curriculum, most people lack a knowledge framework, a perception and terminology for soils; they are soil illiterate. People that have no education or prior knowledge in soils need to be introduced to it to be able to engage in it and appreciate it. To foster awareness, soils must be introduced in ways that connect with everyday experiences and stimulate curiosity—storytelling offers a powerful approach.

The World Soil Museum serves as an educational hub for researchers, students, and policymakers to learn about soil diversity, functions, and significance of soils. The showcase of the museum are the displays of soil monoliths—undisturbed vertical profiles that reveal natural layering, color, and structure and interactive exhibits. Storytelling is used in guided tours to bring people closer to soils in a way that it inspires and is more easily remembered so that it will be passed on in communication between people. They stick to the mind as they link with perception and understanding of the public on topics such as people, history, land management, food security, and climate change.

To increase impact, decrease the dependency on human guidance and to reach people that are unable to visit the World Soil Museum in the Netherlands, we have developed digital tools that provide access to the stories, information and collections of the World Soil Museum so that anyone with an internet connected device can be exposed to the soils of the world, their stories and their functions.

In 2014 the World Soil Museum of ISRIC launched a virtual soil museum that allowed online visitors to walk through the museum. At the same time collection searchers were developed for online visitors that facilitates access to the whole collection of the museum (≈1000 soil profiles from 75 countries) with full access to the data and high resolution image of the soil.

ISRIC has developed, within the framework of the EU-funded Curiosoil project for enhancing soil literacy, an app that captures the soil stories of the museum on various themes and provides access to the scientific information of the museum. The app is accessible on multiple digital media and screens and can be used both inside and outside of the museum. It contains quizzes, videos, audio-guide and textual information. It stimulates curiosity driven exploration of soil information and stories. The app differentiates the content for children and adults and is multilingual. In addition the World Soil Museum launches a new website that contains educational content for pupils and students and provides exercises and modules for teachers to use, with self-guiding instructions, with school groups.

# Symphony of Biological Vitality

**Jiaqiang Wu, Zhuomin Zheng, Miaoxian Li, Chunchan Liang, Xiaohong Zheng**

## ABSTRACT

Symphony of Biological Vitality* is a stage play created by Guangdong Just Agro-Tech Co., Ltd. Through the personified interactions between soil organisms, crops, and farmers, this play vividly depicts the destruction and restoration of soil ecology in traditional agricultural production: It advocates for an ecologically friendly, scientifically sustainable approach to agriculture, emphasizing respect for natural laws and protection of soil biodiversity, aiming to achieve crop health, food safety, and agricultural sustainability by restoring soil vitality.
The script progresses through three stages:
1. Revealing the Problem: Excessive human interventions such as the overuse of chemical fertilizers, pesticides, and mechanical tillage disrupt the original biological balance of the soil, leading to microbial exodus, soil compaction, crop sub-health, and frequent diseases.
2. Proposing Solutions: Through the technical character "Jace," scientific diagnosis and ecological restoration methods are introduced, including the use of organic compost, small-molecule organic carbon, and biological activators, to rebuild the soil biological community and its functions.
3. Envisioning the Future: Promoting natural farming methods like cover cropping and mulching to restore soil vitality, ultimately achieving healthy crop growth and sweet fruits, echoing the vision of "striving for soil health, crop health, and human health."
Using humorous and vivid performances, the entire play calls on agricultural producers to "hear the voice of the soil and life," shifting towards a planting method that follows nature's way and conforms to ecology. This ensures yield while achieving harmonious coexistence between people and the land.
Keywords: Biological Vitality, Soil Vitality, Soil Health, Ecological Planting, Biological Activation, Bioremediation

Plot Content
1. The pristine ecological scene of soil, with various organisms cooperating and sharing food.
Narrator: The soil organisms in the virgin forest live and work in peace and contentment, leisurely and carefree, while the towering trees in the forest grow with deep roots and lush foliage. Suddenly, a strong wind blows, and a tree shudders. (All characters move about leisurely.)
Crop: This little wind and wave are nothing! Just shedding a few leaves, perfect to reward my brothers!
(A bacterium is dozing off/slacking, gets woken up by falling leaves.) Everyone starts bustling, discussing how to divide the work.
Bacillus: Brothers and sisters, we have a task. This piece of food is a bit big; we need more hands.
Filamentous Fungus: Coming, coming! (Extends hyphae.) I'll cut this giant into smaller pieces.
Nitrogen-fixing Bacteria: This carbon suits me perfectly. Local produce really does taste better.
Actinomycetes: How can you have something good without me! Found a great spot, quite comfortable here, dry and breezy. (Hides under a leaf.)
Earthworm: Let me take this back to nibble on slowly.
(Microbial-mineralized nutrients are thrown towards the tree base (basket). Nitrogen-fixing bacteria, after consuming leaves, reduce nitrogen gas into nitrogen and share it with the tree and other little companions.)
Crop: My meals this month are so abundant! Here, here, I'll also give you more sugars. Everyone has worked hard.
Microorganisms (together): 3, 2, 1, thank you, top supporter!
#2. Human intervention gradually begins to deplete and damage the soil. (The farmer cannot hear the tree's dialogue or the voices of the organisms.)
Narrator: People begin to enter this land for production, domesticating fruit trees.
Farmer: (Holding a compass) This is truly a treasure land! These trees are growing so well! Let me add some high-tech magic to make you grow even faster! (The farmer scatters compound fertilizer (chips and cola).)
Narrator: In pursuit of high yield, the farmer aggressively applies compound fertilizer. The crop grows wildly under the influence of massive nutritional fast food.
Crop: Yo-ho, these chips and cola are great! I'm getting fatter and fatter！ (being spoon-fed)
Farmer: (Legs crossed) Looks like trading five acres for a luxury car isn't just a dream！
Bacillus: Eating so well, seems you don't need me anymore. Well, I'm leaving then!
Nitrogen-fixing Bacteria: Brothers, the soil nutrients are so abundant; we can slack off a bit! (Throw away their function tags, lie down lazily near the roots, creating a chaotic scene of disarray.)
Narrator: With excessive nutrient elements added, the microorganisms think the big tree no longer needs their help. They all start slacking off.
Farmer: This high-tech magic is great! A bit more fertilizer, go all out, I'm going to get rich!
Crop: Boss, I can't eat anymore! I feel like I have indigestion. Why can't he hear me?
Narrator: The farmer doesn't know his crop is already over-nourished. He continues to apply fertilizer frantically. He not only wastes a lot of nutrients, causing an imbalance in soil nutrition leading to spindly growth, bloating, and "three highs" (metabolic issues) in the crop, but also breaks the soil's ecological balance, causing the soil microorganisms to flee, losing many free laborers! One wonders if he will regret it when he learns the truth.
#3. Microorganisms complain bitterly and begin to flee. Pathogenic bacteria gain the upper hand.
Actinomycetes: Sigh, working for such a boss is really no good!
Crop: Really sorry I couldn't provide a better environment for you. I couldn't help it either! Afraid I wouldn't have enough to eat, he just kept adding more, couldn't persuade him to stop (sighs)!
Farmer: Why isn't it growing even though I've applied so much fertilizer lately? These weeds must be stealing the tree's nutrients!
Crop: (Impatiently) That's because my roots are starting to rot. This soil is so salty and sour, like a pickling jar.
Narrator: On the nutritionally imbalanced soil, weeds begin to grow wildly!
Farmer: Weeds, what a nuisance! Now you'll see my true power! (sprays herbicide frantically)
Crop: Hey~ Boss, your high-tech magic is a bit overwhelming. My feet feel a bit hot.
Farmer: (Stomps foot, scratches the ground with hand) Why is the soil getting harder and harder? Let me get a rotary tiller to plow it.
Filamentous Fungus: Ahhh~ (Screams) It's over, it's over! I'm going to be shattered to pieces!
Earthworm: (Cut in half) Watch me perform the art of division!
(Pests and diseases start increasing.)
Pathogenic Bacteria: Hahaha (stands up), how come you're all out of commission! My chance has come! Full assault! (The pathogenic bacteria invade the entire soil environment.) You just fight each other! The more chaotic it is, the less anyone notices me (tiptoes across the stage, grabs the root's leg, and starts nibbling)!
Crop: Have mercy! My boss wants to trade for a luxury car!
Farmer: What's going on? Why are there so many pests and diseases? I just took a nap, what's happening? (Takes insecticide and fungicide to spray.)
Pathogenic Bacteria: Hmph, you think your mere fungicide can kill me? You know what they say: after three days apart, view a man with new eyes! (Upgrades equipment.) I can upgrade my combat power.
#4. Unstable weather ignites the fuse.
Narrator: Following this, two consecutive months of overcast and rainy weather add insult to injury. The tree begins to weaken, leaves droop, fruit drops. Farming the land becomes increasingly difficult, the trees grow worse and worse. What should we do about our future? The farmer constantly seeks solutions.
Off-stage voice (A childlike girl's voice rings out): Dad, Mom, will we still be able to eat healthy and delicious fruit in the future?
#5. Jace appears to diagnose the tree's condition.
Farmer (holds head, shakes it).
Then a soil technical specialist arrives.
Jace: I'm here!
Farmer: Welcome! Oh my, I used the best fertilizers and medicines, how did it end up like this?
Jace (Takes out instruments: EC meter, soil penetrometer, various test report boards): Saving the tree depends on the soil. We need to use scientific methods to see the current condition of the soil.
Jace: Look at this report, all nutrients are in excess ( shows EC meter).
Farmer: Isn't more nutrients a good thing? I even saved it for the tree, didn't keep it for myself.
Jace: (Very helplessly) You see, this is the common psychology of growers: excessive parental love, overdoing it.
Jace: You give a lot, but it can't eat that much.
Crop: (Concurs) Exactly, exactly! You understand me.
Then Jace checks the root condition (lifts the root's leg): The roots are peeling. Look, how can the tree roots absorb your nutrients like this? First stuffed full by fertilizer, then root damage. Damaged roots mean it can only starve. Starving makes it prone to sickness.
Farmer: So that's how it is.
Jace: (Takes out soil penetrometer; the penetrometer breaks.) This ground is so hard it broke my penetrometer.
Farmer: So I plowed the land several times. It's really hard work.
Jace: That doesn't solve the fundamental problem! We need to improve the biological vitality of the plot!
Jace: Where are your soil organisms? Why aren't they here? They may be small soldiers, but they are the great heroes of the soil, also the free laborers of the underground factory. How could you let them run away?
Farmer: I didn't chase them away either...
Jace: But every step you took destroyed their habitat, scared them all away! (Takes out a stethoscope for the farmer, lets the farmer hear the voices of the crop and organisms.)
Crop: I miss my little companions so much!
Jace to the organisms: Don't hide! All of you, come out and tell him!
Bacillus: When you were killing the pathogens, you took me out too!
Earthworm: When you were plowing, you broke me in half! (Shows broken leg.)
Fungus: Me too! My fungal network is all shattered!
Jace: Look, they are all injured like this. How can they work for your crop, how can they work for me?
Farmer: What you say seems to make sense.
Nitrogen-fixing Bacteria: (Pointing at a pressure gauge) And the work pressure is too high! I feel like I'm suffocating. In such a high-pressure environment, how can I work properly for you?
Filamentous Fungus: Look at this EC meter again. The value is so high, there are so many charged ions inside. Every time you water, my legs get shocked. I'm literally numb.
Farmer: It's all my fault for not hearing your voices earlier, causing such consequences.
Jace: (Everyone freezes.) Do you all think we should blame this farmer? (Pause.)
Jace: Actually, we farmers face four major pain points in the planting process: high fertilizer costs, soil degradation, unstable weather, and lack of professional planting knowledge. This farmer here has encountered these difficulties.
Jace to Farmer: Can't blame you entirely. It's caused by our common planting mindset. A very common problem is the "three highs and one low": high salt, high acid, high nutrition, low vitality.
Farmer: Sigh, I want to grow well too, just don't know how. No one ever properly taught me.
#6. Cultivation Theory and Product Intervention
Jace: Actually, there are free resources in nature itself. The deep-rooted, lush virgin forest also benefits from nature's gifts. So why don't we try using the power of nature?
Farmer: There are free resources?
Crop: Come on, brothers, let's show the boss the power of nature.
What is the sun above our heads? (Together: Photosynthesis, energy source!)
What are the carbon dioxide and nitrogen in the air? (Together: Carbon source, nitrogen source!)
How is our soil? (Together: Compacted!)
Is everyone breathing smoothly? (Together: No!)
Why? (Together: Lack of oxygen!)
Does everyone have enough food? (Together: No!)
What do you want to eat? (Together: Organic carbon!)
Jace (to Farmer): So, boss, what do you say we do?
Farmer: I don't know either.
Jace: You need to improve the soil first.
Farmer: How?
Jace: What does compacted soil lack? (Together: Carbon!)
Should it be small molecules or large molecules? (Together: Large molecules!)
Soil likes large carbon for improvement. So, on three, two, one... (Together: Show your talent!)
Organic Compost: I'm here! I'm the large molecule for soil improvement, rich in beneficial actinomycetes, best at improving the soil environment!
Farmer: You seem promising. So, once the soil is improved, what's the next step?
Jace: What is the main food source for our microorganisms? (Together: Organic matter!)
Can large molecule organic matter be absorbed directly? (Together: No, need small molecules!)
Is the conversion to small molecules a long process? (Together: Yes!)
What to do if they get hungry during the conversion? (Together: Water-soluble organic carbon!)
Microorganisms all love small-molecule organic carbon. So, on three, two, one... (Together: Show your talent!)
Strongeen® (Biological Oligosaccharides): Sweep away hunger, be yourself again! I am small-molecule organic carbon! (Distributes sugar.) Here, everyone gets some, none left out. I'll also call Deep Sea Essence to nourish the roots with vitality!
Farmer: Great! The microorganisms' food is also sorted!
Jace: (To microorganisms) Is having just food enough? (Together: No!) Need some stimulation!
Enzyativer®: (Biological Activator): Ignite energy, radiate vitality! Let me give you some "ambrosia," microorganisms, catch! (Scatters activator like a whisk.)
Nitrogen-fixing Bacteria picks up activator: Oh my, what kind of magical water is this? It tastes natural! So refreshing~
(Nitrogen-fixing bacteria busily work, converting nitrogen gas into nitrogen, passing nutrients to the roots and other bacteria.)
Fungus: Hey, my hyphae are growing back!
Enzyativer®:: I'm fermented from food-grade raw materials. Every drop is essence, the best is given to you.
Farmer: Real buyer testimonial! My luxury car hope is alive!
#7. Cover Cropping and Mulching
(Now, grass slowly starts growing.)
Grass: Wow, boss, you've restored this land?
Farmer: Of course! I have a soil doctor and a bunch of free laborers!
Grass: Guess what I want to do? Close your eyes, I'll give you a surprise. (Grass grows wildly.)
Grass: Okay, open them!
Farmer: Grass! (A type of plant) You really know how to make an entrance!
Farmer: Let me show you my power! (Takes out herbicide.)
Jace: Absolutely not! Grass roots can break soil compaction and also secrete organic carbon to feed your bacteria. When it grows tall enough, you cut it and return its nutrients to the field. Also, mulch is a good thing.
Crop: Weeds can also stimulate my root growth, making me focus more on work!
Grass: If you're going to reap my "grassroots revolution," say it quietly! Your plans are so obvious!
Farmer: You shut up! (Cuts it down in one swipe.)
**#8. Flourishing and Full of Vitality**
(The tree begins to regain vitality, flowers, bears fruit.)
Farmer: This whole year hasn't been easy. Who understands the hardship of farming? At the mercy of the weather, constantly worried, earning hard money walking a tightrope.
Jace: The planting end bears the greatest cycle and risk in the entire chain. What we can do is ensure every penny we invest is worthwhile. Use the power of nature wisely, follow nature's way, conform to nature, and nature will reward us with the sweetest fruits.
Child's Off-stage Voice: Dad, Mom, will we still be able to eat healthy and delicious fruit in the future? (Repeats once, echoing the earlier part.)
Narrator: Of course you will! We are all engaged in the cause for soil health, crop health, and human health, striving for the sustainable development of soil and crops, all so that you can eat safe agricultural products. You, like this tree, will grow up healthy and strong under the care of our Biological Vitality Cultivation Method.
All characters sway and wave their hands, presenting a scene of unity. The MV for "Our Soil" plays.
The End!

## ABSTRACT

**1. Early soil science popularization activities,**
China's research on soil as a science should have started with the Soil Research Office of the Central Geological Survey founded in 1930. The activities of soil science communication are relatively early. China Soil Society decided to establish a working group on popular science when it held its fourth member congress in Chengdu in 1979. After more than a year of preparation, it held its first working conference on popular science in Nanjing from November 23 to 26, 1981. Then, from June 27th to July 1st, 1983, the second meeting of the Chinese Soil Society was held in Changsha.
In the first conference on soil science popularization, Lin Putian, a representative of science popularization, has published more than 250 popular science articles in Hunan and national newspapers and periodicals. In addition, the national soil science popularization work has also taken scientific and educational films such as "red soil utilization improvement" and "phosphate fertilizer" and produced slides such as "crop malnutrition", which have promoted agricultural production. The book "Soil Knowledge" compiled by Nanjing Institute of Soil Science, Chinese Academy of Sciences, has issued nearly one million copies. And made some work plans, including: (1) compiling and publishing popular science works such as Soil in China and Application of Trace Elements in Agricultural Production;
(2) Make and distribute a set of slides of "Main Soil Types in China", and a series of popular science slides will be made and distributed according to regions or soil types in the future;
(3) Cooperate with Shanghai Science and Education Film Studio, first complete the science and education film of Boron Fertilizer, and then complete the science and education films of Zinc Fertilizer, Molybdenum Fertilizer and Manganese Fertilizer before 1985;
(4) Learn the form and experience of "Rural Service Desk" sponsored by Jiangsu Association for Science and Technology, and the soil societies of Jiangsu, Yunnan, Hebei, Liaoning and other provinces will cooperate with the popularization departments of provincial associations for science and technology to edit and publish short articles introducing the scientific and technological knowledge of soil and fertilizer for rural agricultural technicians;
(5) Decided to organize the compilation of a set of intermediate popular science books "Soil and Fertilizer Knowledge Series" to comprehensively and systematically introduce the knowledge of various branches of soil science;
(6) With the support of the Popularization Department of the National Association for Science and Technology, 1-2 sets of maps and cards on nutrient deficiency in soil and plants will be produced;
(7) In order to cultivate young people's interest in natural science, since 1982, a popular science summer camp for young people has been jointly organized in Shenyang by Zhongyin Soil Society, Liaoning Soil Society and Liaoning Botanical Society, and will be held once a year in different areas.
(8) In order to meet the convening of the fifth member congress of China Soil Society in 1983, it was decided to hold an exchange meeting on the experience of popular science work of China Soil Society before the convening of the congress in 1983.
The second conference on popular science held by China Soil Society was held as scheduled in 1983. There were 47 members of popular science committee and representatives of provincial societies. The conference exchanged experiences of popular science from all over the country, but the first popular science plan was not completed. At this session, new ideas were put forward, including:
(1). Before 1985, hold a class on soil science creation and soil scientific research photography technology; Seminar on popular science of metered fertilization.
(2) In order to review the achievements of soil science popularization, it was decided to edit and publish the National Collection of Excellent Works of Soil Science Popularization and 100 Cases of Soil Science and Technology Application Achievements, and it is planned to display the soil science popularization materials of various provinces at the fifth national congress of the Soil Society.
(3) The meeting further studied the issues related to the Soil Knowledge Series decided by the first meeting of popular science work, initially worked out the compilers of each volume, and decided to write the first draft before 1985, so as to be published as soon as possible.
(4) In order to strengthen the work of soil science popularization, the meeting asked the provincial and municipal societies to set up science popularization organizations as soon as possible, actively carry out the work of soil science popularization, and make contributions to agricultural modernization.
Unfortunately, the third conference on soil science popularization in 1985 was not held as scheduled, and the work of science popularization was interrupted afterwards.
Before 2018, China's scientific popularization worksheet was in technical training and technology promotion. For example, in 2018, the relevant departments of the Ministry of Agriculture carried out the third phase of national cultivated land quality evaluation technology and the first phase of national supplementary cultivated land quality acceptance evaluation technology training.
In addition, with the rise of self-media, some enthusiastic soil workers have launched Weibo, Blog and WeChat WeChat official account. For example, since 2012, Chen Nengchang has carried out soil science popularization activities in Weibo, and released more than 1,000 pieces of popular science information in one year, which attracted considerable attention. In 2013, Chen Nengchang was invited by a chair to make a video of Sick Land, which caused considerable repercussions.
In 2013, a piece of news, "The whereabouts of 10,000 tons of rice with excessive cadmium in Hunan flowing to the dining table in Guangdong became a mystery", aroused the concern of the whole society about food security and human health, and Chen Nengchang was invited by Hunan Provincial People's Congress to give a special report on popular science. In the following years, Dr. Chen Nengchang made over 200 popular science reports nationwide, covering all aspects of soil in China.
Following the Air Pollution Prevention Action Plan and the Water Pollution Prevention Action Plan, China launched the Soil Pollution Prevention Action Plan in 2015, updated the Soil Environmental Quality Standard in 2018 and promulgated the Soil Pollution Prevention Law in 2019. During this period, Dr. Chen Nengchang participated in the consultation of the above three aspects for many times, which played a driving role.
In 2015, on the occasion of World Soil Day, "Silent Soil", the first large-scale domestic soil science book co-authored by Gong Zitong, Chen Hongzhao and Zhang Ganlin, was published in Science Press, which initiated the systematic dissemination of soil science in China, achieved a milestone breakthrough from technology transfer to cultural enlightenment with the narrative of integration of science and humanities, and reshaped the public and policy's understanding of soil with its international influence and long-term social value. The publication of Silent Soil can be said to be a milestone in the cause of soil science popularization in China.
On the other hand, at that time, WeChat official account attracted people's attention as a new way of communication. From January 20, 2014 to July 4, 2018, the WeChat WeChat official account Soil Watch launched by Chen Nengchang distributed 1,107 articles with 38,072 fans, Soil Home (March 26, 2018) and 67 articles with 2,766 fans, Environment and Health Watch (2008).

**2. Soil science popularization activities in recent years,**
On November 21, 2019, the new Science Popularization Committee of China Soil Society held a meeting in Guangzhou, which established the action of soil science popularization into campus, countryside and enterprises, and the communication of soil science has been greatly developed.
On World Soil Day in 2020, members of the Science Popularization Committee of the Chinese Soil Society launched 111 science popularization activities and marked them on the map of FAO.
In recent years, soil science popularization activities have the following characteristics:
1) The popular science activities of Zhu Yongguan, Zhang Fusuo and other academicians in national media and other media have produced great publicity effects. Many agriculture-related enterprises have also carried out various propaganda on soil science through the media, which has greatly improved people's attention and attention to soil;
2) During this period, many popular science books on soil were published, such as Living Soil (2023) edited by Zhu Yongguan, Soil: the Skin of the Earth-Telling the Story of Soil Science from Postal Culture (Science Press, 2021) edited by Yang Shunhua, and Cultivation and Practice of Healthy Soil translated by Chen Nengchang. and others.
3) The soil song "Our Soil" released in 2023 has been widely spread, which has effectively promoted the spread of soil science.
4) On the celebration day of World Soil Day in 2025, the opening ceremony of the first national soil science museum "Shishi Wansheng Soil Science Museum" was held in Shishi city, Fujian Province, which means that the communication of soil science in China has moved from official to folk, from urban to rural, and the first soil science museum will lay a solid foundation for the normalization, long-term and landing of soil science.
5) The Science Popularization Committee of China Soil Society will vigorously promote the construction of soil science popularization bases and further promote the dissemination of soil science.
6) China's first Law on Popularization of Science and Technology in People's Republic of China (PRC) escorted the dissemination of soil science.

**3. Future of soil science popularization in China.**
The relationship between soil and people is just like the relationship between fish and water. As the foundation of human survival and development, soil health profoundly affects the sustainable development of human beings.
In the future, in addition to actively carrying out your activities of popularizing soil science in campus, enterprise and countryside, China will do two things well.
1) Take the "Shishi Museum of Soil Science" as a template to promote the nationwide development of this model.
2) Strive to build more soil science popularization bases nationwide.
Let every Chinese realize the importance of soil, care for soil, protect soil, make soil healthy, and make Chinese civilization more brilliant!

**ABSTRACT**

Soil science is a small science that affects everyone's health. As the most complex multi-media and multi-interface substance, soil science is highly professional. Soil formation is slow, and the time scale is tens of millions. In the lifetime, human beings can't feel the influence of soil changes on human civilization and sustainable future, but the soil is also very fragile. Soil degradation such as soil pollution and soil acidification can be completed in a short time, and it affects the health of contemporary people.

Therefore, it is our duty as soil scientists to make everyone realize the importance of soil, and to protect and care for soil. The dissemination of soil knowledge cannot be deeply rooted in people's hearts after speeches, and it takes a long time for the public, especially farmers, to have enough knowledge of soil science.

To this end, we took the lead in setting up a non-profit organization “Shishi Soil Science Communication Hall” in Shishi City, Fujian Province, China, which aims to achieve the normalization, long-term and landing of soil science communication and make contributions to rural revitalization and soil protection in China.

At present, the content of the soil science museum has three parts.

The first part is to publicize the dedication of soil scientists and introduce the course and great achievements of famous scientists in studying soil.

The second part is to show the past lives of soil, and introduce the generation and evolution of soil on the earth in an easy-to-understand way; The relationship between major soil degradation events, soil health, soil degradation and human health and sustainable future!

The third part is the library, laboratory and dialect multimedia room, which can improve the local soil by training new professional farmers and play a demonstration role in building healthy soil.

In addition, we also have a lecture hall for soil science, inviting famous scholars at home and abroad to give lectures and exchange views.

Welcome soil scientists at home and abroad to visit our “Shishi Soil Science Communication Hall”!

# Siliceous restrictive layer: a new soil constraint in Northeast China's Black Soil Region

**Zhong-Xiu Sun[1*], Qiu-Bing Wang[1], Ying-Ying Jiang[2], Si-Yi Duan[1], Xiao-Miao Yu[1], and Cheng-Cheng Zhang[1]**

*[1] College of Land and Environment, Shenyang Agricultural University, Shenyang, Liaoning Province, China*

## ABSTRACT

In recent years, extensive soil surveys have revealed a unique silica-clay composite horizon—now identified as the *siliceous restrictive layer (Btq)*—that blankets vast areas of Northeast China's black soil region. Unlike the well-known *fragipan (Bx)* described in Soil Taxonomy—which features loam-dominated composition and yellow-brown prismatic structure—this newly discovered Btq layer stands out with its silt texture and distinctive bright brown granular structure. This layer acts as a "hidden barrier" to sustainable agriculture by limiting root penetration, reducing water infiltration, accelerating slope erosion, and threatening regional food security.

- **Key characteristics**

**a. Physical Properties**: Low organic carbon (<1.43%), moderate total nitrogen (<0.15%), elevated available phosphorus (<30.83 mg/kg), high bulk density (>1.31 g/cm³), and weakly acidic pH (6.08)

**b. Particle Size**: Silt-dominated composition (6.27–20.01%) with minor clay content

**c. Geochemistry**: Enriched $SiO_2$ (>63.41%), moderate Fe/Al ratios, high silicate activity factor (Saf > 2.97), and intermediate eluviation intensity

- **How is it formed?**

The layer forms through dual regulatory processes:

**a. Terrace-Hilly Regions**: Groundwater dynamics interact with biological cycling—periodic groundwater fluctuations drive silica mobilization, while plant roots and detrital recycling enhance silica accumulation

**b. Mountainous Regions**: Dominated by biogeochemical cycling—plant silica uptake and organic matter decomposition create localized enrichment zones

- **what is the spatial distribution pattern?**

Covering 8,137 km² across key agricultural cities (Jixi, Jilin, Tieling, Hulunbuir), this layer occurs at depths of 28.8–65.3 cm with thicknesses of 51.5–92.4 cm. Silica neoformation abundance ranges 18.5–29.6% with densities of 303–630 g/dm³.

- **Practical implications**

Understanding this layer's distribution, characteristics, and genesis provides critical tools for:

**a. Soil Management**: Targeted interventions to mitigate root penetration barriers and water movement restrictions

**b. Agricultural Sustainability**: Enhancing food production while reducing slope erosion risks

**c. Soil Taxonomy**: Refining classification criteria for Chinese Soil Taxonomy's basic units (soil series)

This discovery advances soil science by identifying a novel constraint layer type and establishing formation models that bridge hydrological, biological, and geochemical processes. The findings offer actionable frameworks for sustainable black soil region management and global soil classification systems.

## ABSTRACT

Soil aggregate is an important indicator of soil structure and fertility in tea gardens. The stability of soil carbon pool is seriously affected by the problems of soil compaction and nutrient impoverishment in tea gardens in Guangxi.Mineral elements in red soil tea gardens, especially calcium, iron and aluminum, are closely related to changes in soil acidity and affect the stability of soil organic carbon and the formation of tea quality. Soil calcium-bonded organic carbon and iron-aluminum bonded organic carbon are organic mineral complexes with metal ions and metal oxides as bond Bridges respectively, and they have relatively high stability.A systematic assessment of the effects of applying biochar-based fertilizers in red soil tea gardens on the structural characteristics of calcium-bonded organic carbon and iron-aluminum bonded organic carbon in soil aggregates is conducive to reducing soil obstacles and enhancing productivity in intensive tea garden. In this study, a 40-year old Xishan tea garden in Guiping, Guangxi, located along the Tropic of Cancer, was selected as the research object. Three treatments [biochar-based fertilizer (BF), chemical fertilizer (F), and no fertilizer (CK)] were used for a field positioning test for two consecutive years to explore the structure and distribution pattern of calcium-bonded organic carbon and iron-aluminum bonded organic carbon in the red soil tea garden soil.

Evaluating the effects of biochar-based fertilizer application on the organic carbon structure characteristics and physical stability of soil aggregates in tea gardens can help to reduce soil barriers and improve productivity in intensive tea gardens. The results show that:The research results show that: (1) The application of biochar-based fertilizer increased the contents of Ca and Al in the tea garden soil. The Ca content of BF was 87.74% higher than that of CK, and the Al content of BF was 47.52% and 65.08% higher than that of CK and F respectively. (2) The application of biochar-based fertilizers reduced the content of calcium-bonded organic carbon (Ca-OC) in tea garden soil. The content of Ca-OC in the whole soil of BF decreased by 42.86% compared with CK. In the aggregates with particle size ranging from 0.25 to 2.00 mm, the content of Ca-OC in BF decreased by 75.41% and 63.41% respectively compared with CK and F. The proportion of total organic carbon in the whole soil Ca-OC of BF was 36.76% lower than that of CK. (3)The application of biochar-based fertilizer increased the content and contribution rate of Fe/Al-bound organic carbon (Fe/Al-OC) in the large aggregates of tea garden soil. In the aggregates with a particle size of >2.00 mm, the Fe/Al-OC content of BF was 39.66% higher than that of F, and the contribution rate of Fe/Al-OC (CRFe/Al-OC) of BF was 19.71% and 82.60% higher than that of CK and F, respectively. In the aggregates with a particle size of 0.25-2.00 mm, the Fe/Al-OC content of BF was 23.40% higher than that of CK, and the proportion of Fe/Al-OC in total organic carbon of BF was 26.30% higher than that of F. The application of biochar-based fertilizers is conducive to the optimal management and control of red soil tea gardens and the stability of carbon pools.

**KEY WORDS**

Calcium bond, Iron-aluminum bond organic carbon, Agglomerate, Carbon sequestration in tea gardens

**Acknowledgments**

Mineral elements in red soil tea gardens, especially calcium, iron and aluminum, are closely related to changes in soil acidity and affect the stability of soil organic carbon and the formation of tea quality. Soil calcium-bonded organic carbon and iron-aluminum bonded organic carbon are organic mineral complexes with metal ions and metal oxides as bond Bridges respectively, and they have relatively high stability.

# Addressing the Pains of Chemical Agriculture with Traditional Farming Wisdom: The Practice of the Qinbang Farm Model

**YuYan GUO[1*], Qi LIU[1],Xiaoyang LIU[1],Zhen QIN[2]**

[1] College of Soil and Water Conservation, Nanjing Forestry University, Nanjing, China

[2]Nanjing QBJP Agricultural Development Co., Ltd., Nanjing, China

## ABSTRACT

Soil degradation, heavy metal pollution, and biodiversity loss, stemming from chemical agriculture have resulted in the decline of agricultural ecosystem services.Ecological organic agriculture, as a production system that upholds soil, ecosystems, and human health, integrates economic development with environmental protection and resource utilization through human intervention. It establishes a symbiotic relationship between ecology and economy, achieving sustainable agricultural development[1]. As China's first 100ha whole-system organic ecological farm, Qinbang Farm adheres to biodynamic farming principles. For environmental restoration, it employs a composite fermentation technique using cattle manure and crop straw to produce multifunctional microbial inoculants as dynamic preparations, thereby rehabilitating and safeguarding the farm's cultivation environment. In soil nutrient and energy cycles, indigenous microbial organic fertilizers compensates for the deficiency of mineral fertilizers, enhancing soil nutrient retention and water-holding capacity. For pest control, a synergistic network of natural enemies and plant secondary metabolites replaces chemical pesticides, preserving farm biodiversity by transforming waste into cyclical production inputs. The farm pioneers a sustainable, closed-loop agricultural model. Over nearly two decades of chemical-free farming, the system achieves zero emissions. Soil organic matter rises from 0.6% to 4%, with over 100 earthworms per square meter. Rice yields exceed 9000 kg/ha, and laying hens maintain a production rate above 71%. This model provides a repeatable triad of microbial regulation-material cycling-ecological restoration formation for addressing agricultural non-point source pollution, holding significant practical value for the implementation of Circular Agriculture. Soil microorganisms, as sensitive bioindicators of soil health play crucial role in nutrient cycling, soil structure improvement, and pesticide degradation within the whole-region organic ecological farm model[2-7]. This study aims to investigate their practical value for the implementation of circular agriculture. Emphasis is placed on mining, constructing, and utilizing core microbiome information data from multiple microbial processes. It provides a scientific basis for predicting soil health levels[8-9] by targeting the use of microbial community profiles to enhance agricultural soil ecosystem functions, maintain soil health, and promote sustainable agricultural development.

# Soil aesthetics in the popularization of soil science

**Khirk[1*] A.V., Matyshak[2] G.V., Chepurnova[2] M.A.**

*[1]Dokuchaev Soil Science Institute, Moscow, Russia*

*[2]Lomonosov Moscow State University, Moscow, Russia*

** khirkav@my.msu.ru*

**ABSTRACT**

Soil performs many essential functions in the biosphere, which are studied in detail by soil scientists. However, researchers rarely consider another key function of soil—the aesthetic one. A soil profile is not only a carrier of information but also a painting by Nature itself. Numerous complex chemical, biochemical, and physical processes act like brushes and paints, gradually creating different soil horizons with varied structures and colors. Soil scientists distinguish over 400 colors in soils. In painting, these are often referred to as "earth colors." They have been used since the first cave paintings and continue to be applied in modern artworks. Revealing the aesthetic function of soil is an important element in understanding and popularizing soil science, capable of sparking interest among schoolchildren and students.

In 2017, the idea emerged to create a popularization group at Lomonosov Moscow State University called SoilART, consisting of researchers and students. Its purpose is not only to study soils of the north but also to promote the ideas of aesthetic soil science. The mission of SoilART is to reveal the beauty of soil to a wide audience. Since then, numerous workshops have been conducted at various events, and their number continues to grow. We hold lessons on the aesthetics of soil science for different audiences, using our own original approach to representing images at the intersection of science and art.

The Faculty of Soil Science at Moscow State University hosts a permanent Science and Art exhibition.

Science: soil, its granulometric particles, structure, and soil formations.

Art: pigments, soil-based paints, dorodango (soil balls), installations.

The centerpiece is a panel depicting soil-forming factors. Now, soil science students, teachers, applicants, and guests can explore soil through the lens of Science & Art.

By revealing the aesthetic function of soil, we tell the story of soil, its composition, and structure. When demonstrating the diversity of soil colors and pigments, we explain their chemical and mineralogical composition. While creating dorodango, we discuss the physical properties of soil. Through "Natural Paintings"—beautiful soil monoliths—we identify traces of soil-forming processes and formations, and explain soil genesis. Art allows us to interact with soil on a sensory level. Vivid imagery helps attract people to soil science topics. Listeners captivated by the aesthetic side of soil come to our soil workshop to expand their knowledge.

Thus, the group's activities contribute to the scientific education of schoolchildren, applicants, students, and others, while also showing soil scientists the aesthetics of soils. Each seminar and workshop by the group is unique, as the program is tailored to the audience's needs and prior knowledge. Presenting soil aesthetically helps draw attention to soil genesis and the challenges of soil preservation.

# Performance: Open Hands

**Cristina Angueira**[1] *

[1] *Soil consultant, Former Soil Research /National Institute for Agriculture Technology (INTA), Santiago del Estero, Argentina*

*cristina.angueira@gmail.com

**ABSTRACT**

The Performance began in the 60s, spread internationally,"art that refuses to settle", unrepeatable, actions carried out by the performer or recorded, spontaneous or scripted, answering: if we performatize a meeting, an excursion, a class, a conference, a soil communication? The objective is to generate a rupture for those who observe, to make the extraordinary appear, the difference that exists below the surface, we are unaware of its diversity, with amazement or not, in some spectators there is no strangeness, they already know its landscape. It is carried out in an agricultural high school in Santiago del Estero, Argentina, in the schoolyard, with soil samples of four soil profiles from the area in the corners, in the center a large white wooden square. The performer/s with images makes a tour of the local geoforms and each student takes a soil sample, places it in a container, adds water to make mud, plunges their hands into that material, experiments and then rests their hands on the square leaving that mud attached. He walks around the square, stops, looks at his hands, and the others, washes and starts again. Finally, the square is raised showing all the participants the work of "art made" with the different soils of the area. The scenic event builds on a network of individual and collective possibilities, in a union between, with a dilated scenic power, because it continues in space, in walking the territory, to mentally and fully appropriate the vitality and diversity of the relationship soil landscape.

# Classifying Soils with Artificial Intelligence

**Estrada-Medina Héctor*[1], Álvarez-Rivera Oscar[1]**

[1] *Departamento de Manejo y Conservación de Recursos Naturales Tropicales, Universidad Autónoma de Yucatán, Mérida, México)*

*hector.estrada@correo.uady.mx

**ABSTRACT**

Artificial intelligence (AI) holds remarkable potential across multiple disciplines and is increasingly assisting soil scientists. In this work, we explore one of its applications in soil science: developing rapid and accessible methods for soil classification. We compared usability and workflow simplicity of the three following tools, ChatGPT -conversational AI- (OpenAI), NotebookLM -AI analysis assistant- (Google, 2025) and PartyRock -interactive AI- (Amazon Web Services, 2025) to classify soils according to the World References Base for Soil Resources (IUSS Working Group WRB, 2022). Each system was provided with data sets containing detailed field descriptions and laboratory analyses of soil profiles previously classified. The evaluation focused on the ability of each AI to identify diagnostic horizons and soil qualifiers correctly and deliver consistent classifications. Results showed that ChatGPT accuracy was highly prompt-dependent, which is limited by the expertise of the user, NotebookLM relied strongly on user-uploaded documents but was less prone to "hallucinations", while PartyRock offered superior visualization and user interaction yet required more guidance and time to build and interact with the app to get a reasonable output. None of the AI tools analyzed delivered fully consistent results as repeated runs with the same dataset led to minor variations in the output, underscoring the difficulties in ensuring reproducibility. Nevertheless, these tools demonstrated clear potential for use in teaching soil classification and for supporting preliminary mapping or field decision-making. This study highlights the promise of AI as a complementary aid in generating rapid, reproducible, and transparent classifications, although expert oversight remains essential for final validation.

# Artificial Intelligence Assisted Soil Description and Inference

**Sandra J. Evangelista[1*], Fuat Kaya[1], Budiman Minasny[1]**

[1] *School of Life and Environmental Sciences, The University of Sydney, Sydney, Australia*

*sandra.evangelista@sydney.edu.au

**ABSTRACT**

Detailed soil profile descriptions are essential for site characterisation, soil mapping, pedological studies, soil–landscape modelling, and classification. Soil profile descriptions are also useful for monitoring soil change and the impacts of management practices on the soil. However, delineation and horizon identification can vary among observers, leading to inconsistencies in soil data interpretation. Moreover, soil profile descriptions remain challenging to derive from proximal and remote sensing technologies, including spectroscopy, due to their shallow sampling depth and limited ability to capture the structural and morphological complexity of soil horizons. This study explores the potential of artificial intelligence (AI) to assist in soil profile description and inference. Using two case studies from Turkey and Australia, we tested whether AI could be trained to predict and refine soil profile descriptions.

The study was structured in three stages for five soil profiles from each area. First, ChatGPT was prompted as a soil surveyor to describe and classify soil profiles (USDA, WRB, and Australian Soil Classification) from uploaded profile images. Second, textual profile descriptions were provided for AI-based correction and estimation of horizon properties, including clay content, organic carbon (OC), calcium carbonate ($CaCO_3$), and available water capacity (AWC). Third, laboratory data was introduced to refine estimates and calculate OC and inorganic carbon stocks and AWC. Subsequently, new profiles similar to the original five were used to evaluate whether the AI could transfer knowledge from previous examples to improve predictions.

The study demonstrates a workflow for evaluating AI-assisted soil description and inference, providing insights into the potential ofAI as tools for supporting soil survey and classification across diverse environments. Such capabilities can enhance the consistency and interpretability of soil profile data and facilitate their integration into digital soil mapping and comprehensive soil assessments.

**ABSTRACT**

Digital tools are transforming how soil science is documented, taught, and disseminated. Following the logic of Industry 5.0, digitalization and immersive visualization (AR/VR) combine with mobile devices and lightweight data streams to bring edaphological heritage to diverse audiences. Soil monoliths preserve the morphology and structure of representative profiles; however, their consultation is usually in person.

This work presents a web platform integrating interactive 3D models and augmented reality (AR) experiences of 12 monoliths from Mexico's National Soil Museum, located at the Colegio de Postgraduados, Campus Montecillo (Texcoco, Mexico). The proposal expands access for students, teachers, and specialized audiences to interact with soil heritage without time or location barriers.

Digitalization was performed using photogrammetry, capturing a series of multi-view images in a controlled environment. Preprocessing reconstructed point clouds and meshes; texturing was applied for export in standard formats using photogrammetry software. Subsequently, the models were normalized in open-source 3D mesh editing software (unifying scale, orientation, and position), and texture touch-ups were made to improve color and lighting continuity. Likewise, controlled decimation was applied to reduce the polygon count without losing relevant features, generating smaller GLB files that favor fast loading times and smooth AR performance without overloading devices.

The site implementation was built with Angular, TypeScript, SCSS, and HTML, prioritizing performance and ease of use. To offer AR without requiring app installation, the platform invokes Scene Viewer (Android) and Quick Look (iOS) directly from the web. Thus, the user can place the monolith to scale in their environment, rotate it, and zoom in on details like structure, aggregates, or horizon boundaries. On desktops, the 3D viewer allows fluid exploration with simple controls. Each model includes essential metadata, and a uniform 3D "table-like" base was designed to standardize presentation.

To assess educational utility, a semi-structured survey was administered to students. The response was positive; participants noted that interacting with 3D models improves morphological comprehension, encourages autonomous study, and is more motivating than static resources. They also highlighted 24/7 access from personal devices and the ability to "bring" the monolith into the classroom or home as practical support for classes and labs.

Overall, the project provides a reproducible and affordable workflow (sensor + photogrammetry + processing + web AR) that democratizes access to soil collections, reduces handling risks for physical specimens, and opens opportunities for teaching, outreach, and digital conservation. Future work includes expanding the collection and languages, implementing usage analytics, and linking each model to laboratory data and geospatial context.

# Technology in Soil Science Education in the 21st Century: Web, Software, and Apps for Generation Z

**Francisco Bautista[1]*, and Angeles Gallegos[1]**

[1] *Centro de Investigaciones en Geografía Ambiental, Universidad Nacional Autónoma de México. Morelia, Michoacán, México.*

FB leptosol@ciga.unam.mx

**ABSTRACT**

Soil science has been trending since the beginning of the Decade of Soils in 2015, with the global population seeking to understand the importance of soils. In the educational sphere, the digital native generation, known as Generation Z, demands new learning methods using social media. Therefore, it is urgent and necessary to generate soil science content for this new audience, as traditional soil science education has failed to engage young people due to a lack of access to audiovisuals appealing to scientific information, a lack of practical applications, and outdated teaching methods. The objective of this work was to create and develop a virtual museum of Mexican soil geography, providing accessible digital information for all audiences, and to acquire scientific knowledge in soil science. This effort aimed to modernize soil science education in Mexico and globally.

In 2021, a website called Virtual Museum of Soil Geography of Mexico (https://museosuelos.ciga.unam.mx/) was created with the intention of: a) organizing the YouTube channel videos by topic; b) organizing blog posts by topic; c) showcasing the technology developed (software and apps); d) creating a repository of soil maps of Mexico using geopedological, digital, and ethnopedological approaches, as well as digital maps of heavy metals in 14 Mexican cities; e) creating a museum blog to disseminate ideas about soil mapping and environmental functions; and f) creating a module for the automated evaluation of soil profiles in the state of Michoacán with an agricultural focus. The story begins in 2013 with the creation of the YouTube channel Soils, Environment, and More, which now boasts 309 videos, 2,716 subscribers, and nearly half a million views (508.5k views and 23.7k plays). That same year, the first blog, also named "Soil Scientists, Pedometricians, and Soil Lovers," was launched and currently features 234 posts and 143.3k reads. Also in 2013, the Facebook group "Soil Scientists, Pedologists, Pedometricians, and Soil Lovers" was created, which has almost 14.2k members and over 35k views per month.

The website for the "Virtual Museum of Soil Geography of Mexico" now features 328 videos, over 315 blog posts, geopedological and pedometric maps, and technology developed for the study and application of soil science. The museum's website has received over 94.4k visits worldwide, mainly from North America, Europe and Asia, in that order, but with intermittent visits from Oceania and Latin America. The website is an international benchmark for teaching soil science.

# Agricultural land assessment using a web portal in Michoacán, Mexico

**Francisco Bautista[1]*, Uriel Gómez[1] and Angeles Gallegos[1]**

[1] *Centro de Investigaciones en Geografía Ambiental, Universidad Nacional Autónoma de México. Morelia, Michoacán, México.*

FB leptosol@ciga.unam.mx

**ABSTRACT**

Michoacán is a state of national importance in fruit production, boasting, for example, 240,000 hectares of avocado orchards, thousands of hectares of lemon groves, and berries such as blueberries and raspberries, among others. However, agricultural activities are responsible for environmental degradation, and 40,000 hectares of agricultural land are lost annually due to poor land selection. The objective of this work was to design and develop an Automated Land Evaluation System (ALES) for Michoacán, Mexico. Information on topography, climate, and soils was analyzed to establish References intervals for evaluating land and soil profiles. The evaluations were automated in a web module developed using a combination of technologies. For example, the user interface was built with HTML, CSS, and JavaScript, complemented by jQuery to facilitate application programming interface manipulation and enhance interactivity. The Python framework Django was used for the backend, providing a secure structure for web application development. PostgreSQL was used to manage the relational database. The web module generates an agricultural site assessment based on topography and climate. It also generates a soil profile assessment by horizon, allowing for the identification of horizons with agricultural limitations. This efficient system enables a precise and rapid evaluation of the information. The assessment can be performed directly or through an external form embedded on the website. The system classifies the terrain and soil profile variables into five classes (very low, low, medium, high, and very high suitability), coloring the profile horizons and terrain classes from green to red, corresponding to the suitability levels from very low to high. This simple way of expressing the assessment will facilitate understanding for agricultural technicians training in the state of Michoacán through agricultural preparatory schools, as well as for the work of technicians in the federal "Sowing Life" program. The assessment report can be exported to an Excel file. The web portal and the agricultural soil profile assessment method have been specifically designed and developed for the state of Michoacán, Mexico. The primary soil groups in this region include Andosols, Cambisols, Luvisols, Vertisols, Leptosols, and Regosols. Therefore, it is not necessary to include characteristics in the assessment model that pertain to soils that do not exist in this state. This method of evaluating soil profiles is beneficial for assessing all the government's pedological information, which comprises more than 500 soil profiles. The website is in the Virtual Museum of Soil Geography of Mexico (https://museosuelos.ciga.unam.mx/) of the Centro de Investigación en Geografía Ambiental de la Universidad Nacional Autónoma de México.

**ABSTRACT**

The discipline of soil science is undergoing a profound transformation, shifting from static, destructive measurements to continuous, high-throughput data acquisition. However, the resulting volume and complexity of multi-dimensional data have outpaced traditional analytical frameworks, creating a critical need for advanced computational tools. This review examines the emergence of Artificial Intelligence (AI) as an essential "algorithmic lens" for unraveling the complexity of soil structure across scales. We explore how Deep Learning, particularly Convolutional Neural Networks (CNNs), is revolutionizing micro-scale characterization by automating the segmentation of X-ray Computed Tomography (CT) imagery with high fidelity. At the macro-scale, we discuss the use of Machine Learning (ML) to interpret hyperspectral and remote sensing data, bridging the "scale-divergence problem" by linking landscape observations to soil structural proxies. Furthermore, this paper highlights the capacity of AI to predict critical soil functions, such as hydraulic conductivity and aggregate stability, by modeling complex, non-linear biophysical interactions. Finally, we address current challenges regarding data scarcity and model interpretability (the "black box" problem), proposing a future research agenda focused on Hybrid Models (Physics-Informed AI) and Explainable AI (XAI) to ensure predictive accuracy is matched by mechanistic understanding. Ultimately, the integration of AI facilitates a fundamental shift in soil structure research from a descriptive discipline to a quantitative, predictive science capable of addressing pressing environmental challenges.

# Machine learning-based prediction of plant-available nutrients in soils using multiple variable selection strategies

**Seung Jun Lee[1*], and Jin Hee Park[1]**

[1] *Department of Environmental & Biological Chemistry, Chungbuk National University, Cheongju, Chungbuk, 28644, Republic of Korea*

*jjun3607@naver.com

**ABSTRACT**

Accurate quantification of soil nutrients is essential for precision agriculture, enabling optimized fertilizer application, yield improvement, and mitigating environmental impacts associated with nutrient overuse. Although machine learning based prediction models provide a rapid and cost-effective alternative to conventional laboratory analyses, their development is often limited by insufficient training datasets derived from small-scale laboratory experiments. To overcome this limitation, this study used an open soil database comprising approximately 16,000 samples. Three machine learning algorithms–random forest regression (RF), extreme gradient boost (XG-Boost), and support vector regression (SVR)–were implemented to predict soil macronutrients, including nitrogen (N), phosphorus (P), and potassium (K). Also, three correlation analyses–Pearson correlation analysis (LCA), mutual information evaluation (MI), and random forest-based importance ranking (IR)–were used to evaluate their impact on model performance. When the LUCAS database from European Soil Data Centre (ESDAC) was used, soil pH, electrical conductivity (EC), organic carbon (OC) were chosen as key variables. The OC was the most influential variable for predicting N, with a correlation coefficient of 0.89 in the LCA. In addition, all machine learning algorithms achieved high $R^2$ value and low root mean squared error (RMSE) for N prediction, especially with RF ($R^2$ = 0.90, RMSE = 0.81) and XG-Boost ($R^2$ = 0.90, RMSE = 0.81). For the prediction of available P ($P_2O_5$) and K, soil physicochemical characteristics database from Rural Development Administration National Institute of Agricultural Sciences (NASS) was used. The XG-Boost performed better than RF for both nutrients. For $P_2O_5$ prediction, RF model resulted in an $R^2$ of 0.18 and an RMSE of 361,13, while XG-Boost described $R^2$ of 0.30 and RMSE of 334.08. For K prediction, $R^2$ and RMSE showed 0.33 and 0.62 for RF, whereas XG-Boost achieved values of 0.41 and 0.58, respectively. The results indicate that further improvement in data processing and modeling is required. This study presents a systematic framework integrating open soil databases, machine learning modeling, and feature selection strategies to improve soil nutrient prediction. The approach can be further extended by integrating machine learning models with sensor-based measurements such as EC and near-infrared (NIR) to enable rapid, scalable, and cost-effective nutrient monitoring systems for data-driven precision agriculture and sustainable soil management.

# Automatic segmentation of soil micromorphological images using a Convolutional Neural Network

**Komkova D.**[1*]

[1] *Laboratory of soil minerology and micromorphology, Federal Research Centre V.V. Dokuchaev Soil Science Institute, Moscow, Russia*

*daria.komkova.lu@mail.ru

**ABSTRACT**

Commonly used software tools for the analysis of micromorphological images typically require well-defined and non-overlapping color characteristics for each object class. However, digital images of soil thin sections are characterized by pronounced non-stationarity. The overlap of color ranges among different micromorphological elements leads to errors in automatic classification, making expert involvement necessary and significantly slowing down the analysis workflow. To address the issue of non-stationarity and improve segmentation accuracy, convolutional neural networks with a U-Net architecture were developed. A first dedicated training dataset was compiled using Thixomet Pro and included thin sections of various soil types: chernozem, gleysol, solonetz, kastanozem, podzol and other.

A binary segmentation model was created to identify pores and aggregates. Segmentation quality was assessed using the Intersection over Union (IoU) metric, which reached 0.94 for PPL and 0.89 for XPL. These values indicate high segmentation accuracy, further supported by expert evaluation. The model reliably excludes air bubbles and regions of epoxy resin birefringence from the “aggregates” class, thereby improving the delineation of adjacent aggregates.

In addition, a model for multiclass segmentation was developed to differentiate the following micromorphological components: groundmass, pores, minerals, clay coatings, optically oriented clay, iron–manganese nodules, and black constituents including humus and plant residues. Multiclass segmentation presents particular challenges due to the overlap of color characteristics among micromorphological elements and the labor-intensity of producing a sufficiently representative training dataset. According to IoU metrics, the model confidently identifies groundmass and pores, whereas iron–manganese nodules, humus, and plant residues are segmented less accurately. Optically oriented clay and clay coatings are currently segmented poorly. These low metric values are explained by the pronounced class imbalance in the training dataset rather than limitations of the model itself.

Overall, the developed models demonstrate high performance in segmenting aggregates and pores, as well as solid results for the remaining micromorphological components.

[4] *Colorado Agricultural Experiment Station, Colorado State University, Fort Collins, USA*

*John.Blackwell@colostate.edu

**ABSTRACT**

Drought severity is increasing across the western United States, placing growing pressure on ecosystems, agriculture, and water resources. Soil moisture is a master variable influencing plant stress, hydrologic responses, and drought development, yet it remains one of the least monitored and least understood components of the water cycle, despite being the largest reservoir of fresh water on Earth. This project integrates artificial intelligence (AI) with soil moisture sensors and drought indicators such as NDVI and thermal imagery to improve real-time detection and forecasting of drought conditions. Using the NSF Sage platform, which enables AI processing at the edge and supports integration of environmental data streams such as climate sensors, cameras, and other field-based measurements, we combine remotely sensed and ground-based observations to track soil water availability more accurately and at finer temporal scales. The goal is to demonstrate that AI trained models combining thermal data, vegetation indices, and soil moisture measurements can enhance the detection of early drought signals before they are visible in traditional monitoring products. This work will establish a scalable framework for real-time drought assessment across the Western Great Plains, providing timely, actionable information for stakeholders ranging from land managers to policymakers.

# AI-Driven Data Mining of Scientific Literature: A Framework for Soil Research

**Yikang Cheng**[1*]

[1] *Nanjing TAG-HUB Innovation Technology Co., Ltd., Nanjing, China*

*taghub003@163.com

**ABSTRACT**

With the continuous output of research findings related to the soil environment, the volume of relevant scientific literature has grown exponentially. This presents formidable challenges for researchers to synthesize existing knowledge and identify research gaps through literature reanalysis. Traditional literature analysis methods, such as expert-led systematic reviews and meta-analyses, are constrained by manual processing limitations. These methods are typically limited to a few hundred publications, making them insufficient to meet the demand for in-depth mining of large-scale literature datasets. Accurately extracting in-depth scientific research data from extensive literature is a core prerequisite for advancing data-driven research in the soil environmental field. However, conventional manual data extraction methods suffer from inherent drawbacks, including high labor intensity, time-consuming procedures, significant subjective biases, and a high risk of human error. These limitations severely impede the efficiency of literature data utilization and the speed of research translation. In recent years, artificial intelligence (AI) technologies centered on machine learning have gradually demonstrated their capacity for large-scale literature analysis, providing a critical technical pathway to resolve the contradiction between the exponential growth of literature quantity and the inadequacy of effective comprehensive analysis capabilities. In particular, the rapid iteration of large language models (LLMs) has broken through the limitations of traditional semantic analysis, enabling researchers to accomplish complex, multi-dimensional scientific research tasks. This study proposes an LLM-based workflow for literature data mining, which can efficiently extract data from scientific literature with high precision ( $F1 > 0.95$ ). By adopting a human-in-the-loop expert feedback strategy, the workflow's feature extraction capability is effectively enhanced. This workflow exhibits excellent performance in literature data mining for soil environmental research and can provide robust support for the construction of domain-specific datasets for model training.

# 3D Two-stage Multi-modal Soil Pore Segmentation based on Flow Field

**ABSTRACT**

The morphological characteristics of soil pores are the core factors determining soil functional differentiation. There is significant heterogeneity in pore structure of different types of soil. However, current soil pore segmentation methods still face three core challenges when facing multi-type soil CT images, including soil type-specific interference, insufficient generalization of cross-type features, and unbalanced data in small samples. In order to solve the above problems, in this study, three typical soils, black soil, brown soil, and sandy loam, were selected as the research objects. Three-dimensional image data of soil pores were obtained by CT scanning, and a multimodal soil pore segmentation method based on flow field information was proposed. A one-dimensional flow model was constructed based on Darcy's law, and combined with the pore area heterogeneity distribution model and the dynamic pressure gradient between layers, the flow velocity distribution of soil pores was calculated. The reliability of flow field data was ensured by triple verification of physical rationality, numerical validity, and interlayer connectivity. The flow velocity information was used as the key modal feature and combined with the structural features of CT images to construct a multi-modal fusion segmentation framework (3DTM-UNet) to enhance the ability of the model to identify different types of soil pores. The results showed that the accuracy, precision, recall, and F1-score of 3DTM-UNet reached 99.8%, 95.5%, 94.5%, and 94.9%, respectively. Compared to the sub-optimal method ConvUNext, the F1-score was 6 percentage points higher. This study provides an efficient and reliable technical tool for the quantitative analysis of the pore structure of various types of soil, and the results can support research and practice in soil function optimization, quality assessment, and precision agriculture management.

*zhaoyue0609@126.com

**ABSTRACT**

Computed tomography (CT) has been widely applied to quantify soil pore architecture and structural properties. However, most CT-based soil studies simplify soil structure into a binary system consisting of pores and mineral matrix, which limits the representation of soil heterogeneity and obscures the contribution of individual soil constituents. In particular, particulate organic matter (POM), rock fragments, and roots are rarely distinguished explicitly, despite their important roles in soil structural organization and biophysical processes.

In this study, a multi-class soil component segmentation framework is developed to identify and separate multiple soil constituents from CT images, including pores, POM, mineral soil matrix, rock fragments, and roots. High-resolution CT images were used to construct a multi-class representation of soil structure, moving beyond conventional pore segmentation. Deep learning-based image segmentation methods were employed to capture differences in grayscale intensity, textural features, and spatial context among soil components.

The proposed approach enables the explicit delineation of POM that is resolvable in CT images and allows its spatial distribution, volume fraction, and spatial associations with pores and roots to be quantitatively analyzed. Compared with traditional binary segmentation, the multi-component framework provides a more realistic and interpretable description of soil morphology and micromorphology. Preliminary results indicate that distinguishing POM and other solid components significantly improves the characterization of soil structural heterogeneity.

This work demonstrates the potential of deep learning-driven multi-class segmentation for advancing CT-based soil morphological analysis. By enabling explicit identification of CT-resolvable soil constituents, the proposed framework supports improved interpretation of soil structural organization and facilitates the integration of soil CT image repositories into quantitative soil process modeling.

# AI-Assisted Applications for Soil Science Education: Tools for Teaching and Learning

**Estrada-Medina Héctor*[1], Álvarez-Rivera Oscar[1]**

[1] *Departamento de Manejo y Conservación de Recursos Naturales Tropicales, Universidad Autónoma de Yucatán, Mérida, México*

*hector.estrada@correo.uady.mx

**ABSTRACT**

Artificial intelligence (AI) is rapidly transforming education, creating new opportunities for improving the teaching and learning of soil sciences (Memari and Ruggles, 2025). Generative AI offers practical solutions to help students understand complex concepts and save time in analytical or repetitive tasks that often reduce instructional efficiency and student engagement (Holmes et al., 2019). Beyond simple interaction with existing AI assistants, a unique opportunity lies in the collaborative development of AI-assisted Applications (AI-apps), where users iteratively prompt AI systems through a natural language dialogue until the application meets their precise needs. This human-AI collaborative approach democratizes software development, allowing educators without programming experience to create specialized tools for specific teaching contexts and regional requirements. This work presents three examples of (Spanish/English) web-based AI-apps, developed primarily using Claude Sonnet 4.5 AI (Anthropic, 2025), ChatGPT PRO 5.2 (OpenAI, 2025) and Gemini PRO (Google DeepMind, 2025). 1) **EdafoConvert**: an application for unit conversions of basic physical, chemical, and biological variables used in soil science, including water potential (kPa, bar, atm), density, and nutrient concentrations. 2) **EdafoTexture**: an application for soil texture classification based on the USDA textural triangle. Users can input sand, silt, and clay percentages manually or interact directly with the triangle diagram to determine the textural class. It also includes batch processing capabilities for analyzing multiple soil samples simultaneously through Excel file uploads, and 3) **Soil-Water-Retention**: is an application for calculating soil water dynamics, including field capacity, permanent wilting point, and available water. Users can select from predefined soil textures (clay, silt, loam, sand) or input custom values, along with current moisture content, root depth and daily evapotranspiration rates for agricultural water management and irrigation planning. All these applications are freely accessible at https://sueloestudiarsuelos.com/apps. These AI-apps benefit both students and instructors, enhancing learning through interactive visualization of complex soil concepts, promoting autonomy and conceptual clarity (Kaur et al., 2023), automatizing repetitive tasks and enabling rapid creation of customized tools without programming experience, lowering technical barriers to educational innovation (Holmes et al., 2019).

# SpecSINFERS: Soil Inference Systems in the AI era

**J. Padarian, Ll. Huang, A.B McBratney, B. Minasny**

*Sydney Institute of Agriculture & School of Life and Environmental Sciences,*

*The University of Sydney, New South Wales, Australia*

*Email: jose.padarian@sydney.edu.au*

## ABSTRACT

A soil inference system is a software engine for the systematic prediction of soil properties from other soil properties readily available. Traditionally, tt consists of a collection of pedotransfer functions (PTFs) which are the knowledge rules that drive the inference process. In the AI era, advanced machine learning can also be integrated, combining powerful pattern extraction from large datasets and conventional soil knowledge. Given a user input (records with values of one or more soil properties; or measurements from a sensor), SpecSINFERS starts by predicting soil properties using all possible combinations of inputs and PTFs, assessing the uncertainty of each prediction. Then, a new round of predictions is started, using the input and predicted properties, automatically propagating the uncertainty at each step. This process continues until all the combinations of soil properties and PTFs are exhausted (Figure 1). During this process, SpecSINFERS also identifies when new predictions are outside the data domain in which the PTFs were generated, penalising the uncertainty in the presence of extrapolations. SpecSINFERS provides a way of organising knowledge in a carefully curated collection of PTFs that fulfil the requirements needed for uncertainty assessment. Additionally, it provides a systematic and consistent way of executing PTFs and applying uncertainty propagation. This tight coupling of model and uncertainty assessment ensures the correct use of PTFs. By using such a system, PTFs can be well documented and organised, not just in a journal paper, and thus promoting their use. It also opens the possibility of integration with other systems such as handheld devices (e.g. spectrometers) that can be used directly in the laboratory and the field to generate multiple predictions from a single reading.

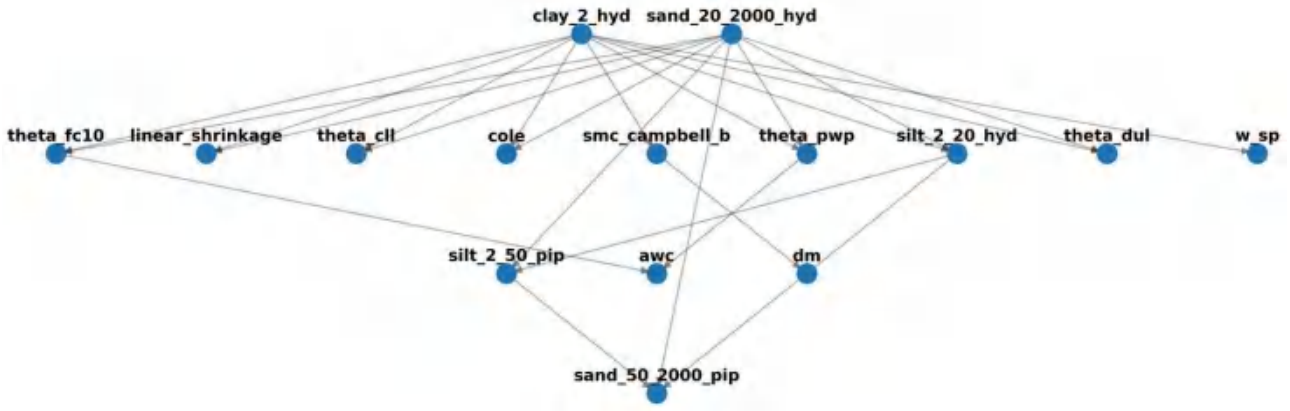

**Figure 1.** Example of the sequence of pedotransfer functions triggered by two soil properties (clay and sand content).

**ABSTRACT**

Soil structure plays a key role in regulating soil physical and biological functions. In soil micromorphology, its assessment from soil thin sections remains largely qualitative and strongly dependent on expert interpretation. This subjectivity limits reproducibility and hampers the systematic use of micromorphological information in quantitative soil analyses. Recent advances in deep learning offer new opportunities to support soil structure interpretation by learning spatial patterns directly from images; however, their applicability to soil micromorphology has not yet been systematically evaluated.

In this study, we investigate the feasibility of using deep learning–based semantic segmentation as a support tool for classifying soil structural units in thin section images. A dataset of binary thin section images, in which pores and solids were previously separated, was annotated according to major soil structural classes (massive, granular, crumb, blocky, and laminar). Several convolutional neural network architectures commonly used in semantic segmentation were trained and compared within a consistent experimental framework.

Model performance was evaluated on an independent test set using standard pixel-wise metrics, alongside a class-specific analysis. All tested architectures achieved high segmentation performance. Architectures explicitly designed to integrate multi-scale contextual information showed the most consistent performance across structurally heterogeneous classes.

This work provides an evaluation of the extent to which deep learning approaches can support soil structure interpretation from thin section images. The results suggest that deep learning–based segmentation has the potential to act as a decision support tool in soil micromorphological analysis, complementing expert interpretation and contributing to more reproducible and systematic assessments of soil structure.

# CSDMS BMI model coupling for Soil Digital Twins

**Danila R. Bardashov**[1]

[1] *V. V. Dokuchaev Soil Science Institute*

*alperf97@gmail.com

**ABSTRACT**

The work presents a Soil Digital Twin (SDT) integration framework coupling physically-based models across spatial scales from pore microstructure to landscape level for predictive simulation of soil-water-plant interactions. The integration follows CSDMS Basic Model Interface (BMI) methodology [1], enabling interactive runtime variable exchange where outputs from one model directly feed as inputs to another.

We developed a unified standard for model description containing model identification, physical description, BMI metadata including variables with CSDMS Standard Names, grid, time parameters, and coupling protocols allowing for compatibility verification and unit conversion during model linkage.

The SDT couples four model types: Erosion models include WaTEM/SEDEM [2] implemented in Python, and LISEM [3] with C++ core for event-scale Richards equation infiltration and kinematic wave routing. Crop models feature AquaCrop [4] with Fortran implementation for crop productivity and canopy dynamics, alongside DSSAT [5] for phenological modeling. ParFlow-CLM [6] couples subsurface flow with land surface processes. PNFlow extracts pore networks from X-ray CT, calculating van Genuchten parameters and permeability curves.

Models register as Python packages with pymt.plugins entry points exposing initialize(), update(), and finalize() methods. Runtime data exchange occurs through get_value() and set_value() methods. Grid information retrieves via get_grid_*() methods. Babelizer generates Python wrappers for non-Python components (C++, Fortran) enabling coupling across heterogeneous codebases.

Extensive validation of the system was caried out at Dokuchaev Soil Science Institute experimental site (Tver Oblast, Russia)

## ABSTRACT

Accurate identification of heavy metal pollution sources and their spatial distribution is critical for soil pollution control. However, the complex spatial heterogeneity of these pollutants poses significant technical challenges for large-scale source apportionment and high-risk area identification. Taking one of the largest megacities in China, such as Shanghai, this study integrates multi-source environmental data to systematically compare the predictive performance of eight machine learning models (ML), including Random Forest, Extreme Gradient Boosting, and Extra Trees, for five heavy metal contents in farmland soil: arsenic (As), cadmium (Cd), chromium (Cr), mercury (Hg), and lead (Pb). Results show that the Extremely Randomized Trees (ET) model achieved optimal predictive performance, with test-set $R^2$ values ranging from 0.57 to 0.67, demonstrating both strong predictive accuracy and robustness. Spatial predictions based on the ET model indicate significant enrichment of Cd and Hg in traditional industrial zones such as Baoshan and Jiading. Meanwhile, elevated concentrations of As and Pb are primarily distributed in Chongming, Pudong, and along riverine industrial-transportation corridors. In contrast, Cr shows a relatively uniform spatial distribution, consistent with natural background controls. Further analysis of driving factors reveals that the distributions of Pb and As are primarily influenced by climatic and hydrological processes, Hg accumulation is dominated by soil physicochemical properties, and Cd exhibits a characteristic “natural-anthropogenic” composite driving pattern, with significant contributions from GDP and population density. This study confirms the effectiveness of ML in integrating multi-source data to elucidate the spatial variability and driving mechanisms of soil heavy metals, providing methodological support for precise source identification, risk zoning, and targeted pollution control in megacities.

# Improving Conservation Tillage Systems: Soil EC and pH Management through Rotation, Nutrition and Microbial Interventions

**Banghai Wang**[1*]

[1] *Banghai Wang (Yunnan Dili Technology Co., Ltd., Shilin, China)*

*E-mail Address: 2264501078@qq.com

**ABSTRACT**

This presentation addresses core challenges in conservation tillage, emphasizing the critical impact of soil physicochemical indicators—particularly EC and pH values—on crop growth and farmland quality. Analysis of a wheat cultivation case study in Shilin County identifies excessively low EC values as a key constraint leading to crop growth inhibition and even plant death, highlighting widespread soil fertility deficiency as a prominent issue in cultivated land quality.

In response, a systematic improvement framework is proposed and practiced in Shilin County: optimizing crop structures through rotations such as tobacco–buckwheat–potato–corn, combined with integrated nutrient management emphasizing organic and micronutrient fertilizers, continuous application of microbial inoculants, and straw return to the field. These measures aim to enhance soil organic matter, stabilize pH, rationally adjust EC levels, and effectively control potential contaminants.

The ultimate objective is to establish a location-adapted, crop-structured, and scalable conservation tillage protocol that promotes sustainable soil quality improvement, balancing economic, ecological, and social benefits in agricultural production.

# Jingmai Mountain's Ancient Tea Forests: A Model of Forest- Tea Symbiosis, Biodiversity, and Cultural Heritage

**Kang Nan**[1*]

[1] *Kang Nan (Jingmai-Mangjing Tea Planting and Management Association in Huimin Town, Lancang County, Puer, China)*

*E-mail Address:191108231@qq.com

**ABSTRACT**

The ancient tea forests of Jingmai Mountain in Yunnan are an outstanding example of the ecological wisdom behind "forest-tea symbiosis." This system mimics the structure of a natural forest: a canopy formed by tall trees such as camphor at the upper layer, tea trees in the middle layer, and dense herbaceous plants at the lower layer. The forest provides shade and maintains humidity for the tea trees, while fallen leaves and branches decompose into natural green manure, nourishing the soil. This multi-layered, low-intervention model not only shapes the distinctive aroma profile of Pu'er tea but also creates an integrated habitat where birds, insects, orchids, ferns, and small mammals thrive, achieving deep synergy between agricultural production and biodiversity conservation.

The rich biodiversity also enhances both the flavor and value of the tea. For instance, the Blang people utilize microorganisms from the forest floor to ferment tea leaves, producing their unique Blang sour tea. The ethnic culture, passed down through generations, further injects enduring vitality into the sustained protection and rational use of this system.

# Effects of Dry Direct-Seeded Rice and No-Till Soybean Cropping After Rice on Soil Health and Nutrient Utilization in the Puer Region

**Xiaohua Li**[1*]

[1] *Xiaohua Li (Puer Agricultural Science Research Institute, Puer City, China)*

*E-mail Address: 422512926@qq.com

**ABSTRACT**

To address water resource constraints and enhance the multiple cropping index in mountainous regions, Pu'er City in Yunnan, China, has promoted two innovative planting models: Dry-seeded Rainfed Rice and Post-rice No-till Soybean.

Results indicate that compared to traditional paddy fields, the Dry-seeded Rainfed Rice model reduces irrigation water usage by 60%, significantly improves soil physical structure, and enhances soil aeration and infiltration capacity.

Planting no-till soybeans after the rice harvest fully utilizes the soil ecological environment and residual nutrients of the preceding crop. This model reduces the system's reliance on external nitrogen fertilizers through the biological nitrogen fixation of the leguminous crop. The study reveals that the soybean rotation phase increased Soil Organic Carbon (SOC) and Total Nitrogen (TN) stocks to 59.04 Mg/ha and 4.03 Mg/ha, respectively, significantly outperforming monoculture cereal systems. Additionally, this conservation tillage approach minimizes soil disturbance, helping to reduce nitrogen and phosphorus losses caused by surface runoff by approximately 25%.

The integrated application of these two models serves as an effective strategy to enhance soil productivity, boost carbon sequestration, and promote sustainable agricultural development in mountainous drylands by optimizing the soil water-air environment and stimulating soil biological activity.

# A Climate Change Perspective on Yunnan's Diverse Response Strategies

**Zuo Zhi[1*], Xurui Dai[2]**

[1] *Zuo Zhi (Pesticide Eco-Alternatives Center, Kunming, China)*

*E-mail Address: zuo.zhi@qq.com

**ABSTRACT**

In response to climate change, Yunnan is tapping into its rich natural environment and agro-biodiversity. Given the province's diverse geography, climate conditions, and ecosystems, its core approach is "using diversity to confront uncertainty." This includes deploying varied crop varieties and farming systems across different elevations; promoting multi-layered mountainous agriculture to improve resource efficiency; preserving and applying traditional ecological knowledge and adaptive practices from local ethnic groups; and developing climate-resilient specialty crops and adapted varieties. Together, these measures help farmers manage climate risks while strengthening the overall resilience and adaptive capacity of agricultural systems in the region.

To further explore these strategies, we are convening a Panel Discussion focused on Yunnan's Diverse Pathways for Climate Adaptation. We invited guests from across Yunnan to join us and share their experiences and insights.

# Building Climate-Resilient Agriculture through Multi-Stakeholder Engagement: The PEAC Model

**Hao Zhao[1*] and Xurui Dai[2]**

[1] *Hao Zhao (Pesticide Eco-Alternatives Center, Kunming, China)*
[2] *Xurui Dai (Pesticide Eco-Alternatives Center, Kunming, China)*

*E-mail Address:416202363@qq.com

**ABSTRACT**

Established in 2002, Pesticide Eco-Alternatives Center (PEAC) is a provincial-level 4A social organization dedicated to collecting, systematizing, and promoting environment-friendly and climate-friendly agricultural technologies. It focuses on exploring integrated pathways to reduce agricultural pollution, lower carbon emissions, and enhance climate adaptation, thereby advancing sustainable agricultural development. Currently, PEAC's work centers on three key areas: climate-smart rice farming, soil conservation, and agro-biodiversity.

In its efforts to address climate change and promote conservation agriculture, PEAC has developed a systematic working strategy grounded in "science-based evidence, community-driven practice, and network-enabled collaboration." This approach is implemented through three interconnected levels:

First, PEAC engages deeply with the local communities through participatory innovation. By conducting on-farm demonstrations, organizing farmer training, and facilitating co-creation of adapted techniques in rural Yunnan, it ensures that farmers can use and validate the technologies. Their feedback is continuously integrated to refine technical manuals and enhance the practicality and effectiveness of the approaches.

Second, PEAC actively builds cross-sector collaboration networks to foster multi-stakeholder engagement in sustainable agriculture. It brings together diverse actors such as local agricultural extension stations, Yunnan Normal University, provincial academies of agricultural sciences, NGOs, village committees, family farms, farmer associations, and local farmers. By integrating policy, academic, and social resources, PEAC strengthens collective action and amplifies impact.

Finally, PEAC works to develop scalable and replicable regional solutions. Through participatory testing, it identifies climate-resilient crop varieties and promotes practices that save water, enhance soil moisture retention, and reduce chemical fertilizer and pesticide use. These field-tested experiences are systematized into standardized technical materials and training modules. Through hands-on demonstration, knowledge exchange, and policy advocacy, PEAC helps transition climate-smart agricultural practices from local piloting to broader industry recognition and policy support.

This "research–practice–network–advocacy" model highlights the crucial role of multi-stakeholder engagement in advancing climate-resilient agriculture. It provides actionable and sustainable guidance for locally adapted agricultural transformation toward greener development.

**ABSTRACT**

Organic-inorganic fertilization is a key practice for enhancing soil fertility and crop yield, yet its response mechanisms under different fertilizer combinations in low-latitude plateau upland red soils remain poorly understood. Based on a 45-year long-term field experiment (1978–2022) in the red soil area of Qujing, Yunnan, this study evaluated the effects of various fertilizer regimes—including chemical fertilizers (N, NP, NPK) and their combinations with organic manure (NM, NPM, NPKM)—on maize yield, soil nutrients (pH, soil organic carbon (SOC), total nitrogen (TN), total phosphorus (TP), available nitrogen (AN), available phosphorus (AP)), and aggregate structure (the proportion of aggregates > 0.25 mm ($R_{0.25}$), water-stable aggregates($WSAC_{0.25}$), mean weight diameter (MWD), geometric mean diameter (GMD), percentage of aggregate disruption (PAD), fractal dimension (D)). Results showed that compared with the no-fertilizer control (CK), organic-inorganic fertilization significantly increased maize yield by 178.83%–188.19% and raised economic returns by 116.32%–122.10%. It also alleviated soil acidification, maintaining topsoil and subsoil pH above 6.0, while significantly increasing SOC, TN, and AN by 22.08%–31.69%, 11.18%–26.32%, and 20.00%–31.82%, respectively. In terms of soil structure, organic-inorganic fertilization enhanced macroaggregate content ($R_{0.25}$) and stability (MWD, GMD) in the 0–15 cm layer by 13.40%–41.18%, 7.37%–44.21%, and 19.44%–66.67%, respectively, while significantly reducing PAD by 25.00%–26.92%. These effects were more pronounced in the topsoil than in the 15–30 cm layer. Correlation analysis indicated that maize yield was closely associated with both soil chemical properties and aggregate structure, with chemical properties exerting a stronger influence. Random forest modeling identified TN and AN as the primary yield contributors (both 12.5%), while $R_{0.25}$ was the most influential aggregate parameter (7.9%). In conclusion, long-term organic-inorganic fertilization promotes maize yield by synergistically improving soil nutrient availability and structural stability. The NPM treatment performed best in terms of yield, economic benefit, soil quality enhancement, and nutrient retention, offering a sustainable fertilization strategy for upland red soil agriculture.

**Keywords:** organic amendment; inorganic fertilizer; acidic upland soil; yield enhancement; aggregate stability; soil fertility.

# An Ecological Farming Model for Climate Adaptation: Synergizing Soil Health and Community Resilience in Yunnan's Rice Paddies

**Chonglie Xu**[1*]

[1] *Chonglie Xu (Jianshou Family Farm, Dali, China)*

*E-mail Address: xixi-rain@live.cn

**ABSTRACT**

Chonglie Xu operates an experiential ecological farm in Eryuan, Dali, and manages a Community Supported Agriculture (CSA) network in Dayun. In rice cultivation, he actively practices ecological farming principles by integrating multiple climate-friendly agronomic measures, systematically developing a cultivation model that enhances both environmental and production benefits. Through field management techniques such as ridging, trenching, and furrow irrigation, combined with the rice-fish co-culture system, he has significantly reduced the reliance on chemical fertilizers and pesticides, achieving truly ecological cultivation. Water-saving practices like furrow irrigation not only lower water consumption but also effectively suppress methane emissions from paddy fields.

Furthermore, this model highlights climate-friendly measures such as variety selection, organic fertilizer application, and soil conservation, which continuously increase soil organic carbon storage and enhance the carbon sequestration capacity of farmland. These practices improve the agricultural system’s adaptability to climate change, promote the virtuous cycle of the field ecosystem and soil fertility, and ultimately boost comprehensive ecological benefits while strengthening the climate resilience and sustainability of community livelihoods.

# Functional characterization of key transporters regulating iron distribution in rice node

**Jing Che[1, 2 *], Yuting Qu,[1, 2], and Renfang Shen[1, 2]**

*[1] State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 211135, China*

*E-mail jche@issas.ac.cn

**ABSTRACT**

Iron (Fe) distribution in rice is a critical determinant of both plant productivity and grain nutritional quality, with nodes serving as central hubs for inter-vascular nutrient transfer. Here, we integrate the functional characterization of three key node transporters—OsVIT2, OsVMT, and OsIET1—that orchestrate Fe homeostasis through distinct subcellular mechanisms. OsVIT2 (vacuolar iron transporter) and OsVMT (vacuolar mugineic acid transporter) are tonoplast-localized proteins that sequester $Fe^{2+}$ and the phytosiderophore 2'-deoxymugineic acid (DMA) into vacuoles of parenchyma cell bridges and aleurone layers, respectively. Knockout of either gene disrupts vacuolar sequestration, resulting in enhanced Fe/Zn accumulation in polished grains (1.4–2.1-fold increase) without yield penalty, demonstrating their potential as sustainable biofortification targets. In contrast, OsIET1 (iron efflux transporter 1), a plasma membrane-localized VTL-clade protein, functions as a proton-coupled $Fe^{2+}$ efflux transporter specifically expressed in the xylem region of diffuse vascular bundles. Its disruption impairs Fe reloading into the xylem, causing excessive Fe deposition in nodes, chlorosis in young leaves, and a 38–48% yield reduction under Fe-limiting conditions. While OsVIT2 and OsVMT act as molecular "gates" that limit Fe mobility through sequestration, OsIET1 acts as an essential "pump" that drives preferential Fe allocation to developing tissues. Collectively, these transporters reveal a coordinated system where vacuolar storage capacity and plasma membrane efflux activity balance Fe partitioning between vegetative tissues and grains, providing complementary genetic strategies for either enhancing grain micronutrient content or ensuring optimal plant growth.

## ABSTRACT

Over the past three decades, soil acidification in China's southern red and yellow soil regions has intensified, posing severe threats to agricultural sustainability and national food security[1]. Based on the 2015 National Soil Survey, acidic (pH ≤ 6.5) and strongly acidic (pH ≤ 5.5) soils account for 32.4% and 4.7% of China's terrestrial area, respectively [2], inducing soil fertility degradation[3, 4], increased heavy metal bioavailability[5], reduced microbial community diversity[6], and over 20% crop yield loss in strongly acid-stressed areas[1]. As a major oil crops supporting national oil supply security (contributing 27.9% to China's oil crop yield growth from 2007-2022[7]), peanuts face persistent yield limitation in these acidic soils: 2007-2016 monitoring shows southern peanut yields are only 70.6% of the national average[8]. Previous studies identify strong acid stress and low soil fertility characteristics as key yield-limiting factors [2, 9], with field data confirming significantly reduced peanut biomass and fresh pod weight at pH 4.70 (strongly acidic) compared with pH 5.58 (suitable acidity)[10]. To address this bottleneck, this study aimed to: (1) clarify how soil acid intensity regulates peanut yield-related traits across genotypes; (2) screen acid-tolerant varieties suitable for southern acidic soils; and (3) explore nutrient dynamics underlying genotype-specific acid stress responses.

To achieve these objectives, a field plot experiment was conducted with three soil pH gradients (pH 4.44, pH 4.70, and p H 5.23; 4 replicates each) and four peanut varieties (S23_0202, S23_0310, ZYH100, and Pukehua 16). were selected for p lanting. Key yield traits (pod dry weight, 100-kernel weight) and nutrient dynamics (bulk/rhizosphere soil available P/K, pl ant N/P/K contents) were measured to evaluate genotypic differences in acid stress responses.

Regarding yield trait regulation, pod dry weight correlated positively with soil pH for ZYH100, S23_0202, and Pukehua 1 6 (significant gradient differences), while S23_0310 maintained stable pod dry weight—confirming soil acid intensity indire ctly regulates yield via pod number and kernel weight, with substantial genetic variation in responses. This finding further raised a critical follow-up question: Do peanuts adopt resource allocation trade-offs (prioritizing pod formation vs. kernel development) under acid stress?

For acid tolerance screening, 100-kernel weight (a key commercial value indicator) identified pH 5.23 as the optimal soil pH. At pH 4.70, S23_0310 (90%), S23_0202 (86%), and Pukehua 16 (89%) retained high relative 100-kernel weights, whi le ZYH100 dropped to 62% (severe kernel inhibition). At pH 4.44, tolerance rankings were: Pukehua 16 (88%) > S23_02 02 (77%) > S23_0310 (65%) > ZYH100 (52%).

For nutrient dynamics, bulk soil available P/K was medium-to-high (sufficient for growth), and all varieties had higher rhi zosphere available K than bulk soil (potentially drought stress adaptation[11]). No genotypic differences were observed in ro ot N/P/K or aboveground P/K, but S23_0310 had significantly lower aboveground N—suggesting a potential link to its uni que yield stability under acid stress (needing further investigation).

These findings carry significant practical and scientific implications: we provide targeted acid-tolerant peanut varieties for g raded acidic soils (Pukehua 16: strongly acidic; S23_0310/S23_0202: moderately strongly acidic; ZYH100: weakly acidic), establish a basis for exploring nutrient allocation and nitrogen metabolism mechanisms of acid tolerance, and thus facilitate high-yield, high-quality peanut production in southern China's acidic soil regions.

**ABSTRACT**

Managing the accumulation of toxic cadmium (Cd) and the biofortification of essential zinc (Zn) in cereals is a critical challenge for global food security and human health. Due to their similar chemical properties, these elements often share transport pathways from soil to grain, making it difficult to differentially regulate their accumulation. This presentation synthesizes findings from Sino-French collaborative research using cutting-edge technologies, including stable isotope tracing, synchrotron X-ray fluorescence, and laser ablation ICP-MS, to reveal the eco-physiological mechanisms governing the distribution of these metals in crops.

Research into the flux of Cd and Zn in soil-plant-grain systems shows that soil management is the first line of defense: organic amendments contribute essential Zn by increasing its available pool while effectively immobilizing Cd, thereby reducing its availability. Within the plant, remobilization from pre-anthesis vegetative pools contributes significantly to grain metal loading, typically accounting for 35–60% of total grain accumulation. However, Zn is remobilized much more efficiently than Cd, which is often trapped by high-transpiring vegetative organs. These organs, such as flag leaves and bracts, act as irreversible sinks for Cd, limiting its allocation to the edible grain. In contrast, these same tissues serve as primary sources for Zn remobilization during senescence.

Within the grain of wheat, the crease and periphery (maternal tissues) function as critical regulatory point. High-resolution imaging identifies the crease as the main barrier to Cd and Zn loading into the edible endosperm, while isotope tracing reveals that this barrier is more restrictive for Cd than for Zn. During grain development, while Cd remobilization remains restricted within the maternal tissues, Zn is significantly remobilized from the crease and periphery to the endosperm. These findings demonstrate that agronomic strategies targeting soil organic matter, tissue senescence, and post-harvest processing can be applied to selectively reduce Cd while maintaining or increasing Zn levels in cereal-based foods, thereby improving food safety while supporting micronutrient biofortification.

# Advancing the rhizosphere metabolic circular economy framework

**Kunkun Fan**[1,2*], **Haiyan Chu**[1,2]

[1] *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, No.298 Chuangyou Road, Nanjing 211135, China.*

[2] *University of Chinese Academy of Sciences, Beijing 100049, China.*

*E-mail: kkfan@issas.ac.cn

**ABSTRACT**

The rhizosphere metabolic circular economy (RMCE), first explicitly defined by Korenblum et al. (2022), operates as a coevolutionary system underpinned by three interconnected core mechanisms: reciprocal metabolic exchange, iterative reuse of resources, and adaptive remodeling of plant-microbe interactions. At its foundation is the unidirectional yet reciprocally beneficial flow of C from plants to microbes, a complex mixture of primary metabolites (sugars, organic acids, amino acids) and specialized secondary metabolites (flavonoids, coumarins, triterpenes), which act as both nutritional substrates and signaling molecules to select and nourish specific microbial taxa. Since its formal definition in 2022, accumulating research—spanning multi-omics, synthetic microbiology, field ecology, and molecular genetics—has expanded the RMCE framework beyond the initial "binary plant-microbe interaction" model, integrating spatial, functional, regulatory, and ecological dimensions that refine its complexity and practical relevance. A primary update lies in the recognition of spatial heterogeneity as a defining feature of RMCE, replacing the view of the rhizosphere as a homogeneous habitat. A second critical update is the expansion of RMCE's circular carriers to include the "live-dead microbe continuum"; the microbial necromass—accounting for 30–50% of SOM—functions as a slow-cycling C sink. Third, the framework now incorporates quantitative functional metrics that move beyond qualitative "no-waste" descriptions. Fourth, RMCE is now recognized as integrated with regulatory networks and complex multi-trophic interactions (e.g., viral-bacterial-fungal-plant cross-talk) that balance nutrient acquisition and defense. Fifth, RMCE is now viewed as an environmentally adaptive system capable of restructuring under various stress. Together, these updates redefine RMCE as a spatially structured, dynamically regulated, and ecologically complex system, providing a more comprehensive foundation for its optimization in sustainable agriculture.

[*]Correspondence: Luqing Zheng (zhenglq@njau.edu.cn).

**ABSTRACT**

Iron (Fe) is an essential element for plants, yet becomes toxic when in excess. Plant Fe homeostasis is primarily controlled by many basic Helix-Loop-Helix (bHLH) transcription factors (bHLH TFs). Our previous studies identified three IVb bHLH TFs—OsbHLH061, OsbHLH062, and OsbHLH063—as important negative regulators of Fe homeostasis, although coordinated function of subgroup IVb bHLH TFs remained unclear. Here, we show that rice subgroup IVb proteins play critical, redundant, yet functionally divergent roles in responding to changes in Fe availability. Higher-order mutants of *OsbHLH061/062/063* exhibited hypersensitivity to Fe deficiency and a marked overaccumulation of Fe under sufficient-Fe conditions. We demonstrate that OsbHLH061, which is induced by Fe and exhibits the highest affinity TOPLESS/TOPLESS-RELATED co-repressors (TPL/TPRs), plays a predominant role in repressing Fe accumulation and related gene expression under sufficient-Fe conditions. In contrast, OsbHLH063 is largely induced by Fe deficiency and plays more critical roles in Fe deficiency adaptation; notably, OsbHLH063 is essential for preventing photobleaching under low-Fe conditions. In addition, OsbHLH064, another IVb member, has minimal impact on Fe homeostasis. Our work elucidates a sophisticated regulatory paradigm in which orchestrated expression, genetic redundancy, and functional divergence within a transcription factor subgroup enable tight tuning of Fe homeostasis in rice.

# Unveiling the Microbial Terroir: Soil-Driven Microbiota Assembly Modulates Grapevine Potassium Uptake and Fruit Volatile Accumulation

**Menglong Liu** [1,2,3], **Zhanwu Dai** [1,2,3*]

## ABSTRACT

Agricultural products with unique flavor compounds were attributed to their place of origin, which is known as 'terroir'. In grapevine, the contribution of soil terroir (physicochemical properties) to wine grape quality has been well documented, yet the mechanisms linking soil nutrients, plant-microbe interactions, and fruit metabolism remain elusive. This study investigated the effect of soil-driven microbial terroir to grape flavor quality.

In this study, the multi-omic analysis were conducted for the soil property, microbiome (soil, rhizosphere and fruit surface), transcriptome (root, berry) and metabolome for three grapevine cultivars (Cabernet Sauvignon, Merlot, and Chardonnay) of six sites in Ningxia region (China). Results showed a strong positive correlation between soil available potassium (K) levels and grape berry pH. Transcriptomic profiling of grapevines growing in high-K soils indicated an upregulation of $K^+$ transporter genes (*VvKUP8* and *VvKUP10*). Co-occurrence network analysis further highlighted that these high-K conditions were associated with distinct shifts in the rhizosphere microbiome structure, specifically an enrichment of bacterial genera such as Niastella, Ensifer, and Sphingomonas. These findings suggest a potential link where soil K availability shapes specific microbial communities that co-exist with high-pH fruit phenotypes.

Beyond the rhizosphere, we further explored how these edaphic-driven microbial patterns extend to the carposphere (fruit surface) to shape fruit flavor (Liu et al., 2025). Results showed the assembly of the grape carposphere microbiome was primarily driven by environmental conditions rather than grape genotype. Further, operational taxonomic units (OTUs) within the genus Sphingomonas were strongly correlated with the production of C6 aldehyde volatiles, also known as green leaf volatiles (GLVs), which contribute to the fresh, green taste of the grapes. A key core gene set enriched in lipid metabolism was found to regulate both bacterial colonization and the activation of C6 aldehyde volatile synthesis, and the *VvLOX* gene playing a crucial role in this process. The microbe-metabolite relationship was further confirmed through inoculation of Sphingomonas sp. on the berry skin of two grape cultivars, resulting in increased GLV production.

Collectively, our findings establish a microbial link between soil properties and fruit quality attributes. We propose that soil factors not only directly supply nutrients but also act as selective filters for functional microbiomes that regulate both fruit acidity (via K uptake) and regional aromatic typicality (via VOC metabolism). This study offers a theoretical basis for manipulating the "soil-microbiome-fruit" continuum to improve grape quality in distinct terroirs.

**ABSTRACT**

Soil pollution poses a profound threat to ecosystem and human health. Moving beyond the traditional, often ineffective single-species remediation paradigm, this review proposes and elaborates a novel framework: biological interaction networks as the core engine driving efficient and sustainable soil decontamination. We systematically dissect the architecture and dynamics of key interactions, including plant-plant, plant-microbe, and microbe-microbe interactions, within remediation contexts, elucidating how mechanisms like mutualism, competition, and cross-kingdom signaling govern the fate of heavy metals, organic pollutants, and complex mixtures. Crucially, we explore how these natural networks can be actively engineered through strategies such as targeted bioaugmentation, precision biostimulation, and rational plant community assembly to enhance remediation outcomes. Furthermore, we highlight how cutting-edge multi-omics, synthetic ecology, and computational modeling are transitioning the field from descriptive ecology to predictive network design, enabling the decoding of the soil black box and the rational construction of tailored, resilient remediation consortia. Finally, we discuss the ecological challenges of introducing designed networks and outline a future road map toward precision restoration ecology, where theory-guided interaction network management enables effective, stable, and ecologically sound soil clean-up. This network-centric paradigm represents a fundamental shift from experience-based trial-and-error to a principled design approach for restoring soil health.

## ABSTRACT

Manganese (Mn) is an essential micronutrient but becomes toxic when accumulated in excess. The leaf sheath is proposed to function as a buffering compartment that temporarily stores Mn, ensuring a steady supply to developing tissues while preventing excessive accumulation in young organs. However, how rice coordinates Mn distribution and detoxification between these tissues remains poorly understood. Here, we identify OsYSLc, a member of the Yellow Stripe-Like (YSL) transporter family, as a plasma membrane-localized Mn-nicotianamine (Mn-NA) transporter with dual functions in Mn distribution and detoxification in the rice leaf sheath. GUS staining showed that OsYSLc is predominantly expressed in the leaf sheath, specifically in the phloem and cortical parenchyma cells. Heterologous expression and in planta transport assays demonstrated that OsYSLc mediates Mn transport in complex with nicotianamine. Loss-of-function *osyslc* mutants accumulated excessive Mn and Zn specifically in the leaf sheath of old leaves, including both the apoplastic and symplastic fractions, whereas metal levels in the leaf blade and developing tissues were slightly reduced.This indicates that disruption of OsYSLc traps Mn in the leaf sheath, leading to functionally reduced Mn availability in growing organs despite high total Mn levels in old tissues.Transcriptome analysis further revealed that several metal uptake genes, including *OsNRAMP5*, were significantly upregulated in the roots of *osyslc* mutants, likely as a systemic compensatory response to the perceived Mn deficiency in developing tissues. This shoot-to-root feedback enhances metal uptake but further aggravates Mn overaccumulation in the leaf sheath due to impaired internal redistribution. As a consequence of impaired Mn redistribution, *osyslc* mutants exhibited strong sensitivity to excess Mn, indicating that OsYSLc is required not only for Mn allocation to growing tissues but also for preventing toxic Mn accumulation through controlled internal detoxification. Field experiments showed similar ion distribution patterns, confirming the physiological relevance under agronomic conditions. In addition, *osyslc* mutants displayed increased concentrations of Fe, Mn, Cu, and Zn in grains. Thus, we propose that OsYSLc functions as a regulated “reservoir-and-valve” system in the leaf sheath, with cortical parenchyma cells serving as a Mn storage reservoir and the phloem acting as a conduit to developing leaves; OsYSLc mediates Mn release to young tissues as needed while retaining excess Mn in the reservoir to prevent toxicity. Furthermore, the increased micronutrient accumulation in *osysl1c* grains suggest that OsYSLc may be a promising target for mineral biofortification in rice.

## ABSTRACT

Peanut (*Arachis hypogaea L.*) is a globally important economic crop and oil crop, with an oil content ranging from 40% to 60% [1]. In 2024, China's peanut planting area will reach 4.837 million hectares, with a total output of 18.983 million tons, ranking second worldwide in planting area and first in total output, accounting for 16.7% and 37.7% of the global total respectively [2]. Fertilizers are critical for ensuring stable and high crop yields; however, long-standing issues in China's agricultural production—such as excessive fertilizer application, low utilization efficiency, neglect of soil nutrient resources, unregulated environmental nutrient inputs, underutilized crop yield potential, and ineffective control of nutrient loss—have not only increased production costs but also triggered environmental problems [3,4]. While strategies to improve fertilizer use efficiency exist (e.g., soil structure improvement, pH adjustment, scientific fertilization, and optimized fertilization techniques), these methods often require high technical expertise and incur substantial costs. Thus, leveraging the yield potential of existing peanut varieties, rather than relying on large-scale water and fertilizer inputs, is essential to simultaneously achieve high yields and efficient nutrient utilization.

Current research on fertilizer use efficiency globally has primarily focused on major food crops such as rice [5], wheat [6], and corn [7], with relatively limited attention to oil crops like peanuts and rapeseed. Additionally, much of the existing research on peanuts relies on laboratory pot experiments, which poorly simulate natural field conditions and lack practical applicability, leading to a gap between research findings and real-world agricultural production. Furthermore, research on peanut nutrient utilization efficiency lags behind, particularly regarding differences in nutrient use efficiency among diverse germplasm resources and the underlying mechanisms. To address these gaps, this study integrated field and pot experiments, employed a multi-index comprehensive evaluation system, and aimed to screen peanut germplasm resources with efficient nutrient utilization, and clarify the mechanisms governing this efficiency.

In this study, six fertilization treatments were established, each with four replicates: no-fertilizer control (CK), nitrogen omission (PK), phosphorus omission (NK), potassium omission (NP), full nitrogen-phosphorus-potassium (NPK), and NPK + organic fertilizer. A total of 18 representative peanut varieties from different regions were initially evaluated. Based on measurements of single-plant yield under different nutrient treatments, six varieties (YH76, S23-0303, ZYH100, S23-0202, Pukehua 16, S23-0044) were selected as key research objects to explore the relationship between nutrient utilization efficiency and yield.

Significant differences in nitrogen utilization efficiency (NUE) were observed among the six peanut varieties. Specifically, the NUE of S23-0044 (≈34%) and Pukehua 16 (≈33%) was significantly higher than that of YH76 (≈21%) and S23-0303 (≈22%). Nutrient supply exerted a significant positive effect on yield: all varieties achieved the highest yield under the NPK treatment, and yields in nitrogen-containing treatments (NP, NK) were significantly higher than those in the nitrogen-deficient treatment (PK), confirming that balanced nutrition promotes peanut nutrient absorption. Correlation analysis revealed a weak positive correlation between NUE and single-plant yield under NPK treatment ($r = 0.444$), which was not statistically significant ($P > 0.05$). This finding challenges the conventional assumption that "high NUE necessarily corresponds to high yield": for example, S23-0044 exhibited high NUE (34%) but a relatively low single-plant yield (61 g), while ZYH100 achieved both high NUE (29%) and high single-plant yield (87 g). These results demonstrate that peanut nutrient efficiency and yield do not follow a simple linear relationship, providing critical foundational data for future research on variety-fertilization interactions.

## ABSTRACT

Phosphorus (P) is essential for agricultural production but remains one of the least efficiently used nutrients, leading to both resource depletion and environmental losses. In France, organic fertilizers have been increasingly applied since the 1950s to reduce reliance on mineral P inputs. While long-term organic fertilization generally increases total soil P (TP) stocks, its effects on plant-available P (AP) are highly variable and poorly understood. In many cases, increases in TP do not consistently increase AP, highlighting the role of soil processes in influencing P availability. Soil AP includes not only by dissolved phosphate in soil solution but also by diffusive phosphate replenished from solid-phase pools. A substantial fraction of soil P is stored in colloidal and particulate forms, which act as dynamic buffers affecting P availability. Among these pools, P associated with water- dispersible colloids (WDC-P, <450 nm) represents a highly mobile and potentially bioavailable fraction. Despite its recognized role in off-site P transfer and environmental pollution, the contribution of WDC-P to sustaining soil P availability under different organic fertilization regimes remains largely unexplored. This contribution proposes a process-based perspective in which WDC-P acts as a dynamic phosphate reservoir whose contribution to soil AP depends on colloid behavior, fertilization type, and time since application. Focusing on long-term organic fertilization, the presentation will discuss (i) how different organic fertilizers affect WDC and WDC-P dynamics, (ii) how WDC-P may contribute to both chemically defined and diffusion-controlled AP pools, and (iii) how temporal changes in colloidal behavior influence soil P availability. By linking soil colloidal processes to P availability, this work highlights the potential of organic fertilization strategies to sustain soil fertility through controlled-release mechanisms rather than repeated P inputs. Understanding these processes is essential for developing sustainable P management strategies that improve fertilizer efficiency while reducing environmental losses.

# Preliminary assessment of humic substances from chicken-manure hydrochar as drivers of soil microbial activity

**Francisco J. Moreno-Racero, F.J.[1*], Jorge Medina[2], Laura J. González[2], Humberto Aponte[2], and Heike Knicker[1]**

[1] *Group of Interactions Between Soils, Plants and Microorganisms, Department of Food Biotechnology, Instituto de la Grasa (CSIC), Building 46, UPO Campus, Ctra. de Utrera km 1, 41013 Seville, Spain*

*fjmoreno@ig.csic.es

## ABSTRACT

Hydrochar (HC) has shown promising effects on soil biological functioning, although the mechanisms underlying these responses remain unclear. In previous greenhouse experiments, the application of 6.5 t ha$^{-1}$ of chicken-manure-derived HC to a Cambisol cultivated with sunflower increased bacterial and fungal abundance, enhanced microbial activity, shifted microbial community structure, and improved plant performance under both well-irrigated and water-deficit (WD) conditions (unpublished data). However, physicochemical characterization of the HC revealed low total organic C (5.86%) and N (0.47%), low water holding capacity (32%), and limited nutrient contents (Moreno-Racero et al., 2025), insufficient to account for the observed biological responses. These findings suggest that, beyond these bulk properties, specific labile or bioactive fractions may be responsible for the stimulation of the soil–plant–microorganism system.

Here, we present a preliminary evaluation of humic substances (HS) extracted from HC as potential drivers of these effects. HS were extracted using 0.1 M NaOH, followed by sodium removal via ion-exchange membranes, rotary evaporation (40 °C, 2 h), and lyophilization. Solid-state $^{13}$C NMR analysis showed that the extracted HS were characterized by reduced O-alkyl and N-alkyl C regions and a relatively higher proportion of aromatic C compared with the original HC.

A 77-day incubation experiment (25 °C) was conducted using the same Cambisol under well-irrigated and WD conditions. Treatments included: (i) unamended control (CTR), (ii) HC at 6.5 t ha$^{-1}$, (iii) HS equivalent to 6.5 t ha$^{-1}$ HC, and (iv) HS equivalent to 20 t ha$^{-1}$ HC. Soil microbial functioning was assessed using the MicroResp technique to determine basal respiration (BR), together with fluorescein diacetate (FDA) hydrolysis, arylsulfatase, arginine ammonification, urease, and phenol oxidase activities. HS increased BR similarly to HC and stimulated specific enzyme activities. Arylsulfatase showed a positive, dose-dependent response irrespective of irrigation regime, indicating stimulation of S cycling processes in soil (12–33% increase relative to CTR). Under WD, FDA hydrolysis increased at the higher HS dose (equivalent to 20 t ha$^{-1}$ HC) compared to CTR. The remaining enzyme activities were unaffected.

Overall, these preliminary results indicate that HS may partially account for the previously observed stimulation of microbial activity by HC, pointing to mechanisms beyond simple nutrient supply. The findings support the hypothesis that specific bioactive fractions within HC may contribute to improvements in soil microbial functioning, potentially influencing plant performance.

**ABSTRACT**

Urbanization disrupts soil ecosystems, yet the mechanisms linking biodiversity loss to the persistence of ecosystem functioning remain poorly understood. Here, we investigated how 12 urban stressors—including heavy metals, pesticides, microplastics, and macro-litter—shape soil biodiversity and ecosystem multifunctionality (EMF). Our results reveal that urban soil systems undergo a functional reorganization as the number of multistressors (nMS) increases. Biodiversity declined significantly as the number of urban stressors increased, whereas EMF remained comparatively resistant to stress accumulation. Although several ecosystem functions weakened under urban pressure, others—particularly soil fertility—remained stable or even increased. Importantly, persistent ecosystem functions were more strongly associated with chemical, climatic and urbanization pressures, including heavy metals, salinity and microplastics, than with biodiversity itself. This decoupling between biodiversity and multifunctionality suggests that urban soils can maintain aggregate ecosystem functioning despite significant biodiversity declines. Furthermore, we show that stressor networks differentially regulate biodiversity and ecosystem functions, generating divergent ecological responses across functional dimensions. These findings challenge biodiversity-centered conservation paradigms and highlight the need for urban management frameworks that recognize the growing role of these anthropogenic filters in sustaining ecosystem functioning under chronic urban stress.

# Drivers of soil health of olive groves and their impact on the sustainable production of olive oil in the Mediterranean

**Victor Valenzuela Polo[1], Victoria Ochoa Esteban[*2], and Antonio Manzaneda Ávila[1,2]**

[1] *Department of Animal Biology, Plant Biology and Ecology, University of Jaén, Jaén, Spain*

[2] *University Institute of Research in Olive and Olive Oils, University of Jaén, Jaén, Spain*

*vochoa@ujaen.es

**ABSTRACT**

Olive cultivation is one of the most socioeconomically important agricultural systems in the Mediterranean Basin, yet it faces increasing threats from land degradation, climate change, and unsustainable management practices. These pressures contribute to soil erosion, biodiversity loss, and reduced agroecosystem functionality, ultimately affecting olive yield and oil quality. Despite its importance, the drivers of soil health in olive groves and their implications for sustainable production remain poorly understood.

Here, we present a comprehensive large-scale assessment of soil health in Mediterranean olive groves, integrating agronomic management, climatic conditions, soil properties, biodiversity indicators, and productivity metrics. Using multivariate analyses and network correlation approaches, we evaluated how different levels of agricultural intensification, landscape context, soil types, and the presence of soil pollutants influence soil biological communities and ecosystem functioning. Our results reveal strong associations between soil biodiversity, environmental conditions, and olive yield, highlighting the key role of soil ecological processes in sustaining production. Furthermore, we identify critical drivers shaping soil health and demonstrate how management practices can either enhance or compromise ecosystem services.

This integrative approach provides novel insights into the mechanisms linking soil health and agricultural sustainability in Mediterranean olive systems, offering valuable guidance for management strategies to improve resilience, productivity, and environmental sustainability under ongoing global change.

# Towards the identification of microbial indicators of soil health: a one-year field study in a Mediterranean olive grove

**Gismero-Rodríguez, L.[1*], Knicker, H.[1], and Valverde, A.[2]**

[1] *Instituto de la Grasa – Consejo Superior de Investigaciones Científicas (IG-CSIC), Seville, Spain*

[2] *Instituto de Recursos Naturales y Agrobiología de Salamanca (IRNASA-CSIC), Salamanca, Spain*

*lgismero@ig.csic.es

**ABSTRACT**

Worldwide, approximately 50,000 km² of fertile soil are lost each year; largely as a consequence of inadequate land management practices. Soil degradation may result from insufficient vegetation cover, complete removal of vegetation cover, excessive tillage, over-irrigation, or the intensive use of fertilizers. These factors, together with the increasing frequency of extreme weather events, underscore the urgent need to monitor both land use practices and soil health. In this context, continued investigation of the soil microbiome under different management regimes is essential to anticipate ecosystem changes and to identify reliable bioindicators of soil quality. Advancing our understanding of soil status requires deeper knowledge of microbial community composition and its responsiveness to management practices.

To address this, we selected soils from an olive grove located in southern Spain subjected to three contrasting management regimes: conventional tillage (CT), mixed vegetation cover (MC), and herbicide application along the tree line (TL-Herb). Olive cultivation represents one of the most widespread agricultural systems in the Mediterranean basin, making its sustainable management particularly relevant. Moreover, olive groves are often established on sloping terrain, where inappropriate management can exacerbate erosion and accelerate soil loss. To evaluate potential topographic effects, samples were collected separately from the upper and lower positions within each plot. Seasonal variability was also considered by conduction sampling across all four seasons.

A comprehensive soil characterization was performed, including measurements of pH, electrical conductivity, macro- and micronutrient content, phospholipid fatty acid (PLFA) profiles, and 16S rRNA gene sequencing. This study presents the results with particular emphasis on differences in microbial community structure. Preliminary analyses indicate that plots with vegetation cover showed the highest microbial biomass, with the most pronounced seasonal differences observed in spring and autumn. Taxonomic shifts were also detected, including an increase in Actinomycetota in the upper slope positions and a decrease in Bacillota in the lower slop areas under conventional tillage and vegetation cover treatments. These findings will be complemented by effect size analyses integrating all measured soil parameters to assess their relative contribution to microbiome composition and to identify potential indicators of soil health.

**ABSTRACT**

Iron is an essential micronutrient for plant growth and development, as well as for crop productivity and the quality of their derived products. Despite its abundance in the Earth's crust, iron is often poorly available to plants, particularly at neutral to alkaline pH, which account for one-third of cultivated lands. To cope with this poor bioavailability, plants have evolved sophisticated mechanisms to mine iron from the soil. Recently, it has emerged that non-grass species secrete iron-mobilizing coumarins (specialized metabolites derived from the phenylpropanoid pathway) by the plant root system, via the PDR9/ABCG37 transporter, to improve Fe uptake (Robe et al., 2025). The secretion of iron-mobilizing coumarins is a complex and dynamic process that most probably involves several transporters (Robe et al., 2021; Watanabe et al., 2026). My project focuses on understanding the dynamics of coumarin transport by identifying and characterizing the molecular actors involved, through the characterization of newly isolated loss-of-function *Arabidopsis thaliana* mutants, and by setting up a genetic screen.

## ABSTRACT

Agriculture offers significant potential for carbon sequestration when sustainable management practices are adopted, thereby contributing to atmospheric $CO_2$ removal. A clear example is the use of spontaneous cover crops in perennial systems such as olive orchards. These crop types not only play a key role in carbon management but also underpin the socio-economic and cultural fabric of many regions in Andalusia, where they shape the dominant agricultural landscape. Most research assessing the effects of cover crops has primarily focused on soil organic carbon (SOC) dynamics, often overlooking the potential influence of this practice on inorganic carbon (SIC) pools. This gap is particularly significant because Mediterranean regions, where these perennial crops are commonly grown, SIC stocks can exceed SOC by several times. The global objective of this study was to quantify the stocks of soil organic and inorganic carbon and explore the changes in soil aggregation distribution and associated carbon after cover crop implementation under rainfed conditions. To accomplish it, fifteen paired commercial olive orchards under different soil management practices in the inter-tree rows (bare soil, NCC *vs.* vegetation cover, CC, for at least ten years) and representing a gradient of precipitation (200-900 mm) and soil pH (7.5 to 8.8) conditions were selected. In each of the CC and NCC olive groves, six soil samples were taken to analyze soil physical-chemical properties, including organic and inorganic carbon and biomass. Preliminary results indicate that about 90% of the total carbon was the inorganic carbon in these soils. CC implementation increased SOC and decreased the SIC stocks in about 56% and 15%, respectively, in the first 30 cm of soil. Two of the fifteen paired olive orchards displayed a different trend with an increase in the inorganic carbon stock (between 17 and 112%) with the CC management. SOC stock depended on the presence/absence of cover crops and local conditions, but no interaction between location and management was detected. Greater differences in SOC stock between CC and NCC were generally observed in those fields with higher mean annual precipitation and elevated soil carbonate content. In contrast, differences in SIC stock between CC and NCC were not related neither with precipitation nor with soil pH. A significant increment (between 21 and 111%) in the percentage of macroaggregates (>250µm) and organic carbon occluded in all the aggregates fractions (macro, micro and silt plus clay) were observed under cover crops. Moreover, no interaction between location and management was observed for the aggregate distribution, whereas a significant interaction was detected for occluded OC.

**Acknowledgments**

We acknowledge the financial support of the European Union through FEDER funds ("FEDER de Andalucía 2014–2020") and thank the participating olive growers for their collaboration.

# Microbial community shifts reveal the multifunctional potential of biobased fertilizers in Mediterranean calcareous soils

**Sana Boubehziz[1*], Vidal Barrón[1], María Carmen del Campillo[1] and Antonio R. Sánchez-Rodríguez[1]**

**ABSTRACT**

The use of biobased fertilizers is increasingly promoted as a sustainable alternative to mineral fertilization. However, their effects on soil microbial biodiversity remain insufficiently characterized, particularly in Mediterranean calcareous soils where high carbonate content and drought constrain nutrient phytoavailability, including phosphorus (P). This study evaluated the impact of five biobased fertilizers on soil physicochemical properties, nutrient dynamics, and bacterial and fungal community structure during two cropping seasons (wheat-sunflower rotation) in southern Spain under calcareous conditions (Vertisol). The tested biobased fertilizers included Commercial Plant Residue (CPR), composted Digestate (DIG), composted Olive Mill Pomace (OMP), composted Urban Organic Waste (UOW), and Vermicompost (VER), and were compared with a mineral P fertilizer (Diammonium Phosphate, DAP) and a non-fertilized control (CON). The objectives were: (i) to assess whether biobased fertilizers enhance soil functions beyond plant productivity (particularly P cycling, organic matter dynamics, habitat provision, and microbial biodiversity), and (ii) to evaluate their potential to replace mineral P fertilizers under Mediterranean conditions. Biobased fertilizers exhibited distinct nutrient release patterns driven by their composition. UOW produced the highest increases in available P, Zn ($Zn_{DTPA}$), and Fe ($Fe_{DTPA}$), as well as crop P use efficiency at the end of the field experiment. Both UOW and OMP significantly increased soil organic matter content after sunflower's harvest. Fungal community shifts were associated with increases in soil organic carbon (C), total nitrogen (N), and C:N ratio, suggesting links between biobased fertilizers and fungal-driven C cycling. In a multivariant analysis (PCA), UOW showed a strong correlation with plant available P, $Zn_{DTPA}$, $Fe_{DTPA}$, and microbial taxa related to nutrient mobilization and turnover, including *Novibacillus*, *Melghirimyces*, *Microascus*, and *Bryobacter*. Overall, biobased fertilizers enhanced key soil functions (nutrient and organic matter cycling), while supporting microbial community in increasing soil nutrient availability and enhancing soil health in a calcareous Mediterranean soil. Among the tested biobased fertilizers, UOW and OMP showed the greatest multifunctional potential, highlighting their suitability as sustainable alternative to mineral P fertilizers in wheatsunflower rotations of southern Spain.

## ABSTRACT

Soil health is the capacity of soil as a living system to provide essential ecosystem functions, including carbon and climate regulation, water purification, nutrient cycling, biodiversity conservation, and plant productivity. Soil health is affected by agronomic practices by altering soil physical and chemical properties, and biological activity. Nematodes are key players in soil processes and are increasingly used as bioindicators of soil health, particularly to assess disturbance and biodiversity. However, the mechanistic linkage between nematode communities and ecosystem functioning is poorly investigated, and whether nematode-based indices (NBIs) can serve as effective indicators of overall soil health and specific soil functions remains unconfirmed.

This study aims to determine how nematode community structure response to long-term agronomic practices (fertilization type and tillage intensity) and to evaluate whether NBIs can predict soil ecosystem functioning in a temperate agriculture system.

We investigate a 4-year rotation system including mineral NPK fertilizer, two digestate products (dried digestate without manure and biothermal organic waste), compost, manure and a second field with different tillage intensity and compost input. Soil cores will be collected four times per year over two consecutive years. Nematode abundance and community structure will be assessed at family/genus level using morphological and molecular approaches. Functional indices, metabolic footprint, and carbon and energy fluxes through the nematode food web will be calculated and integrated with rate measurements of soil carbon cycling, nitrogen transformation, pathogen suppression, and plant growth.

By linking nematode community dynamics to multiple ecosystem functions, this study will shed new light in understanding their regulatory role in various soil processes and provide a solid foundation of nematodes as effective indicators of soil health.

# Andean K'allanp' Community: Navigating mycorrhizal community stewardship of Biocultural Andes, Chichupampa Clan, Cotacachi, Imbabura, Ecuador.

**ABSTRACT**

Soil health is the result of complex interactions between biogeochemical processes, microbial biodiversity, and culturally situated management practices. This work presents a research experience supported by the Society for the Protection of Underground Networks (SPUN) that uses environmental DNA (eDNA) to analyze soil microbial communities under Indigenous agricultural practices in Andean and Amazonian territories of Ecuador. These practices, based on principles of reciprocity, diversification, and stewardship of the land, offer a living framework for understanding how Indigenous management influences the structure and function of soil microbial networks.

The study is being conducted through an intercultural alliance between Indigenous communities, local scientists, and specialists trained in dominant Western scientific traditions (WEIRD). The use of eDNA allows for the generation of high-resolution data on microbial biodiversity and subsurface networks, while Indigenous knowledge guides the ecological interpretation of the results, contextualizing them within biocultural agri-food systems and long-term climate adaptation strategies.

This collaborative approach challenges extractive research models and proposes a more biocultural, relational, and inclusive soil science, where molecular data and ancestral knowledge are co-produced and interpreted in a complementary manner. Preliminary results suggest that Indigenous practices not only support high microbial diversity but also strengthen key ecosystem functions, contributing to soil resilience in the face of climate change.

The study demonstrates how eDNA, when ethically integrated with Indigenous practices and intercultural collaboration, can expand the frontiers of soil microbial ecology and support sustainable and culturally situated management of soil resources.
